Sometimes the symptoms are more severe, constituting those of *collapse*—*faintness*, *frequent pulse*, and *lowered temperature*. Later, at least slight fever, corresponding acceleration of pulse and breathing rate, continue while the condition lasts. Pneumothoraces have also been found postmortem when unsuspected before death, having occurred without producing symptoms. The patient may be orthopneic, or may lie upon the affected side, for the same reason as in pleurisy. Pleurisy is a frequent, but not invariable, consequence, and superadds its own symptoms, most palpably effusion.

*Physical Signs*.—These are the most distinctive symptoms. *Inspection* recognizes commonly a bulging half-chest, with the intercostal spaces obliterated or prominent, as compared with the opposite side. The breathing is frequent and short. *Palpation* recognizes absent or very indistinct vocal fremitus, the lungs being no longer in contact with the chest-wall, which is also in a state of tension interfering with vibration. The *percussion* note is resonant, often ringing and amphoric over the upper part of the side—that containing air—while over the area below, containing the fluid, there is absolute dullness. On the other hand, there may be dullness over the air-containing space, instead of tympany, on account of the extreme high tension checking all vibration. We may also meet here that interesting modification of tympany known as Biemer's change of note, based upon the fact that with a given tension the larger an air-containing cavity, the lower the pitch of the percussion note. If the patient with pyopneumothorax sits, or especially stands, in the upright position, the pleural air-containing space is enlarged, because the weight of the fluid pushes the diaphragm downward, whereas in the horizontal-position the fluid flows into the gutter between the ribs and spinal column, the diaphragm rises, the cavity becomes smaller, and the pitch of the percussion note is raised. There is also the usual change of level of the dullness corresponding with change of position, as in pleurisy with effusion.

*Auscultation* recognizes feeble or absent vesicular murmur in the situation where it is present in health, while amphoric breathing may be substituted—bronchial breathing of a metallic character. Ringing amphoric bronchophony is also heard when the patient speaks. An interesting auscultation sign is the so-called "metallic tinkling," a sound ascribed to the dropping of liquid from the seat of perforation into the fluid below. Here also is produced in its typical expression the "coin-clinking" sound conveyed to the ear of the auscultator listening at the back of the chest, while a coin placed upon the chest in front is tapped by another coin. This is a sign usually limited to pneumothorax, though it may also be produced over bronchiectatic cavities. Here, too, may be produced the well-known Hippocratic succussion sound by shaking the body of the patient, the splashing being intensified in the air-distended cavity.

*Diagnosis*.—Almost the only condition with which pneumothorax may be confounded is *diaphragmatic hernia*, the physical signs of which very closely resemble those of pneumothorax. The causes of diaphragmatic hernia are usually severe traumatic agencies, such as compression between cars or under masses of earth, yet occasionally more trifling causes produce it, as in the case referred to on page 574. If such a condition be suspected,

all doubt may be settled by passing a stomach-tube or sound, which will disclose the exact position of the viscera. A *distended stomach* itself is named as a source of confusion with pneumothorax, and it is true that succussion and metallic tinkling can be elicited in it in great perfection. The absence of distention of the thorax itself, the limitation of the physical signs to the neighborhood of the stomach, their association with movements of the stomach quite independently of breathing, point to the proper source. Pneumothorax is scarcely likely to be confounded with large *tubercular cavities*, for while the latter furnish amphoric signs over them, vocal fremitus is increased, or at least remains distinct, while with pneumothorax vocal fremitus is diminished or absent. Further, there is at least no prominence over cavities, while there is often depression, and succussion signs cannot be elicited. Finally, cavities are circumscribed. *Bronchiectatic cavities* furnish signs behind and below the scapula, and therefore more in the situation of those of pneumothorax, but there is dullness instead of tympany, no bulging, and vocal fremitus probably remains distinct, while there is often pectoriloquy, never present in pneumothorax.

**Treatment.**—This is mainly symptomatic. Sudden pain and extreme dyspnea must be treated by morphin, preferably subcutaneously; embarrassing accumulation of fluid by thoracentesis and draining of the sac, and in extreme cases the air may be liberated in a similar manner. Often pneumothorax gives surprisingly little inconvenience, and it is by no means impossible for spontaneous healing to take place. Potain suggested replacing the air and fluid by sterilized air, but such air would soon be substituted by impure air. Operative interference has been carried out with more or less success.<sup>1</sup>

## MORBID GROWTHS OF THE PLEURA.

These are rare and will be considered to some extent in treating mediastinal disease. The pleura is subject to *carcinoma* and to *sarcoma*, the clinical phenomena of which are identical. Most cases of carcinoma of the pleura arise by contiguous growth from primary cancer of the lung. Secondary cancer of the pleura occasionally arises by metastasis from the mammary gland or lungs.

*Sarcoma* occurs as a primary growth in the shape of the so-called endothelial carcinoma of Wagner, which starts from the endothelial cells of the lymphatics and connective tissue. It also gives rise to secondary deposits in the lungs, lymphatic glands, the liver, and muscles.

The **symptoms** of any one of these forms of growth are those of chronic pleurisy, varying in intensity with the extent of the growth, single secondary nodules often giving rise to no symptoms, while the diffuse forms, spreading from the lungs, cause all the symptoms described as belonging to chronic pleurisy, the lung symptoms being relatively insignificant. In the meantime the true nature of the disease may long remain

<sup>1</sup>See a paper on the "Operative Treatment of Pneumothorax," by Samuel West, "British Medical Journal," November 27, 1897, p. 1568.

unknown, its real nature being determined with the development of cachexia toward the end, the decline of strength, and probably secondary deposits in discoverable localities. The bloody character of the effusion is a sign pointing to malignant disease of the sarcomatous or carcinomatous type.

The **prognosis** is altogether unfavorable, and **treatment** is palliative only.

There are also sometimes found in connection with the pleura *chondroma* and *lipoma*, while *calcification* sometimes takes place in chronic inflammatory products.

*Echinococcus* or *hydatid disease* is occasionally found in the pleural cavity. Of this, the first clinical symptom is hydrothorax, the fluid from which is nonalbuminous, differing in this respect from that of pleurisy and to a less degree from that of ordinary hydrothorax. The only unmistakable evidence of hydatid disease is the presence of hooklets and fragments of the hydatid cysts in the aspirated fluid. Here, also, the product may be purulent.

### MEDIASTINAL DISEASE.

**Definition.**—Under mediastinal disease are included all anatomically morbid conditions situated in the mediastinal space, except diseases of the heart, aorta, trachea, and esophagus. By far the greater number of these are tumors, but simple lymphadenitis, abscess, and hemorrhage are also included.

**Anatomical.**—In consequence of the difficulty attending the conception of the mediastinum and its contents, I precede the consideration of mediastinal disease by a brief anatomical description of the mediastinum and its spaces.

The mediastinum is bounded in front by the sternum, posteriorly by the vertebral column from the lower edge of the fourth dorsal vertebra downward, and laterally by the two pleuræ. Clinicians are in the habit of subdividing this space into the *anterior*, *middle*, and *posterior* mediastinum or mediastinal spaces.

The *superior* mediastinum is that portion of the interpleural space above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebræ behind, and bounded below by a plane passing from the junction of the manubrium with the body of the sternum backward to the lower border of the fourth dorsal vertebra. It contains the origins of the sternohyoid and sternothyroid muscles, and the lower end of the longus colli; the transverse portion of the arch of the aorta; the innominate, the left carotid, and left subclavian arteries; the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, esophagus, and thoracic duct, and the remains of the *thymus gland* with lymphatics.

The *anterior space* of the lower or clinical mediastinum is bounded in front by the sternum, posteriorly by the pericardium, and laterally by

the pleuræ. It is wider below than above, and is narrowest in the middle, since at this point the two pleural edges approach each other, while in some instances they are actually in contact. The anterior mediastinum contains the origins of the triangularis sterni muscles; the internal mammary vessels of the left side; a quantity of loose areolar tissue; a few

FIG. 50.—Section through Frozen Thorax at Second Interspace in Front, Looking from above downward, Showing Mediastinal Space.

lymphatic glands, with lymphatics from the upper surface of the liver and two or three lymphatic glands called anterior mediastinal glands.

The *middle space* contains the heart in its pericardial sac, the ascending aorta, the superior vena cava, the pulmonary artery and veins, the phrenic

FIG. 51.—Section through Frozen Thorax at Second Interspace in Front, Looking from below upward, Showing Mediastinal Spaces.

nerves, the bifurcation of the trachea, and the roots of the lungs, with numerous lymphatic glands. It is broader than the anterior or posterior mediastinal space.

The *posterior space* is triangular in form, and is bounded behind by the vertebral column. Its anterior boundary is the pericardial sac and

the roots of the lungs; its lateral walls, the phleurae. It contains the descending portion of the arch and the descending thoracic aorta; the greater and less azygos veins, the thoracic duct, the pneumogastric and splanchnic nerves, the esophagus, and some lymphatics.

### MEDIASTINAL TUMORS.

**Historical.**—The celebrated English physician and acute observer, Thomas Willis (1621–75), seems to have been the first to have made an observation on mediastinal disease. H. Boerhaave recorded a steatoma of the anterior mediastinum in 1742. Joseph Lieutaud (1703–80) described several cases. Boole published others in 1812, and J. G. C. F. M. Lobstein gave the first text-book description in 1835, after which cases multiplied, although the number which came under the notice of any single observer was always few. F. Strauscheed analyzed 112 cases in 1887, and Hobart A. Hare collected 520 cases in his Fothergillian Essay in 1880. Out of 7566 autopsies at the Marine Hospital at Cronstadt, 158 subjects were found to have tumors of the mediastinum said to be malignant. A study of mediastinal disease by the late William Pepper and Alfred Stengel, published in the Transactions of the Association of American Physicians in 1895, is noteworthy.

**Pathology and Morbid Anatomy.**—The varieties of growth consist mainly of sarcoma, including lymphosarcoma, carcinoma, simple lymph adenoid tumors; more rarely cysts, dermoid and hydatid, fibroma, lipoma, gumma, and chondroma; also the teratoma myomatoides of Virchow. Sarcoma and carcinoma and lymphadenoid tumors make up the larger number. Most observers have found more carcinomata than sarcomata, but in the light of the fact that many tumors formerly described as cancerous are at the present day acknowledged to be sarcomata, it is more than likely that the latter have always predominated. Hilton Fagge and Douglas Powell were the first to announce this, and William Pepper and Alfred Stengel, in their monograph published in 1895, came to the same conclusion.

The majority of tumors in the anterior mediastinum start from the remnant of the thymus gland and are lymphosarcomata. The lymphatic structures in the anterior mediastinum furnish a few. In the middle mediastinum the lymphatic glands are the principal starting-points of the relatively frequent lymphosarcomata. The carcinomata are usually primary, but secondary carcinoma is not infrequent. The breasts, lungs, and stomach are among the primary seats named. The secondary cancers do not usually attain a large size. Cancer may extend from the abdomen to the lymphatic glands of the chest by vascular embolism, by direct spread of the disease to the under surface of the diaphragm, through which it may penetrate along the lymphatics into the chest and glands, or by embolism through the thoracic duct to the chest and then by retrograde embolism to the mediastinal glands.

The pleura is also a frequent starting-point of mediastinal growths. Among these are the so-called endotheliomata of Wagner and Schulz, starting in the endothelium of lymphatic vessels and sometimes the surface endothelium. They are sarcomata or carcinomata according as the endothelium is counted mesoblastic or endodermic in origin. The cases of primary cancer of the pleura are probably endothelioma. Fibrous, fatty, and calcareous tumors of the pleura are of rare occurrence. The

lungs also contribute tumors to this locality—carcinoma, primary and secondary, and sarcoma, primary and secondary. Of the primary tumors, carcinoma is the more common, but primary sarcoma of the lymphatic glands surrounding the bronchi and within the lungs near the root is not very rare. The clinical symptoms are the same as when the glands around the bronchi outside of the mediastinum are affected. The cancers may start from the surface epithelium of the bronchi, from the mucous glands, or from the alveolar epithelium of the lung. Finally, from the esophagus, also, start cancerous tumors invading the mediastinum, usually small, though not always. From these the posterior mediastinum and lungs may also be invaded.

**Symptoms.**—Mediastinal tumors may be *latent*. Their symptoms when present are, in a word, those of *pressure*. Such pressure may involve the lungs, the trachea, the bronchi, the esophagus, the heart, the vessels, and the nerves of this locality. They include symptoms, subjective and objective, of the usual kind, and also physical signs. It will be remembered that the symptoms of aneurysm are also largely those of pressure, and it is chiefly from aneurysm that mediastinal tumor is to be distinguished often a matter of some difficulty. The division by Pepper and Stengel into three groups affords the most convenient mode of studying these symptoms. These groups are:

1. Those in which the anterior mediastinum is the seat of the growth.
2. Those involving the middle and posterior spaces.
3. Those in which the pleura or superficial portion of the lung is involved.

1. *Intrathoracic Tumors Situated in the Anterior Mediastinum, and in which the physical signs are easily observed.*—The symptoms are mainly those arising from pressure exerted on the venous trunks, the superior vena cava, and the right and left innominate veins. The yielding walls of these vessels as contrasted with the firmer adjacent arteries easily suffer compression, and may even be penetrated by the growths which may proliferate within them, sometimes causing occlusion by thrombosis. The consequence is *distention* of the *veins* of the *upper part of the body*—the head, neck, and upper chest, sometimes the arms. Coldness, lividity, edema, and clubbing of the ends of the fingers result, while the superficial venous channels may be dilated and tortuous.

From pressure on the arteries may result *inequality* of the *radical pulses*. Of the nerves, the inferior laryngeal is especially liable to compression, with resulting *hoarseness* and *aphonia*. The sympathetic is also sometimes compressed, with consequent *inequality of pupils*, the pneumogastric being less frequently involved than when the tumor occupies a more posterior situation. As the tumor enlarges and the air-passages are intruded upon, dyspnea makes its appearance. *Dyspnea* is usually of the inspiratory kind. *Pericarditis* and *pleurisy*, with pain, hydro-pericardium, and pleural effusion may be present. With the prolongation of the disease the patient wastes, but it is said that *cachexia* is *less apt* to develop than in malignant growths of the posterior mediastinum. *Pain* is not always present—indeed, it is said to be *less marked* than in aneurysm.

*Physical Signs of Growths in the Anterior Mediastinum.*—To *inspect*—

tion the sternum is frequently pushed forward, and in a few instances eroded. Vocal fremitus may be either increased or diminished. *Percussion* elicits abnormal dullness, characterized by more or less irregular shape. Pulsation may occur, but is rare, while the sharp diastolic shock of aneurysm is wanting. If the tumor extends upward sufficiently, it may be felt in the suprasternal notch. *Auscultation* over the area of dullness may be negative, but sometimes the breath-sounds and heart-sounds are well transmitted, while a distinct systolic bruit may be produced by pressure on the aorta or the pulmonary artery. Eustice Smith's sign may be elicited. It is a murmur heard over the upper part of the sternum when the head is bent far backward, caused by pressure of enlarged bronchial glands on the aorta. Secondary enlargement in the cervical lymphatic glands sometimes makes its appearance.

*Intrathoracic Tumors in the Middle and Posterior Portions of the Spaces around the Bronchi, Esophagus, Aorta, and Nerves*, and in which the symptoms predominate over the physical signs.—The first effect is likely to be pressure on the trachea and bronchi. Hence dyspnea is an important and early symptom of tumors in this situation, and the inspiratory effort is extreme. Pressure here is also exerted upon the vena cava ascendens, whence result edema of the *abdominal walls* and *lower extremities*. The effect of pressure on the arteries is not serious. From pressure on the vagus nerve arises *peculiar cough*, paroxysmal and whooping. Sometimes it is loud and ringing, at other times constant and hacking. This cough is said to be due to the joint involvement of one vagus and the pulmonary plexus; whereas experimentally two pneumogastrics are required to be cut to produce it. The explanation is in the involvement of the pulmonary plexus. Mucopurulent and even *blood-stained sputa* may attend the cough. The latter is sometimes a sign of perforation of the bronchial wall. *Dysphagia* from pressure on the esophagus is a symptom in this group, sometimes, indeed, the only one. It is not, however, invariably present. Vomiting, cardiac palpitation with irregularity, and syncope, when present, are also ascribed to the pneumogastric involvement. *Pressure upon the azygos veins* may cause edema of the upper part of the abdomen and serous effusion in the chest, while pleural effusions are also due to complicating inflammations or neoplasms of the pleura. *Fever* may be a symptom of tumor of the posterior mediastinum. It is usually moderate but is sometimes high and irregular, followed by sweating. On the other hand, there may be lowered temperature, as in tumor of the anterior mediastinum from impeded circulation.

*Cachexia* is much more frequent with this group of symptoms, as might be expected from the greater severity and disturbing effect of the disease, including, as it does, destructive process involving bone and lung structure, as well as severe and deep-seated pain.

*Physical Signs of Growth in the Middle and Posterior Mediastinal Space*.—It is evident that in this group the physical signs play a secondary rôle, and except as a result of modified breathing by pressure and impairment of resonance to percussion, have little significance.

3. *Tumors Originating in the Pleura and Lung*, and in which the symptoms and physical signs are of equal prominence. The former is the

more frequent starting-point, but the underlying lung is usually soon invaded and may be more frequently the actual starting-point than is commonly supposed. Naturally, the *symptoms first produced are those of pleurisy*, and the disease is generally so regarded at first, being characterized by the comparatively sudden onset, sharp pain, cough, embarrassed breathing, and pleuritic effusion. Instead of abating ultimately, as is the course in pleurisy, these symptoms grow worse, especially the pain, which extends along the intercostal nerves and their distribution and to the neck and arms. The cough also persists, while the expectoration may become bloody and include sometimes cells from the morbid growth.

Paracentesis, too, is successful, and often furnishes in the peculiarity of its product valuable aid in the diagnosis, because, instead of being clear or nearly so, it is apt to be bloody or slightly chyliform from the presence of fatty matter. This fatty character has been found where there were cancer and sarcoma. The diagnostic importance of certain large, swollen cells of endothelial nature, which seem to become detached and transformed only in case of pleuritic disease of malignant character, is insisted upon by Fraenkel. To the information gained from the fluid obtained by tapping are added also unusual resistance to the trocar and imperfect relief to the dyspnea. Rapid emaciation, anemia, and cachexia complete the picture, while all doubt is removed if secondary growths make their appearance in the lungs, as not infrequently happens.

*Physical Signs of Mediastinal Growths Originating in the Pleura and Lung.*—These are those caused by pleurisy, pleuritic effusion and consolidation of the lung.

**Diagnosis.**—In view of the similarity of symptoms to *aneurysm*, the history of the case in mediastinal disease becomes of the utmost importance, but shortness of breath, the bulging of the thorax, irregular outline of percussion dullness, the feebleness of breathing sounds, the dislocation of the heart and sometimes of the abdominal organs, the symptoms of venous engorgement, which are usually more marked in mediastinal disease, the more rapid course, and secondary metastatic deposits are strong points in favor of the latter as contrasted with aneurysm. Laryngoscopic examination with a view to discovering any constriction of the trachea from pressure by the tumor may be availed of. The subjects of mediastinal disease are usually younger than those of aneurysm. Bony erosion and pain are less frequent. Constitutional disturbance and emaciation are more marked. Diastolic shock is never present in mediastinal disease, while pulsation, if present, is not expansile.

Confusion with *pleurisy* and *pericarditis* is a natural error when the symptoms involving the pleura and pericardium are recalled, and here the slower development of the symptoms associated with those of compression of the various mediastinal tissues and absence of tendency to improve should lead to suspicion of the true nature of the disease.

The nature of the tumor may even be suspected from certain features. Thus, rapid growth, metastatic deposits in the glands of the neck and apices of the lungs, cachexia, tumors and in other situations point to malignancy. Especially may sarcoma be suspected if the subject be a youthful one. Abscess may be suspected if there is a history of injury,

caries, or pyemia, or if there is abscess of the lung or empyema attended by the supervention of pressure symptoms. Hemorrhage may be suspected also when there is trauma and the symptoms develop very rapidly.

**Treatment.**—There is no treatment for mediastinal disease, except such as may suggest itself for the palliation of symptoms.

*Mediastinal Abscess.*—Separate mention should be made of mediastinal abscess, since it is relatively not a very rare disease. Out of Hare's 520 cases of disease of the mediastinum 115 were abscesses, as contrasted with 134 cases of cancer and 98 of sarcoma, 21 cases of lymphoma, 7 of fibroma, 11 of dermoid cyst, 8 of hydatid cyst, with isolated cases of gumma, chondroma, and lipoma.

The abscesses were found in the majority of instances in males, most often in the anterior mediastinum, and most could be traced to traumatic causes. Other causes were tuberculosis, the eruptive fevers, and erysipelas. A few cases of mediastinal abscess also originate in the bronchial and tracheal lymphatic glands, as tubercular lymphadenitis. In 54 cases the abscess was acute.

Of **symptoms**, *substernal pain*, sometimes throbbing, was the most conspicuous. To this was added *fever* in acute cases; sometimes *chills* and *sweats*. Erosion of the sternum and burrowing along a rib into the abdomen were noted, also rupture into the trachea and esophagus. In chronic abscess the pus may become inspissated—cheesy. Suppurative lymphadenitis has been known to terminate thus, previous symptoms having been masked by the lung affection. Rarely are we able to detect fluctuation at the edge of the sternum and in the suprasternal notch, where there may be pulsation. Only as the abscess becomes large enough to encroach upon the air-passages does it cause dyspnea.

The *physical signs* are not distinctive. They are essentially those described in the general description of mediastinal disease. Fever, throbbing pain, fluctuation, and the history of trauma are symptoms which, if added, aid the diagnosis.

As to **treatment**, given a correct diagnosis, operative interference is justified, and likely to afford relief if the pus is reached.

*Simple Lymphadenitis.*—This probably occurs to a degree, in all inflammatory affections of the bronchi and of the lungs, but is rarely recognizable. The glands are mostly in the posterior mediastinum, and their enlargement may be appreciable to percussion in the upper interscapular region behind, though lymphatic enlargement may contribute also to dullness in the region of the manubrium. Tuberculosis may affect these glands.

## SECTION IV.

### DISEASES OF THE HEART AND BLOOD-VESSELS.

#### GENERAL SYMPTOMATOLOGY OF CARDIAC DISEASE.

**1. Shortness of Breath, Cardiac Asthma.**—Dyspnea or shortness of breath is commonly the first symptom of cardiac disease. At first it is very slight, being felt only on exertion. As the disease advances it is induced by slighter effort, and finally it is more or less permanent. The higher degrees are commonly characterized as *cardiac asthma*. It differs essentially from bronchial or spasmodic asthma:

1. In that there is no spasmodic contraction of the bronchial tubes.
2. In that the essential morbid change is an overfilling of the pulmonary capillaries which, intruding on the lumen of the air vesicles, interferes with the access of air to the blood, causing an *ἄσθμα*, or panting, an effort by frequent and deep breathing to accomplish aeration. The overfilling of the pulmonary capillaries is commonly caused by a backing of blood from the left heart into the lungs, because of valvular insufficiency, or it may be caused by a weak right heart.

The same results follow in the so-called *paretic* cardiac asthma due to dilatation and weakness of the left ventricle. This is a common condition of the senile heart in consequence of its imperfect nourishment, and is especially prone to occur when a feeble heart is forced to overcome an unusual resistance. Such is the increased arterial tension due to arteriosclerosis and chronic renal disease, both of which are often associated with shortness of breath. In both the blood does not pass from the arteries into the veins as freely as it ought. So long as the heart is well nourished it hypertrophies in these conditions and overcomes the resistance, but as soon as its nutrition fails, it slowly undergoes dilatation, the blood is backed into the lungs, and the asthma occurs.

In cardiac asthma as contrasted with bronchial asthma there is an absence of the wheezing râles which characterize the latter and obscure the vesicular element of the breathing sound, at first unaltered in cardiac asthma. Later, if edema of the lungs occur, there may be small, moist râles crepitant or subcrepitant, and still later, if the air vesicles fill up, bronchial breathing with an impairment of resonance. In bronchial asthma if there happen to be, as indeed there often is, associated emphysema, there is hyperresonance. Under these circumstances the normal areas of cardiac and hepatic dullness are diminished. Bronchial asthma is an asthma of expiration, as spasm of the larynx furnishes an asthma of inspiration. In the former the lungs are overdistended with air and the difficulty lies in getting them emptied. Hence expiration is four or five times longer than inspiration. Yet it is ineffectual. In cardiac asthma there is no obstruction to inspiration or expiration and both share in the overeffort to accom-

plish the perfect aeration of the blood. The air vesicles do not receive enough air to aerate the blood because the latter is in excess. Cardiac asthma and bronchial asthma are sometimes associated.

2. **Palpitation.**—The second symptom characteristic of heart disease and commonly concurrent with shortness of breath is palpitation. By palpitation is meant undue frequency of the heart's action, with or without irregularity. It succeeds very early upon shortness of breath, or is coincident with it, and is more common in mitral disease than in aortic disease. It varies greatly in degree, being at times scarcely noticeable by the patient, and at others exceedingly distressing. The rate attained by the heart under these circumstances is sometimes as great as 200 in a minute, more frequently 120 to 150.

3. **Slow-pulse.**—Unnaturally slow action of the heart as a symptom of organic heart disease is not infrequent. The number of heart-beats is reduced to 40, 20, or even less. It is more frequently associated with degenerative, fatty or fibroid disease of the muscular substance of the heart and of the coronary arteries, and is distinct from nervous bradycardia, to be separately considered. Such diseased state of the muscle, often due to sclerosis of the coronaries, may interfere with prompt contractile response to the stimulus of the endocardial blood on the ventricles.

Slow pulse may also be caused by resistance (sclerosis and high tension) in the peripheral vessels, to overcome which the diastole is prolonged and the pulse thus slowed. In other cases there is deranged innervation.

4. **Pain.**—Pain is not so frequent in heart disease as is palpitation or dyspnea. It is of two kinds—a dull, aching pain and a sharp pain of great severity, radiating through the heart and down the arms, especially the left arm. Sometimes the patient complains of a sensation as if the heart was being compressed, or grasped in a vise. This pain is associated with an anxious expression and feeling, including a sense of impending death, which is characteristic of the severer forms of angina pectoris. Pain of this kind is apt to be associated with disease of the muscular substance of the heart, of its blood-vessels, and of the aortic valves. Pain is less common in mitral-valve disease, and when present is more likely to be of a dull, aching character.

5. **Dropsy.**—Dropsy is another symptom of heart disease. It does not occur with every form, being for the most part absent in disease of the aortic valves and most common in mitral disease. Not every case of mitral disease is associated with dropsy, but it occurs sooner or later in the vast majority of cases. It is sometimes the earliest symptom noticed, and makes its appearance first almost invariably in the lower extremities. It is the direct consequence of backing of the blood into the venous side of the circulation, and is due to the transudation or filtration of its watery element. The serum is, as it were, strained out. When unchecked, the swelling extends from the feet to the legs, thighs, the trunk, abdominal walls, and, last of all, serous cavities and especially the peritoneal cavity, producing ascites. The pleural sacs may, in rare instances, be the first seats of transudation in heart disease. (See remarks on Hydrothorax, page 589.) These simple transudates are usually free of albumin, as contrasted with inflammatory exudates.

**6. Hypertrophy and Dilatation of the Heart.**—These conditions will be frequently mentioned in the following pages and will be considered at greater length on pp. 647, 650, at present briefly, that a correct application of the terms may be learned. By hypertrophy is meant enlargement of the heart associated with physiological thickening of the muscular wall with or without enlargement of the cavities. When the cardiac cavity remains unchanged in size the hypertrophy is called *simple*; when there is enlargement of the cavity it is called *eccentric* hypertrophy or hypertrophy with dilatation, though I prefer to retain the term dilatation for states in which there is degeneration of the muscular substance. At one time the name concentric hypertrophy was applied to a condition in which there was thickening of the muscle with reduction in the size of the cavity, but it has been found that this supposed concentric hypertrophy was really a postmortem change, and does not exist during life. Even simple hypertrophy is more infrequent in the postmortem room than is supposed.

When the left or right ventricle alone is affected, the hypertrophy may be simple or eccentric; when there is general hypertrophy, it is always eccentric. All true hypertrophies are numerical—that is, there is an actual increase in the number of muscular fasciculi, due partly to a fission of previously existing fibers and partly to a new formation of fibers.

The word dilatation is applied to conditions in which the cavities are enlarged without corresponding thickening of the walls. Usually there is attenuation of the walls. The latter is the typical condition. Dilatation implies degeneration, for it is through intermediate degeneration that the muscular fasciculi waste and ultimately disappear, producing thinning.

Hypertrophy more frequently affects the left ventricle, dilatation the left and right ventricle, but the whole heart may be involved by one or the other condition.

**Morbid Anatomy.**—The hypertrophied and dilated heart is altered in its weight, dimensions, and shape. The adult heart weighs in health, in the male 50 to 60 years old, about 335 grams (11.8 ounces); in the female, 295 grams (10.44 ounces). The average thickness of the wall of the left ventricle in health is from  $\frac{5}{8}$  to  $\frac{2}{3}$  inch (1.6 to 1.7 cm.); of the right ventricle,  $\frac{1}{6}$  to  $\frac{1}{4}$  inch (0.4 to 0.6 cm.); of the left auricle,  $\frac{1}{8}$  inch (3 mm.); the right auricle,  $\frac{1}{12}$  inch (2 mm.).

Hearts exceeding these weights and measurements are, therefore, hypertrophied. Measurements should be made before rigor mortis sets in or after it has passed away. Relaxations may be favored by soaking the heart in water. Commonly, the hypertrophied heart does not exceed 25 ounces (750 gm.), though hearts weighing 48 and 53 ounces (144 to 1590 gm.) have been found.

The shape of the heart varies; in left ventricular hypertrophy it is elongated to the left and lies more horizontally, while the conical shape is less marked; when both ventricles are hypertrophied, the heart is round. In mitral stenosis with hypertrophy of the left auricle and right ventricle it is also quadrate, the right ventricle occupying the chief bulk of the organ, while the left ventricle recedes behind it.

## DISEASES OF THE PERICARDIUM.

## ACUTE PERICARDITIS.

**Definition.**—An inflammation of the serous covering of the heart and of its reflection on the inner surface of the pericardial sac.

**Etiology.**—By far the larger number of cases of pericarditis are due to some toxic substance in the blood, such as is developed in the infectious diseases, or to some excrementitious matters which accumulate in the blood because of deficient elimination. Pathogenic organisms may be the direct cause in certain cases. Other cases arise *per contiguum*, a few cases are traumatic, and those that cannot be accounted for are called idiopathic. Acute articular rheumatism or its cause is by far the most frequent etiological factor, from 30 to 70 per cent. of all cases being ascribed to it. The greater the severity, of the primary disease, the more likely is it that the complication, pericarditis, will occur; yet it arises also in the mildest cases, and has sometimes even preceded the rheumatic attack. It may be that certain seeming idiopathic cases are due to the toxin of rheumatism spending itself on the pericardium instead of on the joints. Other infectious diseases causing it are pyemia, scarlet fever, typhoid fever, diphtheria, and even measles. Bright's disease is one of the best recognized causes of pericarditis though not a very frequent one and it may be the toxic matters which accumulate in the blood in this disease which are responsible for it. Such dyscrasic states of the blood as are represented by scurvy and purpura hæmorrhagica may cause it. Tuberculosis of the pericardium is a common cause of pericarditis. Tubercular pericarditis may be part of a general tuberculosis or a secondary infection from the lungs.

Diseases of adjacent organs which cause pericarditis are chronic valvular disease, pleuropneumonia, pleurisy, especially tubercular pleurisy, morbid growths in the vicinity, ulcerative disease of the esophagus, disease of the bronchial glands and bronchi, disease of the vertebræ, ruptured aneurysm, abscess of the heart, or invasion of the pericardium by suppuration through the diaphragm.

**Morbid Anatomy.**—The appearances vary with the stage of the disease. Ordinary acute pericarditis is met with in one of three stages. The *first stage* is represented by hyperemia and its consequences. The initial events are hyperemia followed by roughness due first to loosening and detachment of the epithelium, and further increased by deposits of fresh inflammatory lymph. This lymph is spread at first in yellow flakes over the surface of the pericardium.

From this point onward morbid appearances vary with the mode of termination. This may be by resolution, when the products described undergo fatty degeneration and are absorbed, restoring the normal state. Or there may be organization and union between the visceral and reflected pericardium (primary adhesive inflammation).

Frequently there supervenes the *second stage*, in which the liquid transudate increases, separating the two surfaces of the pericardium and distending the sac. This transudate is a clear, straw-colored fluid in which

may be found floating flakes of lymph above described. The quantity of fluid varies greatly, amounting sometimes to a liter (2 pints) or more. In favorable cases it, too, is reabsorbed, and the two pericardial surfaces are reapposed with or without union of the apposing surfaces. Sometimes this union is complete and firm, so that the two surfaces are separated with difficulty, or it may be partial, by bands of varying length.

The term *third stage* is usually applied to the phenomena succeeding the transudation described. They include organization or suppuration. The former may be adhesive in various degrees or villous. The latter occurs when, union being prevented by the constant motion to which the two surfaces are subjected, organization takes place without attachment of the opposing surfaces, and a peculiar villous product results, characterized by numerous projections, uniform in size and shape, resembling closely the papillæ on a sheep's tongue. These papillæ, composed of vascular connective tissue, originate in the usual way by an outgrowth and vascularization of the connective tissue of the serous membrane, and not by organization of the exuded lymph, as was formerly supposed. This lymph undergoes fatty degeneration and absorption.

The more unfavorable cases terminate in suppuration, which may also be primary or secondary. In the former instances there is at once a rapid outwandering of leukocytes and the formation of a purulent fluid in the pericardium—pyo-pericardium. In the secondary form the clear, serous transudate is substituted by pus, an event which is usually ushered in by a chill and is followed by hectic fever. The cause of the suppuration in either case is the access of the usual pus organisms, the streptococcus and the staphylococcus. The contents of the pericardium may become cheesy, especially if the inflammation is tubercular.

**Symptoms.**—Clinically, as well as anatomically, we seek to separate the stages, first of roughening, second of effusion, and third of absorption or organization, chiefly by aid of the physical signs.

Pericarditis is sometimes ushered in by a *chill*. More frequently a sharp *pain* in the region of the heart initiates the attack, previous to which there may, however, have been a sense of *discomfort* or *distress* about the organ, which may, indeed, be the only subjective symptom. The pain and discomfort may be referred to the epigastrium. To these symptoms may be added *dyspnea* or orthopnea. There is also *fever*, which is not very high—temperature 102° F. (39.9° C.)—unless there be previous disease with fever, when the pericardial complication adds an increment. The *pulse* is frequent and the patient restless and uncomfortable. There is often *tenderness* over the region of the heart, which may be brought out by percussion or pressure with the stethoscope. The *position* assumed by the patient varies; sometimes he may prefer to lie on the affected side, at other times on his back or on the right side, or he may prefer to sit up. Finally, there may be no subjective symptoms added to those of the primary disease, in which case the pericarditis must be discovered only by the physical examination, or it may escape detection altogether until the necropsy reveals it.

As the effusion distends the pericardium and encroaches on the lung, the difficulty in breathing increases, dyspnea becomes more marked, the action of the heart more disturbed, frequent, and irregular. When large it

may press upon the left lung producing changes in the percussion note which will be discussed when considering the physical signs of the disease.

Still larger effusions produce *dysphagia* in consequence of encroachment on the esophagus. *Aphonia* may occur from pressure on the recurrent laryngeal nerve. The pressure of the full sac on the aorta may produce the *pulsus paradoxus* of Griesinger and Kussmaul, in which the pulse beat is weakened and accelerated during inspiration. (Fig. 52.)

A certain degree of *prominence of the epigastrium* may result from the encroachment of distended pericardium, while the excursion of *breathing movement* may be noticeably greater on the right side.

*Physical Signs.*—In the *first stage* there may be pain in response to pressure, but the physical sign characteristic of the stage is the friction sound. It may be associated with an impulse stronger than natural. The friction sound is of the greatest importance in diagnosis. It is a superficial to-and-fro sound heard directly under the ear, commonly loud and rasping, never blowing, sometimes creaking. *It is loudest over the middle of the heart.* It is not conducted as are the murmurs at the valves in the direction of the

FIG. 52.—Pulsus Paradoxus.

Influence of Respiration upon the sphygmogram (after Riegel); I, During inspiration; E, During expiration.

blood current. It is often influenced by changes of position or by breathing. The rub may sometimes be felt by the hand placed over the heart. In the first stage, at least, it lasts a short time—a day or two at most and sometimes only a few hours—and disappears with the filling of the pericardium by effusion. It may sometimes be brought out or intensified by pressure with the stethoscope.

The *second stage*, or that of effusion, exhibits usually, but not always, signs discoverable to *inspection* or *palpation*, or to both. They depend on the amount of effusion. If large, the precordium may be bulging, the inter-spaces obliterated, and the impulse undulating, tumultuous, and indistinct. As the effusion increases the heart is pushed further and further away from the chest-wall and assumes a more horizontal position, while the impulse, feebler and feebler to vision and touch, may disappear altogether. The friction sound so characteristic of the first stage is found high up and becomes less marked, but, according to George Balfour, never disappears. The site of the apex beat is raised toward the left. *Percussion* furnishes the most striking change. The area of dullness is enlarged—peculiarly enlarged. It becomes rudely triangular or truncated pyramidal with the apex toward the inner end of the left clavicle and the base as low as the seventh rib, and extending in extreme cases from nipple to nipple, even pushing the diaphragm and liver downward. The absence of resonance in the fifth intercostal space, to the right of the sternum, is known as Rotch's

sign in pericarditis, and has been assigned considerable value in the early diagnosis of pericardial effusion.

It is not impossible, however, that a similar dullness may be caused by a circumscribed pleuritic effusion or even great enlargement of the heart. The cardiohepatic angle as determined by percussion, normally an acute or a right angle, may become *obtuse*.

*Auscultation* confirms palpation. The conditions of the friction sound are removed more or less by separation of the opposed pericardial surfaces. Yet the sound does not always disappear. The heart-sounds are indistinct and best heard at the top of the sternum. Sometimes there is a basic systolic murmur.

The *third stage* represents a return to the normal state of affairs, which may come about with the intermediation of a *friction redux* or not; or adhesions may form between the heart and the sac, embarrassing its movements permanently, and producing retraction of the chest-wall with systole. On the other hand, necropsy has often revealed close adhesions between the

FIG. 53.—E, Ewart's posterior pericardial patch. P, Pins' sign. B, Broadbent's sign within dotted lines.—(After Ewart modified.)

heart and the pericardium which were not suspected during life. Permanent roughening, represented by the "sheep's tongue" surface or other roughening or adhesions, may produce permanent friction sound, and the pericarditis is chronic.

*Secondary Physical Signs in the Lungs.*—The enlarged distended pericardium protruding upward toward the left clavicle may produce there Skodaic resonance to percussion in the adjacent lung by indirect relaxation, or it may compress the lung producing dull percussion. More frequently the lower lobe is encroached upon, sometimes completely emptied of air, whence the percussion note over the lung in the lower axilla and about the angle of the scapula may be Skodaic or even dull if the lung is completely emptied of air. Correspondingly the breathing sounds may be feeble, broncho-vesicular and rarely bronchial, and there may be egophomy. These sounds are not to be confounded with those due to a possible associated pleuritic effusion which gives diminished or absent tactile fremitus as contrasted with increased fremitus of the compressed lung. Attention

was called to these symptoms as far back as 1857 by Bamberger<sup>1</sup> whence they are known as Bamberger's sign, though the names of Ewart and Sansom have also become associated with his. The normal state of the lung may be in part restored by changing the position of the patient, causing him to lean forward, to lie on his right side, or assume the knee-elbow position. To this attention was especially called by Pins.

Ewart has also called attention to an area of dullness below the ninth rib, on the left side between the spine and a line drawn through the posterior edge of the scapula, and to a less degree to the right of the spine. In this area known as "Ewart's posterior pericardial patch of dullness" the respiratory sounds are also absent and the voice sounds are feeble. He ascribes this sign to an altered dorsal relation of the liver due to pressure of the pericardial effusion. Ewart has also called attention to what he calls the "first rib sign," also recognized by palpation. The upper edge of the first rib may be followed round by the finger tip because the clavicle is apparently raised above its normal position by the effusion which must of course be large.

*Physical Signs of Chronic Adhesive Pericarditis or Adherent Pericardium.*—These differ materially. They are most easily studied in children, in whom the condition is especially apt to occur after rheumatism. Their study is further facilitated by dividing the condition into two groups:

1. *Simple adhesion of the pericardial and epicardial layers.* These are the cases more frequently overlooked, sometimes giving rise to no symptoms and first found at necropsy. There may, however, be friction and creaking sounds with indistinct apex beat on the one hand, or retraction of the chest-wall below described.

2. *Adherent pericardium, with chronic mediastinitis and fusion of the outer layer of the pericardium with the pleura and to the chest-walls,* a serious form, leading to marked hypertrophy and dilatation, especially in children. To *inspection* and *palpation* the precordium is bulging, the impulse is more diffuse, extending sometimes from the third to the sixth interspace, and from the right parasternal line to outside the left nipple. The *apex* may be *displaced* in various degrees from its natural site; it may be to the right of its normal position and above it or down toward the epigastrium. It is sometimes multiple, or spreads in a wave-like manner over the area named. At other times the systole is associated with a *tugging retraction of the chest-wall*, which is especially evident in thin persons and is regarded by some as the most valuable sign of adhesion of the pericardium. It is most frequently noted between the seventh and eighth ribs in the left parasternal line. This may be followed by a rapid rebound of the chest-wall, known as the *diastolic shock*. It may be associated with a coincident collapse—the *diastolic collapse of the cervical veins*, due to a sudden emptying of these vessels consequent on the expansion of the chest-wall, a sign first described by Friedreich.

Broadbent's diaphragm sign has attracted much attention—a systolic tug which is communicated through the adherent diaphragm to its points of attachment, especially on the left side behind, between the eleventh and twelfth ribs. It is distinct and apart from the tugging in the left para-

<sup>1</sup> "Lehrbuch der Krankheiten des Herzens," von H. Bamberger, Wien, 1857.

sternal line, between the seventh and eighth ribs, to which attention had been previously called. Furthermore, owing to the attachment of the pericardium to the central tendon of the diaphragm this muscle does not descend with inspiration, and consequently the usually visible movement of the epigastrium during this act does not take place.<sup>1</sup>

It is in adhesive pericarditis, too, that we sometimes have the *pulsus paradoxus*, referred to on page 604. First, Griesinger, and later Kussmaul, called attention to it as a constant symptom of cicatricial mediastinitis, due to the dragging of the cicatricial tissue on the great vessels during inspiration. It happens, too, when the great vessels, already compressed by the exudate, are further encroached upon by the expanding lung, making the pulse smaller and more frequent. This is more frequently demonstrable by the sphygmograph, but in extreme cases may be appreciated by the finger. It is not a pathognomonic sign of either event, but if associated with an inspiratory distention of the cervical veins, it points strongly to adhesive pericarditis.

To *percussion* there is usually a large increase in the normal area of cardiac dullness, commonly upward and to the left, sometimes as high as the first interspace. Often the pericardium is adherent to the adjacent pleura, in which event the area of cardiac dullness is not influenced by deep breathing, a sign pointed out by C. J. B. Williams as of great value in diagnosis.

*Auscultation* may be entirely negative, or there may be a modification of the usual friction sound which closely resembles the creaking of leather. A galloping or fetal rhythm may be present, or there may be a loud systolic murmur at the apex, which has often given rise to the erroneous diagnosis of mitral valve disease, being due to relative insufficiency. Endocardial disease may, however, coexist, especially in children. A presystolic murmur is sometimes heard.

The possible association of chronic adhesive pericarditis and mediastinitis with proliferating peritonitis, perihepatitis, and splenitis should be remembered. Rarely ascitis may be one of the early signs of this condition and lead to the mistaken diagnosis of cirrhosis of the liver.<sup>2</sup>

**Diagnosis.**—In all cases of acute articular rheumatism the heart should be frequently examined, because pericarditis often supervenes with feebly pronounced subjective symptoms. At the outset the distinction is to be made between pericarditis and *acute endocarditis*, which as frequently succeeds on rheumatism with subjective symptoms no more distinctive. There is usually not much difficulty in acute cases. The to-and-fro rhythm, heard directly under the ear, usually most distinct over the center of the heart, and the absence of sounds transmitted in accordance with the laws of trans-

<sup>1</sup> Some doubt has lately been thrown on the value of Broadbent's sign by the observations of A. W. Tallant who found as the result of the examination of 130 cases "retractions in the left back are much more common than is generally supposed, although it is probable that they would be noted more frequently if always looked for during the routine physical examination. Systolic retraction of a marked degree, similar to and often identical with that described by Broadbent is found in many cases of cardiac hypertrophy in which there is no other reason to suspect pericardial adhesions. Systolic retraction more often involving the interspaces only may be seen in the left back in thin individuals, especially if there is marked emaciation. The reason for many of these retractions seems to be as follows: Since the pericardium is, even under normal conditions, adherent to the central tendon of the diaphragm it is conceivable that with each systole there is a slight pull on the diaphragm. Ordinarily this is not marked enough to be transmitted to the points of attachment to the chest-wall, but if the heart is hypertrophied or acting very vigorously the pull may be visible, while in a thin individual it would be more easily perceived."

<sup>2</sup> See a paper by A. O. J. Kelly on "Multiple Serositis, the Association of Chronic Obliterative Pericarditis with Ascites, etc.," "Amer. Jour. Med. Sciences," vol. cxxv., 1903, p. 116.

mission of the valvular abnormal sounds, are distinctive features of the cardiac friction. If, however, one of the to-and-fro elements is wanting, the difficulty is greater and errors do occur. Close study must be made as to transmission. It is further characteristic of the friction sound that it is increased in loudness by pressing the chest-wall with the stethoscope, while this is not the case in endocardial murmurs. Such pressure is, however, often painful to the patient. In *chronic valvular defects* there are changes in the size and position of the heart which are not present in the first stage of acute pericarditis. When both acute endocarditis and pericarditis are present, the difficulty is greatly increased and one or the other condition is likely to be overlooked.

The "pleuropericardial" friction sound or "extrapericardial" friction sound is to be distinguished from pericardial friction sound. It is a sound similar in rhythm to the pericardial sound, but the primary condition of its causation is a pleuritis involving the opposed surface of the mediastino-costal sinus of the left side. It is more commonly heard, therefore, over the left border of the heart. It is the combined product of the respiratory and cardiac action, being usually louder during expiration. It generally ceases during a deep inspiration, because at this time the cardiac action cannot produce the required rubbing. On the other hand, this is sometimes the very condition under which the friction sound is loudest. Simply holding the breath may also stop it, though not necessarily, because the heart motion produces it. This influence of the breathing one way or the other is, however, of importance in diagnosis, while other symptoms must also be taken into consideration. Thus, if it be a pleurisy, the pleural friction sound is probably heard elsewhere, and there are the other symptoms of a pleurisy present, while those of a pericarditis are absent. Unlike the true pericardial friction sound the pleuropericardial friction sound is uninfluenced by bending the body forward, but is heard with equal distinctness with the body in any position. Difficulties again increase when it is associated, as it sometimes is in a pleuropneumonia, with endocarditis. It also occurs in tubercular phthisis, where it is sometimes associated with a systolic click due to the simultaneous expulsion of a bubble of air from a portion of softened lung.

For diagnosis between pericarditis with effusion and dilatation of the heart see page 652. It is in this differential diagnosis particularly that Rotch's sign and the difference as determined by percussion of the cardiohepatic angle become valuable. It must be remembered, however, that Rotch's sign is not always present, even when there is considerable effusion. The possibility of a circumscribed pleuritic effusion must also not be overlooked. Bamberger's sign—Skodaic resonance and dullness in the lower axilla and region of the angle of the left scapula—should be sought; also Ewart's posterior pericardial patch.

**Prognosis.**—The course of pericarditis varies with different cases. In an ordinary uncomplicated case passing to recovery, the duration is one to three weeks, even when there is considerable effusion, which is often absorbed with surprising rapidity. In other cases, especially in cachectic subjects, the duration is longer. Relapses occur. When adhesion results, convalescence is greatly prolonged, and in many cases the heart is perma-

nently crippled. On the other hand, extensive adhesions are sometimes found at necropsy where no lesion was suspected. The pyo-pericardial cases are usually fatal.

**Treatment.**—Prompt treatment is of the greatest importance in pericarditis. Rest is an absolutely essential condition. As soon as the diagnosis is made, a blister is of the greatest value. There is no other disease in which I am so satisfied of the efficiency of a blister. It should be at least three inches (7.5 cm.) square. I am confident that it helps to prevent effusion and also to promote the absorption of effusion. Along with this, measures to relieve pain are indicated. Nothing is so satisfactory as moderate doses of morphin administered hypodermically, associated with atropin in the proportion of 1 150 grain (0.00044 gm.) of the latter to 1 4 grain (0.0165 gm.) of the former. Cold applications to the pericardium by Leiter's coil or the ice-bag are sometimes useful. At other times hot applications are more comforting.

Digitalis in moderate doses is usually indicated to steady the heart at its work, without, however, stimulating it too forcibly. For the same reason alcohol and ammonia, especially the aromatic spirit of ammonia, are indicated. Strychnin is a valuable heart tonic. Liquid food, including milk and broths, should be adhered to until convalescence is established. Eggs may, however, be early allowed.

If the effusion is very large, tapping the pericardium may be necessary to relieve the patient, although practically the relief which first follows a successful operation is rarely followed by complete recovery. The aid of the surgeon should be secured if possible, but if not, puncture may be made in the fourth interspace, an inch (2.5 cm.) to the left of the edge of the sternum. If made in the fifth interspace, the puncture should be made a little further out—say 1 1/2 inches (3.5 cm.) A safe point which may be used in large effusions is the left xiphocostal angle, at which the needle should be pushed upward and backward. Still another site is the left fifth interspace between the apex impulse and the outer margin of dullness. When the pericardial fluid is pus, a simple tapping is insufficient. Free incision should be made, and free drainage should be established with aseptic precautions. John B. Roberts<sup>1</sup> collected 35 cases of suppurative pericarditis treated by incision, of which 15 recovered and 20 died. It is not impossible that if operation were done earlier, better results would follow.

The treatment of chronic adhesive pericarditis is mainly symptomatic, and directed to building up the strength of the patient.

## OTHER PERICARDIAL AFFECTIONS.

Other affections of the pericardium are hydropericardium, hemopericardium, pneumopericardium, and tuberculous pericarditis, rarely morbid growths.

**HYDROPERICARDIUM.**—This term is applied to a large accumulation of serous fluid in the pericardium. In health the pericardium is simply lubricated by this fluid. It occurs sometimes as a part of a general dropsy,

<sup>1</sup>"American Journal of the Medical Sciences," December, 1897.

most frequently cardiac dropsy, more rarely in renal dropsy. The accumulation is seldom large in these cases. It is not common, but is sufficiently so to demand frequent examination of the heart, as it is often overlooked. Its signs are the same as those of the inflammatory effusion.

HEMOPERICARDIUM, or blood in the pericardium, occurs only as a result of rupture of an aneurysm in the first part of the aorta into the pericardial sac, from rupture of the heart itself or a wound of the heart. It is rapidly followed by shock and death. The physical signs are those of effusion. It may also be caused by tuberculosis of the pericardium. Cancer of the pericardium may be associated with blood effusion.

PNEUMOPERICARDIUM is a rare condition in which gas is present in the pericardial sac. It is analogous to the much more common one of pneumothorax. As in pneumothorax, the presence of air implies also the presence of liquid and that, usually, pus. It is produced by similar causes, such as perforation into an air-containing space like the lungs or esophagus. Such perforation is usually traumatic. Decomposition of pericardial exudate or morbid growth, it is said, may also produce it.

**Symptoms.**—Its symptoms are pain and pericardial embarrassment, but the physical signs are most distinctive, especially those of auscultation. To inspection there is prominence of the precordium, with indistinctness or obliteration of apex-beat, restored by the patient's bending forward. Percussion furnishes dullness over the lower portion of the cardiac area and tympany above it, the position of both being altered by change in position of the body. To auscultation the heart-sounds assume a striking metallic character, being audible even at a distance from the body. A similar metallic character is given even to a friction sound, if it is present, as it often is.

**Diagnosis.**—The diagnosis of this condition requires differentiation from the effect of an *air-dilated stomach* on the heart-sounds, or rarely of a *phthisical cavity* or *pneumothorax*. All doubt in the case of the stomach is removed by filling it with water. The associated symptoms of the other conditions make a mistake unlikely.

**Treatment** is scarcely available, except in case of external injury, when operation may be of service.

TUBERCULOUS PERICARDITIS presents nothing peculiar in its symptoms or signs as already described.

MORBID GROWTHS OF THE PERICARDIUM are rarely diagnosticated before death.

## DISEASES OF THE ENDOCARDIUM.

### ACUTE ENDOCARDITIS.

SYNONYM.—*Valvulitis*.

**Definition.**—Endocarditis in both its acute and chronic forms is an inflammation for the most part confined to the valves; for such inflammation, therefore, *valvulitis* is a more correct term. The lining of the cavity of the heart is, however, sometimes affected in acute endocarditis, especially

in the more severe cases, when it is known as *mural endocarditis*. It is usually in the apex of the left ventricle that such inflammation occurs.

**Etiology.**—All cases of acute endocarditis unless traumatic, must in the light of modern studies be regarded as infectious—that is, as due to a specific poison commonly associated with some disease which is regarded as the cause of the endocarditis. Acute rheumatism is the best recognized and most frequent of these. Upon this follow closely the infectious fevers, with their various specific organisms or their toxic products. In the disease which is acknowledged to be the most common cause—acute articular rheumatism—no definite causing organism has as yet been found.

There is, however, a great difference in the severity of different cases of acute endocarditis, and the disease is easily separable into two classes, from one of which recovery almost always takes place up to a certain point, leaving often a degree of valvular defect known as chronic endocarditis, while the other is invariably fatal. The first, or milder, of these classes was for a time ascribed to some specific nonorganized agency, even after the more severe and fatal form was recognized as infectious, whence arose the terms simple endocarditis on the one hand, and infectious, ulcerative, malignant, or mycotic on the other.

In attempting to explain why at one time the simple form and at another the virulent form of endocarditis arises, it may be stated that the toxins generated by the less virulent bacteria may pave the way for the operation of the virulent streptococcus and staphylococcus pyogenes, the pneumococcus, the gonococcus, and other organisms which are found in the morbid products of malignant endocarditis. It is not unreasonable to suppose that the former produce the simple form of endocarditis, while the cooperation of the septic bacteria named is necessary to produce the malignant variety. On the other hand, it may be not so much the specific organism as the constitutional or local peculiarities of the individual on whom the disease is engrafted—the nature of the soil, as it were.

#### THE MILD OR SIMPLE FORM OF ACUTE ENDOCARDITIS.

SYNONYM.—*Warty or Verrucose Endocarditis*.

**Definition.**—An acute inflammation of the endocardium, infectious in nature, characterized by its relative mildness and tendency to more or less complete recovery.

**Etiology**—Almost any one of the recognized infectious diseases may become a cause of simple endocarditis. Acute articular rheumatism is, however, the most frequent cause, 20 per cent. of all cases being ascribed to it. After this comes chorea. Indeed, William Osler, who has made the subject a special study, says: There is no disease in which, at necropsy, acute endocarditis has been so frequently found. Vegetations were found on the valves in 62 out of 73 fatal cases of chorea collected by him. This fact has suggested even a microbic origin of chorea, which is sustained by other features in the history of the disease, but not by actual demonstration. In the absence of such demonstration, chorea must be regarded in

the light of a predisposing cause. Scarlet fever, pneumonia, tuberculosis, and peliosis rheumatica are not infrequent predisposing causes; less frequently are tonsillitis, diphtheria, erysipelas, smallpox, and typhoid fever. Endocarditis also supervenes as a complication of Bright's disease. Even in these cases bacteria are found in the vegetations. Cachectic states, such as are caused by tuberculosis and cancer, also seem to favor the development of acute endocarditis. Finally, chronic valvulitis is a predisposing condition to simple acute endocarditis as well as to the malignant form, being often complicated by acute attacks, whence the term "recurring" endocarditis.

**Morbid Anatomy.**—The left side of the heart is more frequently involved, and in this the mitral leaflets first, in at least half of all cases; next the aortic cusps; then, in the right heart, the tricuspid valve, and finally the pulmonary valve. In embryonic life, in which acute endocarditis also occurs, the right side of the heart and the tricuspid valve are most frequently affected, accounting thus for certain congenital valvular defects.

The type of the morbid change on the valves in simple endocarditis is so constantly a product warty or fungous in appearance that the term *warty* or *verrucose* endocarditis is often applied to this form. On the auricular surface of the mitral, and the ventricular surface of the aortic valves, at the line of their contact during closure—*i. e.*,  $1/25$  to  $1/12$  inch (1 to 2 mm.) back of the valve edge—granular and warty excrescences make their appearance. These rise  $1/12$  to  $1/8$  inch (2 to 3 mm.) above the surface and extend a variable extent along the valve. They soon become capped with fibrin, often abundantly, and thus a vegetation is formed. The vegetation begins in a proliferation of the cells of the adventitia and of the connective tissue of the external laminae of the endocardium. Thus formed, it is a friable product, liable to be broken off at any time and carried into the general circulation to a point of lodgment, where it plays the rôle of an embolus. In point of fact, this accident does not often happen in the simple acute endocarditis succeeding febrile diseases. It occurs more frequently in the acute endocarditis engrafted on chronic valvular disease, and in the malignant form. More frequently the vegetation undergoes organization and contraction, and the valve is restored partially to its natural condition, leaving a simple sclerotic thickening, which is especially prone to become the starting-point of new processes. Unless there has been previous valvular disease, there is no enlargement of the heart in acute endocarditis.

**Symptoms.**—These are often masked by those of the previous disease, and sometimes overlooked, the autopsy first disclosing the lesion. There is frequently noticed, however, greater or less *embarrassment of breathing*, orthopnea being not infrequent; the *pulse* is much more rapid and may be *irregular*, the patient is restless, the countenance dusky, while the *temperature* is a degree or two higher than normal. Altogether, it is plain that he is sicker. Yet there is rarely actual pain, as in pericarditis.

**Physical Signs.**—As already stated, in the first attack of endocarditis there is no notable enlargement of the cardiac area as determined by percussion or inspection of the seat of apex-beat. *Auscultation* may recognize a murmur, of which the situation varies with the valve involved. If

the mitral, a murmur is heard in this area, usually systolic, soft, and blowing, at times quite harsh. Very rarely is there a presystolic murmur, though its more frequent occurrence might be expected from the nature and situation of the lesions described. When the lesion is at the aortic orifice, the murmur is heard in the aortic area at the second interspace at the right edge of the sternum. It is usually also systolic, but may be diastolic. But not every aortic murmur heard in acute endocarditis is due to a valvular lesion, as the condition of the blood predisposes to a hemic murmur. Basic murmurs also occur in the pulmonary area to the left of the sternum, which are functional in nature—the bellows murmur.

Nor is a systolic murmur in the mitral area always due to organic change in the valves because the state of the muscle predisposes to imperfect closure of the auriculoventricular orifice. Mitral regurgitation may also occur in rheumatism and in other acute febrile diseases from myocardial changes, as the result of which the basal part of the cardiac muscle is enfeebled and unable to do its part of the work of closing the mitral orifice, and the valve leaflets are insufficient to complete it. Some of the cases of murmur which disappear with recovery may belong to this category. The same excrescences which form on the valve leaflets may also attach to the papillary muscles and *chordæ tendinæ* as well. It is characteristic of endocardial murmurs to come and go.

**Diagnosis.**—This is based almost entirely on the physical signs, as no one of the symptoms is pathognomonic. Nor are the murmurs always to be relied upon, for the reasons assigned.

The distinction of the endocardial from the pericardial murmur was considered in treating of *pericarditis*. The more superficial situation of the latter over the body of the heart, its to-and-fro rhythm, not connected with the heart-sounds, its failure to follow the usual laws of conduction, and the fact that it is made more pronounced by pressure—all serve to distinguish it. A. E. Sansom calls attention to a possible source of error in a pericardial roughening at or about the apex, especially in children, which causes a systolic apical murmur. This should be remembered as a possible, but rare, occurrence.

**Prognosis.**—The subject of the simple form of acute endocarditis rarely dies, but he is likely to recover with a damaged heart—in other words, chronic valvular disease results. This is not, however, always the case, for complete recovery is not impossible. On the other hand, some of the instances of complete recovery after mitral regurgitant murmur belong doubtless to the category described of insufficiency due to myocardial defect without mitral lesion. It should not be concluded, however, that because a murmur has disappeared the patient has certainly recovered, since a murmur due to myocarditis may be succeeded by another true valvular murmur. Finally, one acute attack from which recovery has taken place is liable to be succeeded by another and another, so that, sooner or later, chronic valvular defects are produced.

**Treatment.**—The keynote of the proper treatment of simple acute endocarditis is absolute quiet. It is not often that much else is required. A blister is not of the signal service here that it is in pericarditis, while ice applied over the heart often is. Digitalis is not indicated unless there

is irregularity, when the dose should be moderate—only enough to steady the heart. Dyspnea is best treated by sufficient doses of opium or morphin, which should not be put off too long. The diet should be easily assimilable and liquid until convalescence is established.

#### THE SEVERE OR MALIGNANT FORM OF ACUTE ENDOCARDITIS.

SYNONYMS.—*Ulcerative, Infectious, Mycotic, or Diphtheritic Endocarditis.*

**Definition.**—Malignant endocarditis is a severe form of acute infectious fever due to inoculation of the blood by a bacillus or its toxic products, and characterized locally by a specific valvulitis. It is called primary when not engrafted on some other infectious disease.

**Historical.**—It was recognized as a separate form of disease in 1851 by Senhouse Kirkes, and further studied by Charcot and Velpéau, in France, Virchow, in Germany, and recently in this country by William Osler, who made it the subject of his Gulstonian Lectures before the Royal College of Physicians, England, in 1885. Its mycotic nature was not suspected until after Koch discovered the bacillus of tuberculosis, in 1882.

**Etiology.**—Malignant endocarditis shares with the simple form an infectious origin. No satisfactory explanation has, however, been furnished of its more malignant nature. It has been suggested and the suggestion is sustained by the experiments of Wyssokowitch, Ribbert, Orth, and others, that a state of the blood due to toxins of bacteria may constitute the simple form, and that this state may afford conditions favorable for the operation of the more virulent bacteria found associated with malignant form. It is extremely doubtful whether there can be a primary malignant endocarditis without the intervention of some one of the diseases which usually precede it. The presence of chronic valvular defects affords the most important predisposing cause favoring the action of the causes of the acute malignant form. Goodhart found it in 61 out of 69 cases, and Osler in 54 out of 209. The latter also found it 11 times at 100 autopsies of fatal cases of pneumonia. Of the infectious diseases associated with the malignant form of endocarditis, pneumonia is the most frequent. The disease occurs also in association with gonorrhea, rheumatism peliosis rheumatica, pleurisy, puerperal fever, bone necrosis, and septicemia from any cause. More rarely it has been found in connection with meningitis, smallpox, diphtheria, scarlet fever, tuberculosis, and dysentery. Most frequently, perhaps, the microorganism is the lancet-shaped bacillus of pneumonia; after this, pus organisms, the streptococcus and staphylococcus. They may be found in the blood during life.

**Morbid Anatomy.**—As to the acute cardiac lesions associated, we find, either alone or in addition to the old sclerosis, three sets—*vegetative, ulcerative, and suppurative*. The vegetative is for the most part made up of closely-packed spherical micrococci, more or less commingled with small fibrin masses. The vegetations vary in size from that of a pin's head to that of a pea, and are reddish-yellow in color. The seat of this vegetation becomes rapidly necrotic, and breaks down into an ulcer which may perforate the valve, with or without previous protrusion—the so-called *valvular*

*aneurysm.* More rarely minute foci of pus are found in the deeper tissues of the valve leaflets. The invasion is, however, not always confined to the valves, but may extend to the mural endocardium. Of the valves, the mitral is most frequently involved; next, the aortic; next, mitral and aortic jointly; next, the lining of the heart-wall; next, the tricuspid; and last, the pulmonary valve. In a few instances the right heart alone is invaded, according to Sicard, is more often attacked than the left. Other morbid changes include the lesions of the concurrent affection and the phenomena of embolism due to lodgment of fragments of the vegetation. The result of the latter when complete is a metastatic abscess, though the earlier stages of red infarction may also be present.

The spleen, kidney, skin, and even the cerebral cortex may be seats of embolism. In addition to these, we may also have embolism and hemorrhagic infarct occurring in the lungs from emboli starting in the right heart, as contrasted with those originating in the left heart which lodge in the systemic circulation. The number of embolisms varies greatly in these cases. They may be altogether absent, while they may be counted by hundreds, in which event they are, of course, very small. The spleen is enlarged even when not the seat of embolism, as in other infectious diseases.

**Symptoms.**—Given a pneumonia, pleurisy, the puerperal process, or any one of the diseases named, with the supervention of *chills*, followed by *fever* and *sweats*, this form of heart disease should be immediately thought of and the organ carefully examined for the auscultatory signs of endocarditis. In the primary form, however, should this exist, we have not even the presence of one of the diseases named to suggest the occurrence of ulcerative endocarditis. In this form, particularly, the resemblance to intermittent fever seems at first close, but a careful study of the temperature chart from day to day, and, above all, utter failure of the antiperiodic remedy to produce any effect, will in a short time show that the malarial disease is not present. Doubtless, often the malady under consideration has been mistaken for intermittent fever, and not without reason, for many a case of irregular quotidian and tertian fever presents similar symptoms; but the regular, almost rhythmical, rise and fall of temperature, as exhibited in the chart of an intermittent fever, is wanting. Indeed, I think there is no disease in which extreme irregularity in temperature reaches that of the one under consideration, as a careful study of the appended temperature chart from a case of my own in the University Hospital will show. Note that the maximum is reached at any time of day or night. Yet the temperature is not always so high, nor is the extreme range always so great as here indicated. The absence of the *plasmodium malarie* serves however to distinguish it from malarial disease.

It always greatly aids the diagnosis when to chills and fever are added other symptoms suggesting *embolism*, which so frequently occurs. The occurrence of a hemiplegia, pain in the region of the spleen, with increased dullness on percussion, pain in the region of the kidney with hematuria, or a *sudden blotch in the skin*, of the kind described, is of inestimable value. Unfortunately for diagnosis, these symptoms are not often present. Rarer symptoms of similar origin are *impaired vision* from retinal hemorrhage,

The symptoms added are rigor, irregular fever, sweats, and exhaustion. Yet these are only the symptoms characteristic of pyemia. In fact, it is a pyemia; and the term *arterial pyemia*, suggested by Wilks, is a good one, because the pyemic abscesses result from emboli, starting in the left heart and lodging in arteries. The endocarditis constitutes the distinctive feature of the disease. The resemblance to intermittent fever here exists also, and a quotidian or double tertian type may be simulated. It is in this form especially that leukocytosis occurs, determined by a blood-count.

The symptoms of the *typhoid* type are even more characteristic. We meet here, too, the same prostration, irregular temperature, and sweating; rigor is less frequent, and the onset is more gradual. There are delirium, drowsiness, often diarrhea, with distention of the abdomen and tenderness in the right iliac region, to which a rash may also be added, which, though not identical with that of typhoid fever, is, nevertheless, similar to it. The tongue is dry and brown, and sordes collects about the teeth. The temperature is remittent, like that of typhoid, reaching  $103^{\circ}$  to  $104^{\circ}$  F. ( $39.4^{\circ}$  to  $40^{\circ}$  C.) and even higher. Here again the heart symptoms may be overlooked.

Still another group is the *cerebral*, in which the symptoms simulate meningitis, basilar or cerebrospinal, with acute delirium as the distinctive feature.

*Physical Signs.*—If there is anything peculiar about the physical signs, it is their want of definiteness. When murmurs are present, it is often difficult to locate or time them precisely. They often vary from day to day. They may occur at both base and apex, and with reason, for both sets of valves may be and often are involved. The superaddition of pericarditis adds a further source of confusion in the friction sound superadded. If chronic valvular disease exists, its signs are also present, including those of hypertrophy.

*Complications.*—As to complications, these are mainly the original cardiac disease or the diseases the specific organisms of which most frequently cause the virulent inflammation. Pericarditis and pleurisy are frequent complications in the strict sense of the term; there may also be meningitis. Acute nephritis, the result of sepsis and quite independent of embolism, may be present, with its characteristic symptoms, albuminuria, blood casts, and free blood-corpuscles. Gastro-intestinal derangements not of embolic origin are sometimes conspicuous. Diarrhea may be especially troublesome.

*Diagnosis.*—This is not always easy at first. A few days' study of the temperature, with its extreme fluctuations, the rigors, and the supervening sweats, should at once lead to suspicion, and these, if continued, point only to this disease. If one would always remember the possibility of the occurrence of malignant endocarditis in connection with the diseases named, it would be less frequently overlooked. The fever is a septic one in all cases, the heart symptoms adding the peculiarity. In true *typhoid fever* there is always splenic enlargement and often parotitis, so that the presence of these symptoms naturally suggests that disease, and an erroneous diagnosis is not inexcusable. It is said that splenic enlargement is not so marked as in typhoid fever, and that there is commonly more tenderness in ulcerative endocarditis. This may be true in some cases, and not in others.

At the present day the Widal test should, of course, be made in all doubtful cases of fever and may afford important assistance in diagnosis. The same is true of blood cultures since the micro-organisms causing the disease may generally be found during life.

*Rheumatic fever* often more closely resembles malignant endocarditis, with its high, irregular fever, and copious sweats, while confusion is further contributed to by the fact that endocarditis is one of the most frequent complications of rheumatism, the malignant form being, however, more infrequent than the simple. But recurring rigors are not usual in rheumatism. The joint symptoms of rheumatism are conspicuous at an early stage of the disease; there is no enlargement of the spleen, nor symptom ascribable to embolism, unless secondary to endocarditis. The essential identity of ordinary *pyemia* and malignant endocarditis has been mentioned, and only the endocarditis and its consequences distinguish the disease from ordinary septic fever.

It must not be forgotten that the simple and severe forms are not separated by any sharp line.

**Prognosis.**—The prognosis is always unfavorable, though ulcerative endocarditis may be prolonged for many weeks and even months. Usually, however, five or six weeks measure its course, while some cases are of shorter duration. Eberth reports a case fatal in two days.

**Treatment.**—Treatment heretofore has availed little. There seems reason to believe antistreptococcus serum may be of service, and several cases of cure are reported. Twenty c.c. may be injected daily. It seems quite harmless. The patient should be kept at rest. Remedies should be restorative and supporting—quinin, stimulants, digitalis. Nourishing food is indicated. The high temperature may be treated by sponging or by an ice-cap, or by Leiter's coils applied to the thorax or abdomen; but high temperature is seldom of so long duration as to require special treatment.

## CHRONIC VALVULAR DEFECTS.

**SYNONYMS.**—*Chronic Endocarditis; Chronic Valvular Disease.*

**Definition.**—Permanent alterations in the structures about the cardiac orifices, producing incompetency, narrowing, or other deviations from the normal.

**Etiology.**—The majority of chronic valvular defects are the consequence of endocarditis, acute or chronic. It may be that the very first attack of acute inflammation has left the valve leaflets in so sclerotic a condition that they readily become the seat of the subsequent changes which constitute the chronic disease, or it may be that several attacks are necessary before a permanent effect is produced. On the other hand, we must acknowledge, too, a chronic valvulitis, in which valvular defect is brought about gradually without the intervention of acute inflammation. This process is analogous to chronic endarteritis, consisting in hyperplasia with fatty (atheromatous) and calcareous degeneration of the new tissue. In fact, a chronic endarteritis may spread from the aorta to the aortic valves.

These slowly induced inflammations are variously caused. The rheumatic poison may cause them, as it does the acute forms. Alcoholic indulgence and intemperate eating, whether by the direct irritation of the substances taken into the blood or through the poison of gout engendered by them, are frequent causes. Another cause is prolonged muscular strain, producing overtension of the valve leaflets. This operates in laborers who do much heavy lifting, and sometimes in athletes. Especially potent is it when, as is often the case, hard muscular work is associated with overeating and drinking. To these, syphilis also often contributes a factor in some unknown way. Under all of these latter circumstances it is the aortic cusps which suffer most.

**Morbid Anatomy.**—The anatomical condition of the defective valves is made up of five separate factors, each of which may enter more or less into the lesion. This is true both of the auriculo-ventricular and semi-lunar valves. These conditions are:

(1) Thickening. (2) Retraction. (3) Adhesion. (4) Atheroma, either alone or associated with calcification. (5) Calcification.

1. *Thickening* is the immediate result of an overgrowth of connective tissue. The slighter degrees are seen along the bases of the aortic cusps and at the line of contact in closure of the mitral leaflets. Such degrees do not necessarily impair the function of the valves. More advanced stages produce a distinct thickening and sclerosis of the whole of each aortic cusp and mitral leaflet.

2. *Retraction* or curling is the result of shrinkage of this hyperplastic tissue. The three aortic cusps are often reefed back and fixed, although the very edge of the valve may still remain movable. In the case of the mitral valve, the tendinous attachments of the papillary muscles often contract and draw the valves into the left ventricle, producing a permanent funnel-like extension analogous to that which takes place in physiological closure of the mitral orifice.

3. *Adhesions* unite the valve leaflets, increasing their fixedness and rigidity, interfering with complete opening and closure. The right and posterior aortic cusps are most frequently united. Most serious is the effect of union of the mitral leaflets, which sometimes results in a reduction of the orifice to a mere slit or buttonhole-like opening—the buttonhole mitral orifice.

4. *Atheroma*, or fatty degeneration, is also often found in the shape of yellow spots on the surface of the valves and at the marginal attachments of the aortic cusp, without producing insufficiency.

5. *Calcification* or limy infiltration of the valves thus united may succeed in various degrees, producing in extreme cases firm, bony rings which further diminish the mobility of the valves. In less degrees there are splinter-like projections into the substance of the valve which also interfere with complete closure and opening; at other times there may be simple marginal deposits which impede the function of the valves only slightly or not at all.

Still another form of lesion found at necropsy is *rupture of a leaflet*, the result of strain. This is perhaps not possible with a sound valve, while one weakened by the morbid states described may give way. The physiological

result is insufficiency, while the lumen of the orifice during systole is not encroached upon. Such an accident is not infrequent in acute ulcerative endocarditis in consequence of erosion and partial destruction of the valve.

Insufficiency of the aortic orifice at the time of life at which it is most common—say middle age—is favored by a gradual widening of this orifice from  $\frac{4}{5}$  inch (20 mm.) at birth to a possible  $2\frac{4}{5}$  inches (70 mm.) at 80 years.

*Congenital defects* are relatively common in the right side of the heart, which is the subject also of inflammation during intra-uterine life. The changes resulting from the latter are of the nature of fusions. Such defects also occur on the left side; most rarely in the mitral valve.

The term relative insufficiency is applied when a valve is insufficient or incompetent because of dilatation of the ventricular cavities or vessels which it guards. (See below.)

#### MITRAL INSUFFICIENCY OR INCOMPETENCY.

**Occurrence and Mechanism.**—This is the most frequent of the uncombined forms of valvular disease. The valve leaks. The blood flows backward during systole from the left ventricle to the left auricle. The distended auricle, first attempting to resist the backward flow, hypertrophies but eventually dilates, and the blood is crowded backward into the lungs, which become engorged. The right ventricle, in its efforts to push the blood through the engorged lungs, hypertrophies, and the pulmonary factor of the second sound becomes louder and sharply accentuated. The compensating effect of the hypertrophied right ventricle for a time arrests the mischief. At this stage, perhaps, begins the hypertrophy of the left ventricle, which in all cases of mitral insufficiency presents itself sooner or later, although at first the double outlet for the blood from the ventricle would seem to demand less strength of the left ventricle. The right ventricle, however, in its hypertrophied state, delivers more blood through the lungs to the left ventricle, which demands more power to drive it on, hypertrophy results, and thus compensation is for a time longer maintained. Sooner or later the right ventricle dilates, the tricuspid valve becomes insufficient, the blood regurgitates into the right auricle and thence into the great veins of the neck. The valves of these ultimately yield, the jugular vein dilates with each systole of the right ventricle producing the so-called jugular pulse and the general venous system is engorged.

Incompetency of the cardiac valves is often brought about by dilatation of the ventricles and the great vessels leading from the heart, the valve leaflets themselves remaining intact. Such *relative insufficiency* affects most frequently the auriculo-ventricular valves, and, as a consequence, the latter are not "sufficient" to stretch across their respective orifices and close them. Less commonly the semilunar valves are similarly deficient; more frequently the aortic in dilatation of the aorta; and more rarely also the pulmonary valve when that vessel is dilated. It should be said of auriculo-ventricular insufficiency of this kind that it is found more frequently in the autopsy-room than recognized clinically, for it does not always cause a murmur.

**Etiology.**—Endocarditis, acute or chronic, is the most frequent initial cause of mitral insufficiency.

**Symptoms.**—Often there are no symptoms, because for a considerable length of time compensation keeps pace with the development of the disease unless the latter be sudden, as by rupture of a valve leaflet. The first thing noticeable is usually *shortness of breath* on exertion, the so-called *cardiac asthma*. With this is soon associated *palpitation*, or “beating” of the heart, which increases and abates *pari passu* with the dyspnea. Next is *irregularity of the heart's action*. This is the beginning of waning compensation, of which the immediate result is congestion of the lungs. Dyspnea is now permanent. Thence the engorgement extends to the right ventricle and venous side of the circulation, the pressure in the arteries being proportionately less. The lung engorgement invites frequent attacks of bronchitis, excites *cough* and increases dyspnea. *Orthopnea* is frequent at this stage, and the patient can only rest sitting in a chair. There is sometimes *blood-stained expectoration*, in which may be found alveolar epithelium dotted with pigment granules.

Along with this, or before it, the *liver becomes congested*, enlarged, and tender; the mucous membrane of the stomach also becomes congested, causing *nausea* and *indigestion*. The hepatic enlargement is sometimes very great, and I have known it to be mistaken for cancer of the organ. The liver is often the seat of pulsation, and as often a jugular pulse is seen. Both signs are pathognomonic of mitral regurgitation. Later, this enlarged liver may return to its normal state or contract still further, constituting the so-called *red atrophy*. In advanced stages the *kidneys also become passively congested*, the urine is scanty and its specific gravity high, while there are copious deposits of urates. It contains a small quantity of albumin and there may be hyaline tube-casts, rarely even a few blood-disks. As a secondary result of hepatic engorgement only there may also be enlargement of the spleen.

Concurrent, or succeeding on failing compensation, comes *edema* or *dropsy*, the direct result of venous engorgement and the filtration of the liquid elements of the blood into the subcutaneous connective tissue of the body—first of the feet and legs, then of the trunk, face, and upper extremities, and, finally, into the pleural and peritoneal cavities, causing various degrees of inconvenience. Effusion into the pleural sacs may occur before there is any tendency to dropsy elsewhere. Allusion has been made to the studies of J. Dutton Steele on this subject on page 589.

*Nose-bleed* is a symptom sometimes seen in this disease. It is a natural result of the venous congestion. Among the later and rarer symptoms in children especially, is *clubbing of the finger-ends*.

**Physical Signs.**—*Inspection* discovers increased frequency of breathing movements. The impulse is to the left of its normal position in the fifth interspace, or perhaps a little lower down. It may be in the line of the nipple or even beyond it, more forcible and diffuse than in health. The outward dislocation of the apex is due to the enlargement of the two ventricles. In thin persons an auricular impulse may be seen to the left of the pulmonic area in the *second interspace*, and may be presystolic and active for the auricle—that is, produced when the auricle contracts; or systolic and passive for the

auricle—that is, caused by a filling of the auricle by regurgitation from the ventricle during the latter's systole. In young persons a bulging precordium may be looked for in the second and third interspaces to the left of the sternum; also to the left of the lower part of the sternum from hypertrophy of the right ventricle. In advanced stages there is a jugular pulse, which is also pathognomonic of tricuspid regurgitation. The jugular pulse must be distinguished from the *false* jugular pulse which occurs when the venous system becomes replete with blood from any cause like overexertion. It is commonly more superficial. It is presystolic in time, while the jugular pulse is systolic. Moreover, the false jugular pulse is obliterated by pressure on the vein above the clavicle, while the true jugular remains distinct below the point of pressure.

On *palpation* the apex-beat is found more forcible than normal, at least while compensation is maintained, and there may be a pulsation near the ensiform cartilage, caused by the *systole of the enlarged right ventricle*. As compensation wanes the impulse becomes weaker and irregular. Sometimes an intermittent *systolic thrill* is felt in the *fourth interspace* in the left mammillary line. Very rarely is there a systolic thrill at the apex.

The *radial pulse* in the early stage is comparatively unaltered. Later, it becomes frequent and irregular in volume. Appended (Fig. 55) is a sphygmogram of the pulse in advanced mitral insufficiency. It is of the type of the *pulsus parvus irregularis*.

FIG. 55.—Tracing of Pulse of Mitral Insufficiency.

*Percussion* generally finds enlargement of both the relative and absolute areas of dullness, upward in the direction of the left auricle, downward to the left and also to the right, the right border of the heart extending at times beyond the right border of the sternum. The impaired resonance thus produced rather by the right auricle than by the ventricle which in its enlargement pushes the auricle to the right.

*Auscultation* recognizes a systolic murmur in the mitral area, conducted with various degrees of loudness into the left axilla and under the angle of the scapula. This direction of its conduction is the distinctive feature of this murmur. It is usually soft, but occasionally rough, more rarely musical. Richard C. Cabot says that musical murmurs are heard more frequently at the mitral valve in regurgitation than at any other valve. A fading mitral systolic murmur generally means further failing compensation, and when compensation is completely gone it is substituted by incomplete valvular sounds, great irregularity, gallop rhythm, labored breathing, and all the signs of pulmonary congestion. The mitral systolic murmur is also sometimes heard distinctly to the left of the pulmonic cartilage, and rarely over the entire precordium. Not always loud enough to be easily heard, it may be brought out by exertion on the part of the patient.

The second sound of the heart is heard sharply accentuated at the pulmonary area until the tricuspid valve fails, when the accentuation fades

away. The aortic second sound is less strong, corresponding with the smaller degree of hypertrophy of the left ventricle.

*Differential Diagnosis.*—The murmur of mitral regurgitation is not usually difficult of recognition through the features which have been described. A functional murmur is rarely heard at the apex. Should it happen that it is, it will not be conducted as is the organic mitral systolic murmur, and it is not heard behind and below the angle of the scapula. Aortic roughening produces a murmur heard at the same time as the mitral systolic, and may also be propagated to the apex, but the position of greatest intensity is the second interspace to the right of the sternum and the murmur is transmitted loudly into the great vessels of the neck, which is never the case with the mitral systolic murmur. The tricuspid systolic murmur occurs at the same time, but its point of greatest intensity is at the ensiform cartilage; it is not commonly a loud murmur and is more apt to be obscured by the mitral regurgitant murmur than it is likely to obscure the latter.

### MITRAL STENOSIS.

**Occurrence and Mechanism.**—This lesion occurs as an uncombined or simple form of valvular disease in young persons, especially women, but is more commonly combined with mitral insufficiency. Seventy-six per cent. of all cases are said to occur in the female sex. In the simple form the orifice is stenosed, and the blood is restrained from passing freely into the left ventricle. It is backed into the left auricle, the lungs, right ventricle, and general venous circulation, but the left ventricle is not hypertrophied in simple mitral obstruction because no extra muscular demand is made on it, while hypertrophy of the left auricle is one of its most characteristic signs. Theoretically, the left ventricle should even atrophy from diminished function. Practically this does not occur, but the absence of the enlargement is of great diagnostic value. Excellent compensation is often maintained in mitral stenosis for many years.

The enlargement and dilatation of the left auricle is in rare instances enormous, especially in the form known as horizontal dilatation which has been especially studied by Owen, Fenton and Ewart.<sup>1</sup> The enlargement with corresponding dullness to percussion extends both to the left and right of the sternum and the auricle has been tapped under the impression that it was a circumscribed collection of fluid in the pleural sac.

Pure stenosis without regurgitation is possible if the mitral valve leaflets are fused without retraction, so as to form the funnel-shaped opening already described. In these cases a postmortem demonstration of insufficiency by means of the hydrostatic test is scarcely possible. Less frequently the mitral orifice viewed from above is a mere slit—Corrigan's buttonhole contraction—straight or slightly crescentic, in a smooth septum formed by fusion and contraction of the valve leaflets and tendinous cords. In some cases calcareous infiltration is added, and in a few rare instances

<sup>1</sup> Owen and Fenton, "A Case of Extreme Dilatation of the Left Auricle of the Heart," "Clinical Society's Transactions," vol. xxxiv., 1901, p. 183.

Ewart and Owen, "A Case Illustrating some of the Clinical Features of Horizontal Dilatation of the Left Auricle," "Ibid.," Vol. xxxiv., 1902, p. 142.

Owen, "Horizontal Dilatation of the Left Auricle," "Ibid.," p. 147.

uratic deposits are found. The ratio of buttonhole mitral stenosis to the funnel-shaped orifice varies with different observers—1 to 10 by A. E. Sansom, 1 to 13 by Hayden, 1 to 46 by Hilton Fagge.

**Etiology.**—Most frequently mitral stenosis is the result of endocarditis, acute or chronic, but it may in rare cases be congenital. In these cases, of which a number have been collected by Bedford Fenwick, the stenosis is secondary to narrowing of the tricuspid orifice, thus explained:—a small quantity only of blood being allowed to pass into the right ventricle and lungs, a diminished supply is sent to the left heart, whence both its cavities and orifices are reduced in size. Attention has been called by Teissier to the possible origin of mitral stenosis in tuberculosis and Robert H. Babcock has reported some cases which tend to confirm this view.<sup>1</sup> *No functional disorder can cause mitral stenosis.*

**Symptoms.**—These, often delayed by compensation, as in mitral insufficiency, are the same as in that lesion. In consequence of this similarity of symptoms the diagnosis of mitral stenosis is based largely on the physical signs. As in mitral insufficiency, in long cases and especially in children, clubbing of the finger-ends may be present.

**Physical Signs.**—Mitral stenosis may exist for many years without giving rise to physical signs. *Inspection* consistently with what would be expected in absence of hypertrophy of the left ventricle, recognizes little or no displacement of the apex in pure stenosis. If there is any, it is due to the hypertrophy of the right ventricle which pushes the apex toward the left rather than downward and to the left. Nor is the true apex-beat increased in force, though there may be strong epigastric pulsation because of hypertrophy of the right ventricle, and in persons with thin chest-walls there may be an impulse in the *third and fourth interspaces*, to the left of the sternum, due to this hypertrophy. A left auricular impulse, presystolic, may be noted in the second interspace to the left of the sternum, for the same reason as in mitral regurgitation. A *jugular pulse* may also be present if there is tricuspid regurgitation. A bulging precordium is possible only from great enlargement of the right ventricle and is not often seen. In children the lower sternum and fifth and sixth left costal cartilages may be prominent from this cause. There may be prominence of the right upper quadrant of the abdomen from enlargement of the liver.

**Palpation** discerns that the apex-beat is without undue force, but it may be diffuse, and an impulse may be felt in the epigastrium, the situation of the apex of the right ventricle. The most marked feature recognized by palpation is the *presystolic thrill* at the apex, differing in this respect from the rare systolic thrill of mitral insufficiency. It is usually best felt in the fourth or fifth interspace, within the nipple-line. It is similar in rhythm to the presystolic murmur, but may be present without it. It is often absent. It is pathognomonic of mitral stenosis. Palpation may recognize tenderness in the region of the liver.

In moderate degrees of stenosis the *pulse* is not altered; in high degrees it is small, from want of blood and left ventricular power. Irregularity, like that of mitral regurgitation, is characteristic of advanced stages. Two tracings from cases of mitral stenosis are introduced in the text.

<sup>1</sup>Diseases of Heart and Arterial System, 1903, p. 252.

*Percussion* recognizes cardiac enlargement in the direction of the left auricle and right ventricle, but not of the left ventricle in pure mitral stenosis.

*Auscultation* does not find a murmur in every case of mitral stenosis because of the feebleness of the auricular contraction, especially toward the end of life, when compensation has failed and there is not the force of contraction sufficient to throw the blood stream into audible vibration. Most characteristic is the abruptly terminating *presystolic* murmur, confined for the most part to the mitral area to the inner side of the apex-beat, though it may be conveyed upward, and it is even heard posteriorly, though rarely. It is true that the presystolic murmur is heard in atypical situations, especially in the axilla and below the angle of the scapula, more frequently than has commonly been supposed.<sup>1</sup>

The *presystolic murmur* of mitral stenosis is a diastolic murmur occurring at the end of diastole of the ventricle, because it is at this time that the auricular systole takes place, giving the propulsive force necessary to produce the audible vibration. It is a loud, rough, vibratory murmur terminating suddenly with the first sound, sharp and ringing and coincident with the presystolic thrill. The murmur terminates with the impulse, and as the two are not always easily separable, the former is commonly more readily distinguished by its qualities than by its time. It is often followed by a "thumping" first sound, which, in consequence of this character, is sometimes mistaken for a second sound. As the disease advances the murmur may occupy the entire period of diastole. In such cases there is sometimes a short pause between the beginning or diastolic part and the terminal or presystolic part of the murmur. In the last stage the murmur may disappear altogether, leaving only the snapping first sound.

*Differential Diagnosis.*—The murmur of mitral stenosis ought not to be confounded with the murmur of aortic regurgitation, for the latter is

FIG. 56.—Tracing of Pulse in Mitral Stenosis.

heard loudest in a different situation, but moreover there is enormous hypertrophy of the left ventricle, which is wanting in mitral stenosis. The time of tricuspid stenosis is identical with that of mitral stenosis, but it is heard in a different part of the precordium—in the epigastrium. Tricuspid stenosis is, however, a very rare lesion. Much more reasonably might the murmur of mitral stenosis be confounded with the so-called *Flint murmur*. This murmur is heard at the apex, at the same site as the presystolic, and may be similar in quality. It occurs in high degrees of dilatation of the ventricle, and is due to the fact, according to the late Austin Flint, Sr., that in such dilatation the mitral leaflets cannot, during diastole, be kept back

<sup>1</sup> See an excellent well illustrated paper on this subject by J. P. C. Griffith in the "Transactions of the Association of American Physicians," 1895.

against the ventricular wall, but remain in the blood current, throwing the latter into audible vibration. It may be said of the Flint murmur that it is never as intense as the mitral presystolic murmur. Otherwise the acoustic qualities are similar. The snapping first sound and systolic shock are also apt to be modified or absent. Accentuation of the pulmonic second sound is wanting in marked aortic insufficiency, and the other signs of aortic regurgitation are most helpful to a diagnosis.

A rumbling sound succeeding a pericarditis in children, referred to especially by Broadbent and Rosenbach, has occasioned error, but this, too, is said to be unaccompanied by accentuation of the first sound at the apex. It is a transient murmur often followed by recovery.

These sources of error are well illustrated by the observations of Phear,<sup>1</sup> who investigated 46 cases of presystolic murmur in which no mitral lesion was found at autopsy. In 17 of these there was aortic regurgitation; in 20 there was adherent pericardium; in nine nothing more than dilatation of the left ventricle was found. In none was the snapping first sound, so common in mitral stenosis, recorded during life.

Not infrequently the presystolic murmur is associated with a mitral systolic or regurgitant murmur, usually soft and not very loud, though sometimes it is distinct and is well transmitted into the axilla.

The *pulse* is small, as would be expected from the small volume of blood ejected from the ventricle, but may be quite regular, as seen in the sphygmograms. More frequently it is irregular. Sometimes there is a rhythmical failure of an alternate heart-beat to reach the wrist, while the sphygmogram will show a small rise between two higher ones constituting the *pulsus bigeminus*.

On account of the difficulties mentioned, while the presystolic murmur is a valuable sign of mitral stenosis, it should not be alone relied upon for diagnosis, but should be taken in connection with other signs. Tricuspid stenosis may be associated with mitral stenosis or insufficiency, or both. With the loss of compensation the presystolic murmur disappears together with the thrill, and there remains only the sharp, ringing first sound.

*Accentuation of the second sound* is marked, but confined to the pulmonary area, because there is no hypertrophy of the left ventricle. The *second sound* may also be *duplicated*, because of the want of synchronism in the closure of the aortic and the pulmonary valves. A. E. Sanson regards this reduplication as only a seeming one of the second sound. He regards it rather as the normal second sound followed by another sound due to a sudden tension of the mitral valve itself. He also says it occurs in at least one-third of all cases of mitral stenosis, and is rare in other cardiac conditions. The accentuation of the pulmonary second sound also disappears with the enfeebling of the contraction of the right ventricle.

In slight degrees of mitral stenosis the second sound is heard at the apex, but as the lesion becomes more serious it becomes fainter and eventually inaudible in this situation, though markedly accentuated in the pulmonic area.

The physical signs of mitral stenosis are more changeable and fleeting than those of any other valvular disease of the heart.

<sup>1</sup> "Lancet," September 21, 1895.

Sansom lays great stress on the evidence of the cardiograph in the diagnosis of mitral stenosis, which enables one to judge of the relative length of systole and diastole. In stenosis the diastole may be greatly prolonged, or the diastolic intervals vary greatly in duration. In mitral regurgitation, on the other hand, a short interval only separates the systoles.

*Complications.*—Patients with mitral stenosis are subject to attacks of recurring valvulitis, with consequent embolism in different parts of the body. Embolism is a frequent complication of mitral stenosis. Pulmonary tuberculosis, quite infrequently associated with valvular heart disease, is found more often in association with mitral stenosis than any other form.

#### MITRAL INSUFFICIENCY AND STENOSIS.

**Occurrence.**—More common than mitral stenosis as an uncombined lesion is stenosis associated with insufficiency, in which case we have the double mitral murmur of mitral insufficiency and mitral stenosis, sometimes with difficulty divisible into its two parts. Extreme irregularity of rhythm and pulse, with frequency and smallness of the latter, conspicuous thrill, marked right-sided hypertrophy, and sharply accentuated pulmonic sound are characteristic of advanced stages. The presence of hypertrophy of the left ventricle points to associated mitral insufficiency and stenosis. When this combined lesion exists, mitral insufficiency is said to usually precede.

#### AORTIC INSUFFICIENCY OR INCOMPETENCY.

**Occurrence and Mechanism.**—By aortic insufficiency is meant an inability of the aortic valve to close the orifice of the aorta. This is the most serious and irremediable of the valvular diseases of the heart commonly met. Next in frequency to mitral incompetency, much more frequent than aortic stenosis, with which it more often coexists, it is a disease of men rather than women, commonly adults at or before middle life. It includes 30 to 50 per cent. of all cases of chronic valvular disease. The width of the aortic orifice increases from birth to old age, while the valve cusps tend to shrivel, so that conditions favorable to incompetency coexist. It is more frequently associated with arterial sclerosis and less frequently the result of rheumatic endocarditis, though it may be thus caused. It is the lesion most frequently followed by sudden death.

When it exists, the aortic valves are incompetent to close the aortic orifice, either on account of the large size of the latter or of disease of the valve segments, and the blood flows backward into the left ventricle during diastole. The ventricle, seeking to restore the balance, redoubles its energy and hypertrophies. The blood is thus driven into the aorta with great force, swelling the arteries to an extreme fullness, which, however, falls promptly away, because of the backward flow into the ventricle at the same time with the forward movement into arteries and capillaries. This sudden falling away of the pulse, from extreme distention to collapse, is very characteristic

of this form of valvular disease, and is called the "trip-hammer" or "water-hammer" pulse, also Corrigan pulse. To the careful observer it may even be visible in the exposed arteries, such as the carotid, temporal, and radial, while the aortic beat, ordinarily beyond reach in the suprasternal notch, may be felt in this situation.

The abrupt jerking impulse with sudden recoil is easily recognized by the finger on the pulse, which, however, fails to find the pulse as strong and hard as would be expected from its appearance. On the other hand, it is soft and receding. It is commonly regular. A tracing of this pulse is seen in Fig. 57. It is the typical *pulsus celer et altus*. A frequent and irregular pulse is much more serious in aortic valve disease than in mitral disease. *Sclerotic changes in the arterial walls* are not uncommonly associated with aortic incompetency.

The product of this defect is the largest heart met in morbid anatomy, the left auricle and right ventricle often sharing in the enlargement. From its size the heart is called the *bovine heart*. It may weigh as much as 35 ounces (1050 gm.), and even 50 ounces (1500 gm.) or more. The cavities

FIG. 57.—Tracings of Pulse of Aortic Regurgitation.

are enlarged and the walls are thickened, so that it furnishes an instance of eccentric hypertrophy. There may be ultimate dilatation of the arch of the aorta from the constant pounding of the blood against it in systole, while the carotids may be seen throbbing in the throat.

The gradual enlargement of the ventricle may ultimately cause the mitral valve to yield. Compensation is still maintained for a time by hypertrophy of the left auricle, which also yields after a time, becoming dilated and allowing the blood to engorge the lung. Hypertrophy of the right ventricle then comes to the rescue for a time. Sooner or later it, too, yields, dilates, the tricuspid valve weakens, and finally gives way, allowing the blood to flow back into the venous side of the circulation, producing engorgement of the liver, stomach, kidneys, general dropsy—the train of symptoms described under mitral regurgitation.

**Etiology.**—Causes of insufficiency in addition to those considered under the general etiology of valvular disease are congenital malformations, including fusion of two leaflets, commonly those behind which the coronary arteries come off. Such fused leaflets are especially prone to valvulitis and its

consequences. Aortic insufficiency is quite often caused by dilatation and aneurysm of the ascending aorta, giving rise to *relative* insufficiency.

**Symptoms.**—Like all other forms of valvular heart disease, aortic incompetency may be compensated for a long time, and elude detection for a corresponding time. Indeed, full compensation is said by some to be most usual in this form of valvular disease. Both *dropsy* and *dyspnea* are characteristically *absent* until compensation ceases, which is never the case until the mitral valve begins to yield. Then, however, both appear and may be very distressing. An especially frequent symptom is *dizziness* with *faintness*, particularly on rising quickly. Palpitation ensues on slight exertion, and this effect is in marked contrast to the comfort of the patient when quiet, when the pulse may be slow and breathing regular. In advanced cases, on the other hand, the patient complains of a constant “*beating*” or pulsation all over the body, especially in the head, which is exceedingly unpleasant. The patient is very apt to be *troubled in his sleep* and to dream, probably because of disturbed circulation in the brain. Even permanent mental symptoms may result from this cause, including *insanity* and *suicidal tendency*. Lesser degrees are *irritability* and *peevishness*, though these are not confined to this form of heart disease. *Precordial pain*, present also in stenosis, is frequent in this form of valvular disease. It may be a dull ache with a sense of constriction of the chest, or sharp and radiating down the arms, particularly the left, as in angina pectoris, which condition itself is also common. With the yielding of the mitral valve and loss of compensation come the symptoms of mitral disease already described.

As previously stated, this is the form of valvular disease in which *sudden death* is most frequent. It has overtaken many a victim in the course of his daily vocation and without warning, though it is most apt to be induced by some slight overexertion or mental excitement. The cause of such sudden death is probably interruption of the circulation in the coronary arteries. This may be brought about in one of two ways. These arteries in common with others, are especially disposed to endarteritis with resulting sclerosis and atheroma, a condition which constantly invites thrombosis and obstruction to the circulation; or it may be due to defective circulation in these vessels, caused by the aortic regurgitation, for even if the blood enters the coronary arteries during systole, it must still receive in health some further supply in the recoil of the blood on the closed semilunar valves, which cannot take place when the valves are incompetent. On this variety of valvular disease, too, supervenes not infrequently acute infectious endocarditis of the grave type, with the train of symptoms and the sequelæ described. Embolism in various organs is also a complication.

**Physical Signs.**—*Inspection* often discerns the prominent left precordium, with the apex-beat lowered and to the left, and the visible pulsation far beyond the normal situation of the apex, all confirmed by *palpation*. Palpation also recognizes at times a *diastolic thrill* over the base, in the carotids and subclavians, and sometimes in the aorta at the suprasternal notch. This is, however, much rarer in aortic regurgitation than the systolic thrill in stenosis. The Corrigan pulse may also be felt, but is much more strikingly manifested in the sphygmogram. A *capillary pulse* is also sometimes demonstrable in the skin and mucous membrane. This may be observed by

drawing a pencil lightly across the skin of the cheek or forehead; and on the mucous membrane of the everted lower lip by pressing a glass microscope-slide against it. It may often be well studied around the lunula of the finger-nail. Pulsation in the retinal arteries may be recognized by the ophthalmoscope. Pulsation may even be seen in the uvula as originally pointed out by F. Müller in 1889, by Schlesinger<sup>1</sup> the next year and recently by David Riesman.<sup>2</sup>

*Percussion* discloses increased dullness to the left and downward, and also, sometimes in advanced cases, upward to the left of the sternum, owing to hypertrophy of the left auricle, as well as to the enlargement of the ventricle upward.

*Auscultation* recognizes a diastolic murmur, long, loud, and blowing in quality, usually harsher than the aortic obstructive murmur, though it is also often soft and faintly heard. It may or may not replace the second sound of the heart. It is commonly well heard in the aortic area, but its seat of maximum intensity may be either in this area, in the third interspace to the left of the sternum, or at the midsternum between these two points. The murmur is naturally transmitted downward toward the ensiform cartilage along the left edge of the sternum. It is sometimes also well conducted toward the apex which is in the direction of the regurgitating column, but it is not conducted in the direction of the great vessels of the neck, at least with any loudness. In aortic incompetency also occurs the Flint murmur, described under mitral stenosis. This murmur is additional to the distinctive diastolic murmur being produced at the mitral orifice (see p. 625). *The aortic regurgitant murmur is probably the most widely conducted of all cardiac murmurs.*

*Differential Diagnosis.*—The aortic diastolic murmur is distinguished from the pulmonic diastolic murmur by its wide conduction, the large hypertrophy of the left ventricle, the Corrigan pulse, and the capillary pulse. The tricuspid presystolic murmur is a diastolic murmur, heard in the same situations but it is a rare murmur and is unaccompanied by hypertrophy of the left ventricle. More important sources of error are a few diastolic murmurs without lesions of the aortic or pulmonary valves due to relative insufficiency, to hemic conditions or cardiorespiratory murmurs.<sup>3</sup>

*Auscultation of the vessels* furnishes interesting information in aortic insufficiency. It is well known that if the stethoscope be placed with slight pressure over the carotid artery of a healthy person, two sounds are usually audible, corresponding to the expansion and contraction of the artery. Of these the latter is simply the second aortic sound heard in the carotid. It is probable also that the first arterial sound corresponding with the arterial expansion is produced by vibrations of the arterial wall induced by the blood driven into it from the ventricle. The second arterial sound is greatly diminished in intensity or even absent in aortic incompetency, since the valve remains open. The aortic diastolic murmur is sometimes faintly heard in the carotid. In aortic regurgitation there is *Traube's double sound*, in the distant arteries, especially the femoral and popliteal. The

<sup>1</sup> "Wiener klin. Wochenschrift," October 4, 1900.

<sup>2</sup> "American Medicine," June 15, 1901.

<sup>3</sup> See a paper by Richard C. Cabot and Edwin A. Locke on "The Occurrence of Diastolic Murmurs without Lesions of the Aortic or Pulmonary Valves." "Johns Hopkins Hospital Bulletin," vol. xiv., May, 1903.

sounds are such that the two follow each other closely, so that the first seems preparatory to the second, or they are separated by a longer interval, like the two sounds of the heart. The first is a sharp systolic (pistol-shot) sound and is ascribed to a sudden filling of the unusually empty artery, and is probably an exaggeration of the sound heard in health, as above described. Traube explained the first of his sounds in this way, while he ascribed the second to a sudden relaxation of this tension. Friedreich pointed out that a similar double sound could be heard in the femoral vein in tricuspid insufficiency, which he ascribed to tension of the valves of the vein. It is claimed that the double sound is heard in other diseases of the heart, especially mitral stenosis, and even in aneurysm, but it is acknowledged to be most frequent in aortic incompetency.

Finally, there is *Duroziez's sign*, a murmur produced by pressure with the stethoscope upon the femoral artery, sometimes heard in aortic insufficiency. Duroziez's sign will be more easily understood when it is remembered that a murmur may be produced by pressure with the stethoscope on any artery of the caliber of the carotid—a murmur during the expansion or diastole of the artery. During the collapse or systole of the artery, on the other hand, no murmur can be thus produced in health. In aortic regurgitation, however, it is different, a double murmur may be produced and it is the second murmur which is essential to Duroziez's sign. It is said that this sign dies out as compensation fails. T. Clifford Allbutt does not consider Duroziez's sign peculiar to aortic regurgitation, though Vierordt says it is. A right degree of pressure, to be determined by practice, is necessary, and the artery on which it is obtained is usually the femoral.

The gravity of aortic regurgitation is measured by the degree of hypertrophy of the left ventricle, by the irregularity of its action, a symptom which appears only in advanced stages of regurgitation, the extent of collapse of the artery in diastole, the degree in which the diastolic murmur replaces the second sound as heard at the aortic orifice. Irregularity of cardiac action is a much more serious symptom in aortic regurgitation than in mitral disease. Diminution in the loudness of the diastolic murmur has been regarded as a serious sign, but this, I think, has been exaggerated, as the loudness of the murmur varies greatly, quite independently of the extent of the lesion.

#### AORTIC STENOSIS AND ROUGHENING.

**Occurrence and Mechanism.**—By aortic stenosis is meant a narrowing of the aortic orifice. Pure and uncomplicated aortic stenosis is probably the rarest of the valvular lesions. Writers have been led into error because the presence of an aortic systolic murmur has been interpreted as meaning stenosis, where it has been produced by simple roughening of the valves or of the vessel beyond them. Richard C. Cabot says that out of 250 autopsies made at the Massachusetts General Hospital, there was not one of uncomplicated aortic stenosis. Indeed it is difficult to conceive an aortic stenosis unaccompanied by insufficiency, although it is easy to conceive of insufficiency without stenosis. Stenosis is said to be relative when there is a

normal orifice while the aorta is dilated beyond it. It occurs in older persons, and the older the person, the more likely are there to be calcareous deposits causing it. It may be congenital. When uncombined with insufficiency, it is the least dangerous of the various forms of valvular disease. The narrowed orifice prevents the free discharge of blood from the left ventricle into the aorta. The ventricle attempts to overcome this, and its walls hypertrophy in proportion to the degree of resistance, and often for a long time compensate for the obstruction—until dilatation occurs, when the danger really begins. The hypertrophy thus induced, usually of the simple form, is only second in degree to that produced by incompetency.

**Symptoms.**—The symptoms of aortic stenosis may be long deferred, so long as compensation is maintained, and when they do occur, they are usually those of a deficient supply of blood to the brain and heart itself—viz., *dizziness* and *fainting*. Succeeding exertion there is apt to be a *sense of constriction or oppression* and even *pain* in the precordium, which may develop into the severe pain of a true angina pectoris.

**Physical Signs.**—*Inspection* and *palpation* recognize usually a forcible impulse outside of its normal site, and at varying distances, in accordance

FIG. 58.—Pulse-tracing of Aortic Stenosis.—Anaortic Curve.

with the degree of hypertrophy. Some describe the apex-beat as without force and indistinct. Broadbent says it is "a well-defined and deliberate push of no great violence." Palpation often recognizes a *thrill* of great intensity with each beat of the heart, more marked when dilated hypertrophy is established. A bulging of the precordium may also be present, though less often than in incompetency.

The pulse is the *pulsus parvus et tardus*, slow in reaching its maximum volume, which is small. It is frequent, but regular, contrasting in the latter respect with the pulse of mitral disease. It is sometimes infrequent, *pulsus rarus*. Fig. 58 is a sphygmogram of the pulse in aortic stenosis.

**Percussion** elicits dullness downward and laterally toward the left, since, as a rule, the enlargement is confined to the left ventricle. There may, however, be slight enlargement upward to the left of the sternum if hypertrophy of the left auricle is added.

**Auscultation** discloses a systolic basic murmur, loudest at the aortic area—second interspace at the right of the sternum—conducted distinctly into the carotids, and even sometimes along the course of the aorta, behind and to the left of the vertebral column, into the popliteals and dorsal arteries of the feet. It is not, however, confined to the aortic area, but may be heard over the entire precordium. It is usually rough, at least until compensation fails, but may be soft and musical. It may be heard even at a distance from the chest. It is made louder by exercise. The *aortic factor* of the *second sound* is *very feeble*, or not at all heard, if the constriction be quite marked, because of the feeble recoil, the necessary result of the small amount of blood in the aorta. The first sound is normal, somewhat

louder and more prolonged than natural, because of its powerful contraction of the left ventricle.

*Roughness of the aorta, dilatation and narrowing of the vessel*, however caused, may also produce a systolic murmur; so may roughness within the ventricle in the course of the outgoing column of blood. But these causes have a less positive effect upon the substance of the heart—that is, do not produce as marked hypertrophy of the left ventricle. Nor do these causes interfere with the production of a normal second sound, except, perhaps, dilatation, which in that event is accompanied by an aortic regurgitant murmur. From this it follows that the important point to remember in diagnosis is that an aortic systolic murmur by no means always indicates aortic stenosis. So, also, anemic or hemic murmurs, which are always systolic and for the most part basic, may simulate aortic systolic murmurs, but these occur in young, delicate persons of both sexes, are often intermittent and without other effect on the muscular heart, while they are also unaccompanied by thrill. There may be roughness, too, in the pulmonary artery, which can be localized to the left of the sternum.

As already mentioned, stenosis of the aortic orifice is very apt to be associated with insufficiency, the same rigidity and adhesion which prevent complete patulousness of the orifice preventing also complete closure.

*Differential Diagnosis.*—The signs which distinguish aortic *stenosis* from aortic *roughening* are not many. In aortic stenosis the pulse is small as contrasted with that of simple roughening or dilatation of the aorta. A systolic thrill is more characteristic of aortic stenosis. It may be felt at the base and apex, and rarely at the apex alone. From the last may be inferred that the cusp nearest the mitral leaflets is involved.

#### AORTIC STENOSIS AND INSUFFICIENCY.

**Occurrence.**—This double lesion is a comparatively frequent one; indeed, it is commonly regarded as the next in frequency after mitral insufficiency, and therefore more frequent than either aortic insufficiency or aortic stenosis alone. It occasions a double basic murmur, systolic and diastolic, and is also a grave condition, giving rise to the same dangers as aortic regurgitation, and the same enormous hypertrophy of the left ventricle.

**Diagnosis.**—The diagnosis of this condition requires special mention, because it not infrequently happens that it is mistaken for *aneurysm of the arch of the aorta*, which is associated with a similar double murmur of which the systolic element is due to the roughness of the aorta and aneurysmal walls, and of which the diastolic is a sign of relative insufficiency due to dilatation of the aorta. The distinctive differences between the two conditions will be given in treating aneurysm of the arch of the aorta.

#### TRICUSPID INSUFFICIENCY OR INCOMPETENCY.

**Occurrence and Mechanism.**—Tricuspid regurgitation as a primary condition is extremely rare, and, when present, is probably the result of an endocarditis which during fetal life is more prone to attack the right than

the left side. Endocarditis involving the tricuspid valve may, however, also occur in children—according to Byrom Bramwell,<sup>1</sup> more commonly than has been supposed. Infectious or ulcerative endocarditis also affects the tricuspid valve—according to Osler, in 19 out of 238 cases. More frequently tricuspid regurgitation is the result of a *relative insufficiency*, one of the terminal events of mitral disease, the tricuspid orifice yielding with the dilatation of the right ventricle, which takes place sooner or later, consequent upon the resistance to the movement of the blood through the engorged lungs. It is also one of the possible sequelæ of emphysema of the lungs and long-standing fibroid phthisis or chronic bronchitis, succeeding, too, a primary hypertrophy of the right ventricle, due to these causes.

Thus, out of 405 autopsies at Guy's Hospital in which evidence of tricuspid regurgitation was found, 271, or two-thirds, succeeded on mitral disease, 68 were due to myocardial degeneration, 55 to pulmonary disease, viz., bronchitis, emphysema, and cirrhosis of the lung. The effects of venous obstruction growing out of tricuspid insufficiency have been detailed on page 621.

Tricuspid insufficiency succeeding upon mitral insufficiency is not always accompanied by an audible murmur. It is evident that every case of mitral regurgitation associated with dropsy must be attended with tricuspid regurgitation. Very few of the cases above referred to had been diagnosed during life, and in all of them the valve was itself healthy, but insufficient to close the dilated orifice.

**Symptoms.**—These are those described when treating of mitral disease after the stage of tricuspid regurgitation has been reached, dropsy more or less general, engorgement of the stomach, liver, and kidneys, an enlarged, tender, pulsating liver, and a jugular pulse. The last two symptoms are regarded as pathognomonic.

Jugular pulse is often more forcible in the right than in the left jugular. There is also cyanosis, dyspnea, and pulmonary edema. The jugular pulse is systolic in time, and does not appear until the valves situated at the opening of the internal jugulars into the innominate veins yield. These give way first on the right side, because the course of the right innominate is straighter and communication is more direct. So long as the valve above the bulbus jugularis is closed, the pulse is confined to the bulb, but with the yielding of this valve the pulse becomes general throughout the vein. It is sometimes difficult to distinguish a true jugular pulse from the "physiological" or "false" jugular pulse, which may sometimes be seen in health and whenever the venous system is overfull. Pressure on the vein above the valves will cause the false pulse to disappear while the true pulse, coming from the right ventricle, will remain. The physiological or false jugular pulse alternates with the ventricular systole is presystolic—a negative pulse—while the true jugular coincides with the systole of the ventricles.

**Physical Signs.**—In primary tricuspid disease with regurgitation, *inspection* and *palpation* reveal an apex-beat diffused toward the ensiform cartilage and the epigastrium. *Percussion* detects enlargement toward the right edge of the sternum, due to hypertrophy of the right ventricle, which occurs for the same reason as hypertrophy of the left ventricle in mitral

<sup>1</sup>"Amer. Jour. Med. Sci.," April, 1886, p. 419.

insufficiency. It is not, however, that the right ventricle protrudes to the right as much as that it pushes the right auricle over to the right.

To *auscultation* the systolic murmur thus engendered is almost invariably feeble, and is heard almost solely in the tricuspid area, just above and to the left of the ensiform cartilage. Occasionally only is the second pulmonary sound accentuated. There should be no confounding of this murmur with that of aortic regurgitation conducted toward the same situation, but different in time, nor with that of mitral regurgitation heard at no great distance, for the reasons already given. To these must be added a difference in quality and pitch between the tricuspid and the mitral murmur, not always, however, manifest.

### TRICUSPID STENOSIS.

**Occurrence.**—Tricuspid stenosis is a rarer condition, but it may be an acquired one in association with left-sided heart disease as the result of rheumatic endocarditis, and of unknown causes. Ninety per cent. of cases are associated with mitral stenosis. It is much more frequent in women, fully 80 per cent. of all cases being in them. As in endocarditis of the left side, there are thickening, adhesion, narrowing.

A presystolic tricuspid murmur pointing to stenosis, in a case observed by Gardner, was found due to a growth from the endocardium of the right auricle, so placed as to fall over the tricuspid orifice in the manner of a ball valve. Fred. C. Shattuck has met one instance of tricuspid stenosis with mitral stenosis and regurgitation, along with adherent pericardium, hepatic cirrhosis, and slightly granular kidney, as determined by autopsy. In this case there was a presystolic tricuspid murmur observed for three years before death.

**Physical Signs.**—Simple uncomplicated tricuspid stenosis would be recognized by the presence of a presystolic murmur and thrill, best heard in the tricuspid area, unaccompanied by hypertrophy of the right ventricle. When associated with left-sided heart disease, the diagnosis is seldom made, because the murmur is masked by the coincident mitral *presystolic murmur*. In a very few cases only is it confined to this valve. Frequently there is no murmur. *Percussion* shows dullness to the right of the sternum, if there is dilatation of the auricle, which does not always occur.

Congenital stenosis of the tricuspid orifice occurs, but is usually associated with defects of other valves, which early cause death.

**Other symptoms** are cyanosis of the face and lips and, in the later stages, extreme and obstinate dropsy.

### PULMONARY INSUFFICIENCY OR INCOMPETENCY.

**Occurrence.**—Simple pulmonary regurgitation is rarely seen. It may, however, exist as a congenital defect (fusion of two segments), and the pulmonary valve has been found involved in ulcerative valvulitis.

**Physical Signs.**—It is easy from what has gone before to deduce the physical signs which are to be expected—a diastolic murmur heard in the

pulmonic area, hypertrophy of the right ventricle, later jugular pulse, venous congestion, and cyanosis. The diastolic murmur may be confounded with that of aortic insufficiency, but the latter is accompanied with hypertrophy of the left ventricle, with Corrigan pulse and capillary pulse. A few cases are related in which a diastolic murmur has been found associated with defects in the pulmonary valves—in one, warty, which might have been the result of infectious endocarditis. All others are congenital. Among them is aneurysmal dilatation. Such was the case reported to the Pathological Society of Philadelphia by Edward T. Bruen (see "Transactions" for 1883).

#### PULMONARY STENOSIS.

**Occurrence.**—The great majority of systolic murmurs heard at the pulmonary orifice are functional. Pulmonary stenosis, though very rare, may, however, exist, in which case it is far more likely to be *congenital from arrested development*, although *intrauterine endocarditis* may also cause it. So, also, may infectious endocarditis, and in rare instances, atheroma. I well remember a case of malignant endocarditis with a pulmonary systolic murmur in which I was led from a correct diagnosis, because I thought that such murmurs are so invariably functional that it was scarcely worth while to consider the probability of an organic lesion. The autopsy disclosed a valvulitis of the pulmonary valve. Since then I have met other cases. The valve leaflets are apt to be fused. When the lesion is congenital, it is commonly associated with patency of the foramen of Botal or foramen ovale, together with imperfect ventricular septum and tricuspid stenosis.

**Physical Signs.**—Pulmonary stenosis should furnish a systolic murmur in the pulmonary area, to the left of the sternum. The murmur may even be heard behind, between the shoulders, and it may be rough. It is accompanied by hypertrophy of the right ventricle. There may be a basic thrill, as in aortic obstruction, but the pulse is uninfluenced. Compensation may be set up by means of a patulous foramen ovale, an open ductus arteriosus, or interventricular communication. The invariable presence of cyanosis due to venous obstruction and of attacks of dyspnea complete the picture and aid greatly in the diagnosis. Anemic murmurs at the same time and place are unaccompanied by cyanosis.

Walshe has described a case of death from thrombosis of the pulmonary artery in which he heard a pulmonary systolic murmur before the end came.

#### CONGENITAL DEFECTS.

Congenital defects in the cardiac valves and orifices deserve a passing notice. They may be the result of endocarditis during fetal life or of arrest of development. Their most frequent seat is the right heart, and the most frequent form is *stenosis of the pulmonary orifice*, the effects and signs of which have already been considered. Another is a permanently *patulous foramen ovale*; or there may be a *defect of the septum of the ventricles*, or a communication between the aorta and pulmonary artery—a *persistent ductus arteriosus*—or *between the aorta and the vena cava or aorta and right auricle*. All of these intercommunications produce murmurs difficult to

separate, and it is, after all, by attention to the general condition that the defect is recognized. The patient is a child of arrested development, more or less permanently cyanosed, with continued embarrassed breathing—all of these are conditions which point to the congenital defect. If there be added to these a persistent loud murmur at the base of the heart without other signs or symptoms of valvular disease, this may be due to congenital defect.

In addition to these, there are a large number of defects of development which are rather pathological curiosities than of clinical interest. Among these may be mentioned *acardia*, or absence of heart, met in the monstrosity thus named; *double heart*, sometimes present in high degrees of fetal defect; *dextrocardia*, in which the heart is on the right side, alone or with other viscera. In *ectopia cordis*, or dislocation, which is associated with fission of the chest wall and of the abdomen, the heart may be in the cervical, pectoral, or abdominal regions. Then there are anomalies of the cardiac septa, of which the patulous foramen ovale is the most frequent, various in degree. Next is a small defect in the upper part of the septum, between the ventricles, in what is known as the "undefended" space, or just anterior to it. A *bicuspid* condition of the semilunar valves, from fusion of cusps, is often met—most frequently of the aorta. The combined valve is more liable to sclerotic change. Finally, there is fenestration of the semilunar cusps.

**Relative Frequency of Valvular Defects.**—The order of frequency of the various valvular defects is not entirely agreed upon. As to one, however, there seems to be universal concurrence, and that is that mitral regurgitation is the most frequent. After this, however, statistics differ. Thus, of the older authors, W. H. Walshe presents the following order of frequency for the single or simple murmurs:

1. Mitral incompetency. 2. Aortic stenosis. 3. Aortic incompetency.  
4. Mitral stenosis. 5. Tricuspid incompetency. 6. Pulmonary stenosis.  
7. Tricuspid stenosis. 8. Pulmonary incompetency. Presumably, this list is based upon necropsy records.

This order, in the light of modern studies, must be corrected, except as to mitral incompetency. Frederick J. Smith, analyzing the registers and postmortem records of the London hospitals for eleven years—1877-87—and taking the fatal cases only, arrived at the following order:

- |                            |                                   |
|----------------------------|-----------------------------------|
| 1. Mitral incompetency.    |                                   |
| 2. Mitral stenosis.        |                                   |
| 3. Aortic incompetency.    | } Of practically equal frequency. |
| 4. Aortic stenosis.        |                                   |
| 5. Tricuspid stenosis.     |                                   |
| To these we may add:       |                                   |
| 6. Tricuspid incompetency. |                                   |
| 7. Pulmonary stenosis.     |                                   |
| 8. Pulmonary incompetency. |                                   |

It is evident that the older observers mistook the aortic systolic murmur for mean aortic stenosis, when roughening only of some kind was present.

Out of 705 cases, Smith found 26, or 3.38 per cent., of mitral stenosis, and 25, or 3.25 per cent., of aortic regurgitation; so it cannot be said there is any practical difference in the relative frequency of these two lesions. Von Leube says that, after mitral incompetency, aortic incompetency is the most frequent, and this is my experience. Smith's statistics, being recent and based, as they are, upon the examination of registers and autopsy records, are probably nearly correct, but these two lesions approximate in frequency. Such are to be distinguished from those based on observation at the bedside, regardless of autopsy. Such observation certainly fails to detect all cases of mitral stenosis.

Of "double" *murmurs* heard at one orifice, those of mitral stenosis and insufficiency are more numerous than aortic stenosis and insufficiency, women being the most frequent subjects. It should be mentioned, however, that George S. Middleton, in a clinical study of 150 cases of chronic valvular disease at the out-patient department of the Royal Glasgow Infirmary, found a much larger number—22 per cent.—of the double aortic lesions, as against Smith's four per cent.; also, that Walshe makes the double aortic lesion the second in frequency of all valvular diseases. I am inclined to agree with the latter statement.

**Associated or Combined Valvular Lesions.**—These terms are applied when two valves are diseased at the same time—a very frequent occurrence.<sup>1</sup> The valves which are most frequently jointly affected are, of course, the aortic and mitral, then the mitral and tricuspid, then the aortic, mitral, and tricuspid. Aortic disease of either kind is more frequently associated with mitral incompetency than mitral stenosis, because the former is, sooner or later, a result of the aortic disease, while mitral stenosis arises by a separate process. The very careful analysis by Frederick J. Smith referred to furnishes the following order, which is not far from correct:

1. Aortic incompetency and stenosis; mitral incompetency.
  2. Aortic stenosis or roughening and mitral incompetency.
  3. Aortic incompetency and mitral incompetency.
- There is less than one per cent. difference in the frequency of 2 and 3.
4. Aortic incompetency and stenosis, with mitral stenosis and incompetency.
  5. Mitral incompetency and tricuspid incompetency.
  6. Aortic incompetency and stenosis, with mitral incompetency, tricuspid incompetency.

Too much reliance must not be placed on the order of combined murmurs, as after 1 the arrangement is not altogether what would be expected from a consideration of the natural sequence. From my own experience I should place combined aortic incompetency and stenosis well up in the list, probably second. In children, it is said, the most frequent combination is aortic incompetency and mitral incompetency. One would expect this to be the case with adults also.

<sup>1</sup>Sansom has suggested that the term "combined" be retained for two murmurs at one orifice, commonly known as "double" murmurs—an unfortunate suggestion, as it will be sure to give rise to confusion, while the term double is easily understood.

The diagnosis of these combinations is based upon the quality and situation of the murmurs and their conduction.

**Prognosis of Chronic Valvular Disease.**—Possible positive statements as to the prognosis in chronic valvular disease are few, so uncertain is it and so many circumstances influence it. Undoubtedly, valvular disease often exists where the subject is totally free from symptoms, and therefore quite unconscious of it. Yet such subject is not free from danger. On the other hand, 15, 20, 30, and even 40 years pass over such cases without inconvenience, compensation being easily maintained. Such cases are usually of mitral incompetency or stenosis, or both. Much depends upon the life led by the patient—whether one of ease and quiet, associated with proper food and clothing and without dissipation. Even when such disease occasions symptoms, the same measures may hold them in abeyance for a long time, and occasional judicious medication may raise the patient from a serious condition to one of comfort. It is astonishing with what little disturbance women with these affections sometimes bear children. Of the lesions at the mitral orifice, incompetency is usually most easily compensated, then combined stenosis and incompetency, and finally stenosis only; but even the last exists at times without subjective symptoms in persons who have worked hard. After all, the prospect of life must be judged from the symptoms in each case. The compensation which is obtained by extreme hypertrophy and apex displacement is tottering. An additional danger in mitral disease, especially mitral stenosis, is that of embolism. Recurring attacks of rheumatism not only increase the latter danger, but augment the valvular defect. The supervention of dropsy and dyspnea indicate failing compensation, and though they may be overcome, it is with increasing difficulty at each recurrence.

Aortic incompetency is a much graver condition. It is this valvular disease in which sudden death overtakes the patient. Yet it, too, may be compensated for years. Much here depends upon the state of the arteries, the danger being increased when associated with sclerosis or atheroma, for these conditions are likely to effect the root of the aorta and the valves, and especially the coronary arteries. Any obstruction in these, as already stated, may be the cause of sudden death. Angina pectoris indicates a diseased condition of the coronary arteries, which may at any time be followed by complete obstruction and similar death. Overdistention, such as takes place during exertion, may be too much for a fatty heart already dilated, and becomes also a cause of sudden death.

The most unfavorable of all forms of cardiac valvular disease is tricuspid regurgitation, which occasions obstinate dropsy and dyspnea.

Chronic valvular disease is regarded as much more serious in young children, say those under ten years of age; this, in spite of the fact that many conditions favorable to compensation are present, such as integrity of heart muscle and vascular supply. Notwithstanding this, the valve lesion is apt to increase. On the other hand, there is a popular notion, which I think is not unfounded, that a child may outgrow a heart disease under favorable circumstances, such as abundance of good food and protection against exposure and overwork. This may be true, but it is more likely that compensation is established with the growth and development of the organ.

That the apparent event does sometimes occur, I can attest. Congenital defects in the heart are apt to destroy the lives of children in the first few years of their existence.

Finally, almost any serious illness, especially when involving the lung, increases the danger to the life of the subject of cardiac disease, while mitral disease, and especially mitral stenosis, invites pulmonary congestion and inflammations.

**Treatment of Chronic Valvular Diseases of the Heart.**—1. *Prophylaxis.* There can be no doubt that the number of cases of chronic valvular disease may be decreased by a careful treatment of the diseases which excite them or favor their occurrence, especially acute rheumatism. The student is referred to a valuable monograph by R. Caton, on "The Prevention of Valvular Disease of the Heart."<sup>1</sup> This author emphasizes especially (1) the importance of rest and a minimum of exertion of all kinds for the rheumatic patient; (2) stimulation of the trophic centers by small blisters in the neighborhood of the affected joints, in front of the chest between the clavicle and the nipple on both sides, and in the axilla, with a view to stimulating vasomotor nerves; (3) treatment by absorbents, including the iodid of sodium and mercury. The rest and quiet should be prolonged long after the symptoms of pain and fever have subsided, and a second attack of rheumatism should especially be guarded against, as an apparently cured endocarditis is sure to be followed by another attack. Temperance and the avoidance of excesses of all kinds which tend to load the blood with toxic substances constitute a prophylaxis of no small importance.

2. *Remedial Measures.*—Since there are certain points in the treatment of disease of the cardiac valves which are the same for the different orifices, I shall consider first such measures as are thus common, referring more especially to mitral and aortic disease.

In the first place, it is well known that there exist chronic valvular defects at either of these orifices which give rise to no symptoms whatever and are often accidentally discovered. From the standpoint generally conceded, that such defects themselves are irremediable, it is clear that, in the absence of symptoms, medicinal treatment is quite unnecessary. On the other hand, it is a happy circumstance when the subjects of such lesions are made aware of their presence, because they are enabled so to regulate their mode of life as to prevent harmful consequences, either symptomatically or organically. Such persons should avoid overexercise and excitement. Running or even walking rapidly, hurriedly ascending stairs, extremes of passion of all kinds, and especially of anger, should be avoided, as should also exposure and irregular living. In a higher grade of involvement of either orifice, the same treatment is demanded in a more imperative manner, since its omission results in a loss of compensation, manifested by dyspnea, palpitation, and precordial distress.

In a still more advanced degree of interference with normal functions the treatment becomes different with the seat of the lesion. Let us first consider lesions of the mitral valve, and first the most common of all forms—*mitral regurgitation*. We have seen that the blood flows back into the left auricle during systole of the ventricle, at a time when all communication

<sup>1</sup> London, C. J. Clay & Sons, 1900.

between these cavities should be cut off and the movement of the blood should be forward only. Averted for a time by hypertrophy of the left auricle, engorgement of the lungs ultimately results, with defective aeration of blood, and consequent shortness of breath. This effect is at first counteracted by the increased effort of the *right* ventricle, whence its hypertrophy, with sharp accentuation of the pulmonic second sound.

So long as compensation is thus maintained there is probably no sign of embarrassed breathing, no irregularity, no precordial oppression or digestive derangement; but as soon as compensation begins to fail, in consequence of a suspension of the conditions which cooperate to help it, or of a slight yielding of the heart muscle, assistance is demanded. The heart tonics, of which digitalis is the type, are the agents preeminent for this purpose. That they operate by directly increasing the force of the right ventricle and left auricle, and thus contribute to the compensation, can scarcely be doubted; but that they help also to make the closure of the mitral orifice more complete by forcibly increasing the contraction of the left ventricle seems also reasonably sure, since the experiments of Ludwig and Hesse have made it so plain that this can occur. They have shown that the mechanism for closing the mitral orifice does not reside in the valve alone, but that the surrounding muscles of the ventricle have an active share, not only in floating up the valve curtains, but in reducing also the size of the opening which these valve curtains have to close. This is, of course, less applicable in chronic valvular conditions where there is stiffness from calcareous change, than where regurgitation results from simple feebleness of muscle in anemia and after the infectious fevers.

The effect required of this class of drugs varies with the degree of obstruction to be overcome, and the doses vary accordingly. Very often the heart requires but a little steadying to enable it to accomplish the desired end, and moderate doses—such as 5 minims (0.3 c.c.) of the tincture of digitalis once in six or eight hours—suffice. On the other hand, it is a mistake to give too small a dose, and too great timidity often results in failure. Doses of from 10 to 15 minims (0.6 to 1 c.c.) of the tincture of digitalis every four hours, and corresponding doses of the other preparations, are often necessary and sometimes produce magical effects. The irregular and halting pulse becomes regular, the dropped beat is again taken up, the dusky lips become pink, the scanty urine is increased, the shortness of breath disappears, and calmness and quiet succeed distress and restlessness. As soon, however, as the desired effect is produced, the dose should be lowered. Digitalis is a remedy always better intermitted to obtain its best effects, and a remedy, too, which, having once excited nausea, is thereafter badly borne.

The same principles apply to the management of the still more serious engorgements of the venous system which succeed upon tricuspid insufficiency, and produce dropsies and serous effusions. This engorgement is also relieved by the use of purgatives, and as the portal area, including the liver itself and the stomach, is especially involved, mercurial purgatives are especially indicated. From 5 to 10 grains (0.32 to 0.65 gm.) of blue mass at bedtime, followed by a saline in the morning, relieve the congestion, and with it the nausea and indisposition to take food attending it.

Such remedies may be resorted to occasionally. Sometimes the continued use of small doses for a long time—say  $\frac{1}{2}$  to 1 grain (0.03 to 0.065 gm.) of blue mass three times a day—is more efficient. It is generally recognized that digitalis produces, also contraction of the arterioles, and that through this, in connection with the forcible systole, the arterial pressure is increased. This effect is desirable and useful in the early stages of mitral regurgitation, before tricuspid regurgitation and dropsy have set in. Later in the disease, however, when dropsy has set in, this effect militates against the diuretic action which is so much needed. The manner in which this may be overcome will be described later.

As to the relative value of the different preparations of digitalis: While testimony is generally favorable to the infusion as the most efficient remedy, yet, on account of convenience and accessibility, the tincture is most frequently used. I am inclined to believe that the greater apparent efficiency of the infusion is partly due to the fact that it is generally given in larger doses. Thus, a tablespoonful, or  $\frac{1}{2}$  ounce (15 c.c.), is not an infrequent dose of the infusion, while 10 minims (0.6 c.c.), or 20 drops, of the tincture and 1 grain (0.066 gm.) of the powder are not often exceeded. When it is remembered that  $\frac{1}{2}$  ounce (15 c.c.) of the infusion, as made by the United States Pharmacopeia, represents nearly 3 grains (0.19 gm.) of the powder, or 20 minims (1.2 c.c.) of the tincture, one may understand why it is more efficient. It is true, however, that the infusion is sometimes better borne by the stomach than equivalent doses of the tincture. It may be that the cinnamon water with which it is made has this effect. The preparations of digitalis thus far mentioned are more or less uncertain. An excellent preparation is the fluid extract which is a constant preparation. Each minim representing 1 grain of the drug, and hence the proper dose is easily determined. It may be used hypodermically. Better for hypodermic use is digitalone, a nonirritating watery solution comparable to the digitalin of Schmiedeberg and the digitalin germanic to which is added chloretone as a local anodyne and antiseptic. The dose hypodermically is 8 to 15 minims (.5 to 1 c.c.), internally 15 to 30 minims. (1 to 2 c.c.) increased if necessary.

Of remedies which may be substituted for digitalis, strophanthus should be first mentioned. It was at one time thought that strophanthus might have all the effects of digitalis on the left ventricle without the contracting effect on the arterioles. This is not strictly true, but it is conceded that its effect in this respect is less pronounced than that of digitalis. The dose is the same. It is better borne by the stomach, as a rule, than digitalis.

Caffein is an admirable heart tonic in mitral regurgitation. I do not give less than 3 grains of the citrate (0.2 gm.) at a dose, every four to six hours. When caffein has been given in full doses for some time, it may produce mental symptoms quite characteristic, consisting in hallucinations not unlike those of delirium tremens, the patient imagining there are persons, animals, and other objects about him, and he is sometimes

<sup>1</sup>It is, moreover, to be remembered that of the four active principles of digitalis, viz., digitalein, digitolin, digitoxin and digitonin, digitonin is present in larger quantity, in the infusion. Now, digitonin does not have the contracting effect on blood-vessels of the other three principles, has indeed rather the opposite effect. Hence when a cardiac tonic effect is desired the tincture should be used, and when a diuretic effect, the infusion.

difficult to control. These symptoms, however, cease immediately when the drug is discontinued. Another effect of caffeine which sometimes interferes with its usefulness is insomnia.

Sparteine sulphate is another heart tonic from which I have had results, especially when a diuretic effect is desired. The dose should never be less than  $\frac{1}{4}$  grain (0.016 gm.), increased to a grain (0.032 gm.), four, five, and six times a day. I am sure many have been disappointed in sparteine because they have given too small a dose. Broom itself, in the shape of an infusion or "tea," is a popular and efficient remedy, less well borne by the stomach than its active principle, sparteine. Sparteine and broom are more commonly used as diuretics, and will be again referred to in the treatment of the dropsy of Bright's disease.

In the rarer disease simple *mitral stenosis*, compensation is even easier and longer maintained by nature's own resources than in mitral regurgitation. Here, for evident reasons, there is no tendency to dilatation or hypertrophy of the left ventricle. On the other hand, hypertrophy of the left auricle becomes a conspicuous condition, succeeded by hypertrophy of the right ventricle, for the same reason as in mitral regurgitation. Especially easy is it to maintain compensation if the narrowing is not too great and if there is a well-preserved left auricle and a strong right ventricle. If, however, the mitral narrowing is extreme, it is plain that the pulmonary engorgement will become greater if we increase the force of the right ventricle. Much more cautious must we be, therefore, in the use of digitalis. Much more important under these circumstances is relief to the pulmonary congestion, which in turn will relieve the right heart tension. Blood-letting is the most direct method of accomplishing this, and in severe cases associated with great dyspnea and cyanosis it may be practiced. Purgation may be substituted. Aconite is sometimes of advantage in these cases, in small doses, say 1 or 2 minims (0.06 to 0.12 c.c.) every two hours or every hour watching its effect. It is possible that it is through a somewhat similar action that *convallaria majalis*—a remedy in which most observers have been disappointed—has been found useful by Sansom<sup>1</sup> in mitral stenosis, and also by French physicians. By these observers it has been found diuretic, increasing the 24 hours' urine to 85 and even to 115 ounces (2550 to 3450 c.c.), reducing the pulse rate, regulating irregularity, and improving the breathing, even when accompanied by tricuspid regurgitation. The doses given are from 10 to 20 minims (0.6 to 1.2 c.c.) of the tincture three times a day, and it may with advantage be associated with caffeine. The French physicians give the extract in doses of from 1 gram to 1  $\frac{1}{2}$  grams a day—i. e., 15 to 20 grains. *Veratrum viride* may be used under the same circumstances in 10 minim. (0.6 c.c.) doses<sup>2</sup> More effectual than either of these remedies to relieve pulmonary congestion is purging, sometimes blood-letting, and repeated small bleedings are sometimes of great advantage in this form of chronic valvular disease. It has seemed to me, too, that the irregularity of heart's action, so characteristic of mitral disease, is sometimes better controlled by nitroglycerin than by digitalis in 1/100 gr.

<sup>1</sup> "The Treatment of Some of the Forms of Valvular Disease of the Heart," Lettsomian Lectures, second edition, with corrections, London, 1886.

<sup>2</sup> The tincture of *veratrum viride* is considerably reduced in strength in the new U. S. Pharmacopœia of 1900.

doses every two hours with prolongation of the interval as the symptom disappears, although this seems paradoxical.

The principles governing the treatment of combined mitral regurgitation and stenosis are similar to those governing the treatment of the simple conditions.

And what shall be the treatment of *pure aortic disease*? It will be remembered that both the aortic obstruction and regurgitation give rise to hypertrophy of the left ventricle, and that this is compensatory in purpose. For a time this is quite sufficient to ward off any unpleasant symptoms, and for a still longer time when associated with a quiet life, the absence of excitement, of exposure, and privation. High degrees of hypertrophy are accompanied with a powerful systolic impulse, a symptom which is of itself often a source of great discomfort. Shall we, then, give heart tonics which increase the force of this thumping blow? Certainly not. Shall we give aconite or veratrum viride, which slow the heart and diminish the force of its stroke? Yes, at times these remedies are very useful. Whenever, as the result of overexertion or undue excitement or gastric derangement, the heart is turbulently overactive, and even irregular in its rhythm, then I have often seen aconite in small doses—say 2 minims (0.12 c.c.), or 4 drops, repeated every half hour or hour under close observation—act happily, especially when combined with bromid of potassium, say 15 grains (1 gm.). The tincture of veratrum viride may be given in 10 minim (0.6 c.c.) doses. As soon, however, as this period is past, the aconite should be omitted. Even in mitral regurgitation I have seen aconite act most happily under these circumstances.

We want also in this condition remedies which will help to maintain the integrity of the heart muscle. Such are strychnin, iron in small doses, arsenic, and nutritious, easily assimilable food. Especially useful are well-ventilated living- and sleeping-rooms, wholesome outdoor life, with moderate, deliberate muscular exercise. Like all other muscles, the heart is strengthened by judicious exercise. In the light of this fact even the mountain-climbing advocated by Oertel is not so irrational and dangerous as it seems at first thought. Very cautious and gradually increased exercise is doubtless intended. On the other hand, so much judgment is required in the application of this treatment that it is perhaps better honored in the breach than in the observance.

Such measures as those described tend to ward off the next stage, for sooner or later the integrity of the muscle of the ventricle yields, dilatation is added to hypertrophy, the auriculo-ventricular orifice enlarges, and we have mitral regurgitation. Then the treatment becomes that for mitral disease.

The treatment for aortic regurgitation and of aortic stenosis with regurgitation is similar to that of aortic stenosis.

*Treatment of Dyspnea.*—As the dyspnea is primarily the result of deficient blood aeration in the congested lungs, the same remedies which force the blood through these organs, and thus relieve the congestion, tend also to relieve the dyspnea, and often do so. When the dyspnea persists, it is frequently caused by effusions into the pleural cavity, which are most promptly and successfully removed by tapping, although a blister may also

answer the purpose. Repeated tapping may be necessary. Dyspnea not thus relieved demands an opiate, and of opiates under these circumstances, morphin is the best. One-fourth of a grain (0.0165 gm.) at bedtime, by the mouth or hypodermically, gives unspeakable comfort. Hoffmann's anodyne, given in fluidram doses (3.5 c.c.), will sometimes relieve the milder degrees, and should perhaps be tried first, as it is always desirable to put off the use of morphin as long as possible. Paraldehyd may be substituted for Hoffmann's anodyne in the same doses. Chloralamid is even a better remedy in 30 grain (2 gm.) doses. Sulphonal may be tried in full doses of 15 to 30 grains (1 to 2 gm.). Trional in the same doses is a similar drug. So is veronal in somewhat smaller doses, 7 to 10 grains (0.462 to 0.66 gm.). None of these is an anodyne. They are simple hypnotics, and cannot be expected to take the place of morphin, though they may be tried at first. All the coal-tar products are more soluble in hot liquids, of which milk is a typical form. Inhalations of oxygen should not be forgotten as sometimes giving signal relief in dyspnea.

*Treatment of Dropsy.*—In like manner the measures that relieve the congestion and dyspnea tend also to relieve the dropsy, but special means are also necessary. Here it is that full doses of digitalis are especially indicated, and at closer intervals. It is to be remembered, too, that the infusion is a better diuretic than the tincture.

But these measures are often insufficient. They may be materially aided by restricting the ingestion of liquids. With the tissues water-logged and secretion insufficient, it is plain that copious liquid ingestion only increases the difficulty. I am speaking now of cases in which there is general dropsy which resists the ordinary treatment. The principle of the Matthew Hay method is correct, but in practice it is limited, because, with an already congested stomach, solids cannot be digested without an admixture of liquid, and further embarrassment results from the effort to dissolve them and from the presence of undigested residue. Therefore it is sometimes better to omit solid food altogether and reduce the liquid to a minimum that will sustain life—not more than three ounces every two hours, and that only during the waking hours. To this may be added the use of purgatives. While diuretics sometimes fail us, we can always secure an effect from purgatives. A daily morning dose of Epsom salts or Rochelle salts or compound jalap powder is given. Elaterium or its active principle elaterin must not be forgotten. The latter is less apt to produce nausea. Its dose is  $\frac{1}{40}$  to  $\frac{1}{10}$  grain (0.00165 to 0.0066 gm.), while that of elaterium is  $\frac{1}{10}$  to  $\frac{1}{2}$  gr. (0.0066 to 0.033 gm.). Then, when action of the bowels begins, full doses of digitalis, caffein, or spartein, associated with nitroglycerin, are almost sure to be followed by copious diuresis; and when diuresis starts up in these cases, it is astonishing what quantities of urine are passed. The association of nitroglycerin with digitalis at this stage may be helpful. The object of nitroglycerin is to dilate the arterioles and allow the blood to move freely through them;  $\frac{1}{100}$  to  $\frac{1}{50}$  grain (0.00065 to 0.0013 gm.) may be given as often as the digitalis and simultaneously. One need not be afraid of this drug. I have given this dose every two hours for 24 hours or more at a time. Elimination by the bowels and kidneys being simultaneously stimulated, the sucking up of

the interstitial fluid is greatly favored and often rapidly brought about. If these measures be associated with paracentesis of the chest, which may be required, the diuresis set up is often enormous, while the swelling rapidly declines. As diuresis is established or hunger sets in the quantity of milk allowed may be increased, and when the dropsy has entirely disappeared, a cautious return to solid food may be permitted.

A time-honored remedy in the treatment of cardiac dropsy which should not be overlooked is the combination of calomel, squills, and digitalis, in doses of  $1\frac{1}{2}$  grain (0.03 gm.) of the first and 1 grain (0.065 gm.) of the second and third every three or four hours; this is sometimes most happy in its results. Still another remedy often very efficient in this form of dropsy is theobromin. It is obtained from cacao, and is chemically closely allied to caffeine, the latter being trimethyl-xanthin, while theobromin is dimethyl-xanthin. Like caffeine, theobromin is a renal diuretic as well as a heart tonic. The dose I have found most satisfactory is 30 grains (2 gm.) in the 24 hours, conveniently divided into doses of  $7\frac{1}{2}$  grains (.5 gm.) every six hours. Larger doses may be given. On the other hand, diuretin, which is supposed to contain 50 per cent. of soluble theobromin in combination with salicylate of sodium, I have found of uncertain value as a diuretic. Still it is to be remembered and care must be taken to secure a clear solution. Turbidity is a sign of deterioration of the drug. It may be given in doses of 10 grains (0.66 gm.) every three hours and produces increased diuresis in 48 hours if effectual. A better diuretic of the same class is aceto-theocin (double salt of acetate of sodium and dimethyl-xanthin sodium). It may be given in doses of 4 to 8 grains (10.25 to 0.5 gm.) three to four times daily in capsule or solution.

In many cases there comes a time when the measures above described become inoperative. Diuretics will not act and purgatives are insufficient. Then it is that incisions in the anasarca legs or Southey's tubes inserted in the legs for draining off the liquid effusion are sometimes very efficient. I generally prefer the incision, an inch long and one behind the inner malleolus of each leg. Enormous quantities of fluid are thus drained off after which diuretics again become active, and I have seen many a case rescued from the grave for a time at least. It is most important that antiseptic dressings should be employed to protect the incisions against infection.

*Treatment of Irregularity of Heart Action and Palpitation.*—For these symptoms, in addition to the cardiac tonics mentioned, belladonna is also a useful remedy. It may be combined with digitalis. A good belladonna plaster placed over the palpitating heart is one of the most efficient agents in subduing it. Nitroglycerin as already mentioned is often very useful to the same end— $1/100$  grain (0.00065 gm.), rapidly increased to  $1/50$  grain (0.0013 gm.), every four hours or oftener. It may also be combined with digitalis, as previously directed. Cardiac pain is also sometimes relieved by the same remedies. For this, however, hypodermic injections of morphia are sometimes necessary while palpitation may require the same drug.

For further treatment of dropsy see section on Bright's disease. See also treatment of cardiac dilatation by the Schott treatment and Nauheim baths.

## DISEASES OF THE MYOCARDIUM.

The heart is subject to alterations in its muscular substance independent of valvular defect. Hypertrophy, dilatation, fatty infiltration, and fatty metamorphosis or true fatty degeneration, and atrophy are the most important. Myositis, abscess, and aneurysm of the walls of the heart are such rare conditions that they need only be mentioned in passing, especially as there is no way to recognize them before death.

## HYPERTROPHY AND DILATATION.

**Definition.**—Hypertrophy and dilatation have been sufficiently defined and described under general symptomology of heart diseases, p. 601. It remains only to consider a few details in cause and symptoms.

## HYPERTROPHY OF THE HEART.

**Etiology.**—Hypertrophy implies an overgrowth of muscular tissue, and is naturally the result of extra work, increased effort to overcome increased resistance, whatever its cause.

The term *idiopathic* hypertrophy is applied to such hypertrophy unassociated with abnormality in the valves and no cause external to the heart exciting it to overaction. Such are nervous influences and toxic conditions of the blood. Hypertrophy without valvular disease involves the left ventricle more frequently, but may involve both cavities, and even the right ventricle alone, as when there is pulmonary obstruction as in emphysema.

The resistance needed to excite increased action may be from within or from without, or due to nervous influence. Resistance from within is occasioned by obstruction to the outflow of blood from the heart, or to increased intravascular pressure. Such obstruction is offered in the case of the *left ventricle* by aortic stenosis, congenital narrowing, aortic insufficiency, and mitral insufficiency. Increased intravascular pressure is caused by endarteritis and resulting sclerotic changes in the vessel-walls and by aneurysm; by strong contraction stimulated by the irritation of toxic substances in the blood, such as accumulate in Bright's disease, or as the result of overeating or excessive drinking, especially of large quantities of beer; finally, by excessive physical exertion. All these are, therefore, causes of hypertrophy of the left ventricle.

External obstruction to the contraction of the left ventricle is found in pericardial adhesions and myocarditis. Such hypertrophy is always eccentric. Hypertrophy of the left ventricle from nervous influence is seen in exophthalmic goiter and allied conditions, and in long-continued palpitation. Constant mental excitement is a possible cause.

In the case of the *right ventricle*, internal resistance is produced by pulmonary congestion due to mitral regurgitation or to mitral stenosis, to

narrowing of the same vessel or branches, such as occurs in pulmonary emphysema. Valvular lesions of the right side of the heart produce hypertrophy of the right ventricle, just as those of the left cause it. The greater infrequency of these lesions and their occasional origin *in utero* are to be remembered. Pericardial adhesions also constitute a cause of external resistance to contraction of the right ventricle.

*Auricular hypertrophy* is always eccentric—that is, while the walls are thickened, the cavities are also dilated. Hypertrophy of the left auricle is usually caused by stenosis of the mitral orifice, and to a less degree is a result also of regurgitation of the blood in incompetency of the mitral valve. Hypertrophy of the right auricle might also be expected as a consequence of regurgitation of blood from the right ventricle to the right auricle, but the resistance to the further backward flow into the veins is so much less than in the left side disease, hypertrophy is correspondingly less frequent. In like manner, even if stenosis of the tricuspid orifice is present, the same conditions prevent any marked degree of hypertrophy of the right auricle.

In all cases of hypertrophy due to disease of the valves it is likely that a certain amount of distention of the heart cavity by blood precedes the muscular overgrowth.

**Symptoms.**—Hypertrophy, being a process of compensation, is not at first attended by any symptoms. It is the result of a generous conservative effort of nature, by means of which symptoms are averted. But unlike the hypertrophy of the muscles of the blacksmith's arm, it tends ultimately to degeneration, and thus becomes the initial link in a chain of evil which is well stated by J. G. Adami:<sup>1</sup> "In the first place, it leads to an increased nutrition of the walls of the *arteries*; increased nutrition leads to increased connective-tissue growth of the walls; increased fibrous tissue of the walls leads to contraction and increased rigidity of those walls; the increased rigidity leads to increased resistance to the passage of the blood current. The increased resistance requires increased propulsive power on the part of the ventricular muscle—that is to say, increased work; the increased work of the heart leads to overgrowth and hypertrophy (myocarditis), and with this, heightened blood pressure and further increased nutrition of the walls, and now, at last, the stage is reached, this vicious circle continuing, in which either the vessel walls give way or the heart." From this standpoint increased blood pressure alone is sufficient to explain in some cases the anatomical changes—*i. e.*, the arterial sclerosis, atheroma, and fibroid thickening so constantly seen in valves and heart-walls without calling on chronic inflammation or specific agency. Certain it is that the two conditions react on each other, and it is more than likely that the former (increased blood pressure) may produce the latter (chronic inflammation) *de novo*, and many otherwise unexplained facts are rendered clear.

With degeneration we begin to have symptoms which are at first intermittent, brought about only by some temporary cause which excites the heart, such as exercise, mental emotion, fatigue, mental or physical, tobacco, or alcohol. There is a feeling of vague discomfort about the heart, seldom amounting to pain, sometimes increased when the patient lies on the left side. To this may be added palpitation, a consciousness of the beating

<sup>1</sup>"Notes upon Cardiac Hypertrophy," "Montreal Medical Journal," May, 1895.

of the arteries in the head, dizziness, headache, ringing in the ears, flushes or flashes of light, and a tendency to hemorrhage of the nose. So long as the integrity of the heart muscle is maintained the blood pressure is increased and reaches 160 to 200 or more mm.; as the heart begins to degenerate the blood pressure rapidly falls.

**Physical Signs.**—While symptoms other than physical signs may be wanting, the latter are present from the beginning, increasing with the duration of the hypertrophy. These have been for the most part considered when treating of valvular diseases. I will simply emphasize *accentuation of the aortic second* sound in hypertrophy of the left ventricle and of the *pulmonic second* in hypertrophy of the right ventricle.

**Diagnosis.**—In view of the fact that hypertrophy is a part of the morbid anatomy of chronic valvular defect, we need concern ourselves only with the so-called idiopathic hypertrophy. A resemblance to *hypertrophy* may arise from pericardial effusion, circumscribed pleuritic effusion, aneurysm, or mediastinal tumor in the neighborhood of a normal heart, the latter especially if it push the heart forward. A normal heart may appear enlarged to percussion when it is uncovered by a lung retracted from any cause, as cirrhosis of that organ. Simple *palpitation* of the heart may be mistaken for hypertrophy.

In all cases the situation of the maximum intensity of the apex-beat is a valuable criterion, because, although its position may be changed in pleuritic effusion and pericardial effusion, it is in the opposite direction from that in hypertrophy, while the impulse is feeble instead of being strong. Aneurysm and mediastinal tumor will certainly furnish some of the signs peculiar to them, and thus permit a distinction. Simple palpitation is without the percussion signs of enlargement of the heart. Under none of the circumstances named will its situation be altered.

Hypertrophy may be obscured if the heart is overlapped by an emphysematous lung. This is partly the case in hypertrophy of the right ventricle, which is often associated with emphysema of the lungs. In such cases the pulse does not help, but rather tends to mislead, because it is small in hypertrophy of the right ventricle.

**Prognosis.**—When associated with valvular disease, the prognosis is that of the disease itself, against which hypertrophy is, for a time, a protection, counterbalancing the growing defect of the valve until the nutrition of the heart begins to be impaired and dilatation replaces hypertrophy with loss of compensation. The latter may be sudden, though it may be delayed for a time by treatment. While such malnutrition may be of local origin—that is, resident in the heart muscle itself—it may be due to general causes also, as general illness, hardship and exposure, overexertion, fatiguing occupation, insufficient food, and the like. When it is the result of endarteritis and aneurysm, the termination comes with the rupture of the vessel or of the aneurysm.

In the so-called idiopathic forms due to toxic substances in the blood danger does not threaten until sclerotic changes are established in the blood-vessel walls.

**Treatment.**—This embraces that of the causal conditions and of measures to reduce overaction.

## DILATATION OF THE HEART.

SYNONYM.—*Fatty Degeneration of the Heart.*

**Definition.**—This has already been defined on page 601, so far as the state of the chambers is concerned. Dilated heart is of two kinds: first, acute dilatation; and, second, chronic dilatation, or dilatation accompanied by fatty degeneration. Of the latter, two varieties exist: (1) That succeeding valvular disease; (2) that succeeding hypertrophy due to muscular effort, especially when associated with alcoholic intemperance and other forms of dissipation. Acute dilatation may be unassociated with structural change, except as to mechanical arrangement of the muscular elements. Cloudy swelling may be present. The latter may be associated with fatty change.

**Etiology.**—Chronic dilatation is the last stage in a valvular disease the result of failing nutrition. The conditions under which this manifests itself have been described. Acute dilatation is the result of prolonged muscular effort, such as occurs in rowing, running, and mountain-climbing. Moderate degrees of distention occur with any decided muscular effort. The more marked degrees capable of mischievous consequences are the result of prolonged severe muscular exertion. The effect of moderate, well-regulated exercise on the heart, known as training, by which endurance is developed, is to produce eccentric hypertrophy, or hypertrophy with dilatation, which is not dilatation in the sense under consideration—enlargement of the cavity with thinning of the walls. The right heart is the seat of such dilatation. In overexertion the harmful effect of excessive acute strain is averted for a time by the safety-valve action of the tricuspid valve, permitting a regurgitation of blood into the right auricle. Dilatation has exceeded its physiological limit when the cavity is no longer able to empty itself of blood. While moderate degrees of acute dilatation may be recovered from, either rapidly or slowly, dilatation may be carried to degrees at which recovery is impossible and deaths results. Such results have followed rowing and mountain-climbing.

The so-called *irritable heart*, to which attention was first called by J. M. Da Costa in a graphic description based on a study of the cases of soldiers in the American Civil War, is an example of an abnormally dilated heart, a heart in which compensation has failed. Another example of the idiopathic hypertrophy already referred to is seen in those persons who, through hard work, acquire muscular strength and at the same time, thorough alcoholic indulgence, become obese. Such as the drivers of beer-wagons and workers in breweries where an unlimited amount of beer is allowed—as much as 20 liters (as many quarts) a day. After a while, in these hearts compensation is lost and the symptoms of dilated heart follow. Sudden dilatation may happen to hearts whose muscular substance is degenerated, though seemingly hypertrophied, as in chronic Bright's disease, where overexertion often brings on dilatation. In a few instances in malignant forms of the infectious diseases, such as scarlet fever and diphtheria, the nutrition of the heart may be so rapidly impaired by the

toxic agency which causes the disease that dilatation occurs with very little or no undue intravascular pressure. All these belong to the second category, that of chronic or slow dilatation.

**Symptoms.**—The symptoms of "heart strain" are sudden *pain* in the region of the heart or epigastrium, *faintness*, *shortness of breath*, and *rapid, feeble action of the heart*. If it be not immediately fatal, the symptoms may pass off, but are renewed on the slightest exertion. In the acute cases described as due to the toxic causes of infectious disease, sudden death may be the only symptom. In some cases it may be preceded or not by very brief precordial distress. Less serious degrees may be associated with *faintness* or *palpitation* on exertion, *extreme feebleness* of the heart's action, and *dyspnea*. It is rather characteristic for these symptoms to pass away when the patient is at rest, to be renewed on the slightest exertion.

Symptoms growing out of dilatation of the heart, going also to make up the sum of those constituting chronic valvular disease with failure of compensation, are *general venous congestion*, *dropsy*, *feeble, frequent, and irregular radial pulse*—rarely, on the other hand, a *slow pulse*. Frequent and irregular pulse may be due to impaired pneumogastric inhibition the result of anemia of the brain, slow pulse to scanty nutrition and a loss of the natural irritability of heart muscle. To anemia especially affecting the medulla oblongata may be ascribed Cheyne-Stokes breathing, also a symptom of the terminal stage of the disease. To it may be ascribed, too, symptoms simulating apoplexy, which characterize the slower dying in some of these cases. Palpitation, angina pectoris, and dyspnea—cardiac asthma, with syncopal attacks, coldness, and slow pulse (30 to 40)—are all symptoms more or less associated with dilatation of the heart. It is further characteristic of these symptoms of dilatation that they are often not transient or amenable to treatment by the usual heart tonics, of which digitalis is the type.

In some instances, especially in the dilated heart of pernicious anemia, there may be a full, strong, and regular pulse, but in the majority of cases the blood pressure is lowered.

High-colored, scanty urine of high specific gravity, sometimes containing hyaline casts and blood-disks, also result from cardiac dilatation.

**Physical Signs.**—When the termination is not immediate, physical signs may be recognized. To *inspection*, the impulse, if visible, may be diffused over a wide area, but is feeble and fluttering, a point of greatest intensity or an apex-beat being often wanting. At times it is found higher up and to the left of its normal position. If the right heart is chiefly involved, the beat as far as caused by the left apex, is completely wanting, while an impulse may be felt below or to the right of the ensiform cartilage, as well as a wavy impulse in the fourth, fifth, and sixth interspaces to the left of the sternum. A pulsation may be seen in the second left interspace, which, while sometimes presystolic, is commonly systolic. In the latter event it may be a further expansion of an already dilated auricle by blood regurgitating during systole of the left ventricle; or if presystolic, it may be the pulse of auricular systole. Such at least are possible explanations. The fact that at autopsies, even in extreme dilatation, the left auricle is found so far back from the thoracic wall as to be scarcely able to beat against the

second interspace, does not preclude the possibility of this during life. In dilatation of the *right* auricle, on the other hand, there is sometimes seen an impulse in the third interspace on the right side which is clearly systolic and due to regurgitation from the right ventricle during its systole. The pulsating symptoms described in this paragraph are commonly seen in persons only with thin chest-walls.

To *percussion* there should be increased dullness to the right and downward toward the epigastrium or to the left beyond the normal line, though these boundaries may be obscured by an emphysematous lung. The results of *auscultation* are greatly influenced by complications. If cardiac murmurs are present, they may obscure all else. On the other hand, previous murmurs may disappear. The typical sounds are found in the dilatation following idiopathic hypertrophy. The impulse is feebly heard as well as felt; the first sound is feeble but pure—that is, shorter and more like the second, lacking, as it does, the muscular element. It may be scarcely audible, even in the absence of murmurs. It is sometimes reduplicated because of asynchrony in the action in the two halves of the heart. Sometimes there is a loud systolic murmur at the apex, due to relative insufficiency of the mitral valve, the true nature of which becomes apparent only in the event of its disappearance. The second pulmonic sound may remain sharp if there is dilatation only of the left ventricle and there is compensatory hypertrophy of the right; feeble if the right ventricle is involved. Finally, there is intermittent and irregular action; at times the characteristic *gallop rhythm*<sup>1</sup> which is almost pathognomonic of dilatation, is present. The pulse is very rapid and feeble.

**Diagnosis.**—An acknowledged difficult matter at times is the distinction of *pericarditis with effusion* from the dilated heart. Whether inspection furnishes any information, depends mainly upon the stoutness or leanness of the patient. In the stout person nothing is recognizable in either condition. In the thin-chested the impulse is visible and wave-like in dilatation; it is not visible, or barely so, in pericardial effusion. The same is true of palpation, except that, if the patient leans forward, the impulse may be felt in pericarditis.

*Percussion* affords the most valuable information. If it brings out the well-known triangular shape of dullness, with the apex toward the inner end of the left clavicle, and the base in the fifth or sixth interspace, especially in the absence of a cardiac impulse, there must be *pericardial effusion*. Percussion of the dilated heart elicits a quadrangular shape or triangular with the apex downward. To *auscultation*, while the heart-sounds have lost their characteristic sharpness, they still contrast with the distant and muffled sounds in pericardial effusion. Especially if there is left any of the original hypertrophy, the second sound will retain some of its sharpness, while, if there happens to have been valvular disease, the murmurs remain to help us.

Bamberger's sign, described on p. 606, must be sought for in evidence of pericardial effusion. There may be encroachment on the lung in dilatation, but it is very much less in dilatation than in pericarditis with effusion

<sup>1</sup> For explanation of gallop rhythm see Barth and Roger, "Traité Pratique d'Auscultation," Thirteenth Edition, Paris, 1888, p. 332.

This encroachment in the case of dilatation does not give rise to Skodaic resonance in the axilla. While there is shortness of breath in both, it is less pronounced in dilatation and more influenced by exertion, being less while the patient is quiet.

**Prognosis.**—This is ultimately fatal in chronic dilatation; in fact, the stage of dilatation is the stage in which remedies become unavailing. At the same time, marvelous results sometimes follow treatment. I have seen general anasarca with effusions in the serous cavities disappear when least expected, so that one is never justified in giving an unqualifiedly unfavorable prognosis. In acute dilatation the prognosis depends upon the degree of the stretching and degenerating. If they are extreme, death follows instantly. If not followed by immediate death slow improvement and ultimate recovery are possible.

**Treatment.**—This is essentially that of valvular heart disease. Rest is even more important, while the heart tonics are, of course, indicated. Strychnin is an important remedy, and in dangerous stages may be given hypodermically in  $1/30$  grain (0.0022 gm.) doses every three or four hours or oftener for a short time. Digitalis in  $7\frac{1}{2}$  minims (0.5 c.c.) or Merck's German digitalin, in doses of  $1/10$  to  $1/2$  grain (0.0066 to 0.033 gm.), may be given under like circumstances. Suitable nutritious food and, if the patient survives the primary danger, well-regulated exercise, are indicated. A timely blood-letting may save life if the signs of engorgement of the right ventricle are present—intense dyspnea, lividity. Nitroglycerin is indicated for its vaso dilator effect.

It is in this condition that the Schott or Nauheim treatment is especially useful. It consists in the use of the carbonated saline baths at Bad Nauheim, associated with special exercises called "resistance" movements, originated by the brothers Schott. Fortunately, artificial baths may be substituted for the natural baths, or the treatment would have limited application. Ignoring for the present the rationale of the action of these baths, their therapeutic efficacy is undoubted. The waters at Nauheim have a temperature ranging from  $82^{\circ}$  F. ( $27^{\circ}$  C.) to  $95^{\circ}$  F. ( $35^{\circ}$  C.). Their important constituents are chlorid of sodium and chlorid of calcium.

The baths may be imitated at home by dissolving chlorid of sodium and chlorid of calcium in water, to which carbonic acid is added by decomposing bicarbonate of sodium by hydrochloric acid. K. N. B. Camac has calculated the required quantities of salt to each 40 gallons of water for six different strengths of the baths. In the baths I recommend I have adopted the proportions of sodium chlorid and calcium chlorid calculated by Camac, but have slightly modified the proportions of carbonic-acid-forming constituents, making three strengths of the latter, after the method recommended by Bezley Thorne, of London:

Bath No. 1: Sodium chlorid, 4 pounds; calcium chlorid, 6 ounces.

Bath No. 2: Sodium chlorid, 5 pounds; calcium chlorid, 8 ounces.

Bath No. 3: Sodium chlorid, 6 pounds; calcium chlorid, 10 ounces.

Bath No. 4: Sodium chlorid, 7 pounds; calcium chlorid, 10 ounces; sodium bicarbonate,  $1\frac{1}{2}$  pound; HCl (25 per cent.), 12 ounces.

Bath No. 5: Sodium chlorid, 9 pounds; calcium chlorid, 11 ounces; sodium bicarbonate, 1 pound; HCl,  $1\frac{1}{2}$  pounds.

Bath No. 6: Sodium chlorid, 10 pounds; calcium chlorid, 12 ounces; sodium bicarbonate, 2 pounds; HCl, 3 pounds.

The alkali should always be slightly in excess, unless a porcelain or paper tub is used.

In preparing the bath, the salts, including the right proportion of bicarbonate of sodium, are dissolved in the water which should have a temperature of 95° F. (35° C.) gradually reduced at successive baths to 82° F. (27° C.). A course consists of from 15 to 20 baths. The bottle containing the hydrochloric acid is inverted and lowered until its mouth is below the surface, when the stopper is withdrawn and the bottle moved about so as to diffuse the acid as uniformly as possible through the water. In this way the bath is made ready in a few minutes. The carbonic acid is the most unsatisfactory feature of the artificial bath, since it is rapidly dissipated, and produces only feebly the effect of the acid in the natural baths. Hence the patient should be promptly put into the bath after the HCl is added, lest the CO<sub>2</sub> is lost before he can get the effect of it. My plan has been to give the baths on alternate days, using the weaker until its effects are exhausted, then passing on to Nos. 3 and 4 in the same manner. Nos. 5 and 6 are not often called for.<sup>1</sup>

As already stated, the baths are most efficient in cardiac disease, but they are also useful in renal affections. Their immediate effect is a diminished pulse-rate, intensified heart-sounds, diminished breathing-rate, while the dilated heart is reduced in size—under favorable circumstances to almost its natural limits. The effect is also to increase the action of the kidneys and that of the skin. These effects are apparent in a free flow of urine, which may continue for days and weeks. Metabolic changes are accelerated and improved; the deep-seated organs, especially the liver and pelvic viscera, are relieved of congestion; while the heart, relieved of its burden, and contracting strongly, derives from its improved coronary circulation material for the repair of weakened and damaged tissue.

Theodore Schott<sup>2</sup> has shown that an increase of hemoglobin in the blood succeeds upon the systematic use of Nauheim baths.

The exercises are not usually commenced until some very positive effect of the baths is secured, when they are associated with the baths or substituted after the latter are discontinued. The effects of these gymnastics are described as identical with those of the baths. The extremities become warm, the breathing is deepened, the sense of oppression is relieved, the pulse becomes slower, the dilated heart area reduced. Even the liver, which is so often enlarged in heart disease as a result of passive congestion, is said to be reduced in size.

The following condensed statement of the Schott movements is from Sir T. Lauder Brunton's "Lectures on the Action of Medicines," London, Macmillan and Co., 1898.

"I. The arms are to be raised slowly outward from the side until they are on a level with the shoulder. After a pause they should be slowly lowered.

"II. The body should be inclined sideways as much as possible toward the right, and then to the left.

<sup>1</sup> I have had constructed for use at the Hospital of the University of Pennsylvania an apparatus for introducing carbonic acid into the water of the bath, after a device suggested by Dr. Smitheman, when a student of medicine.

<sup>2</sup> "On some Hemoglobin Investigation." Reprint from the "British Medical Journal," 1904.

"III. One leg should be extended as far as possible sideways from the body, the patient steadying himself by holding on to a chair. The leg is then dropped back. The same movements are repeated by the other leg.

"IV. The arms are raised in front of the body to a level with the shoulder, and then put down.

"V. The hands are rested on the hips, and the body is bent forward as far as possible, and then raised to the upright position.

"VI. One leg is raised with the knees straight, forward as far as possible, then brought back. The movement is repeated with the other leg.

"VII. With the hands on the hips, the body is twisted round as far as possible to the right, and then again to the left.

"VIII. With the hands resting on a chair, and the back stiff and straight, each leg is raised as far as possible backward, first one and then the other.

"IX. The arms are extended and the fists supinated. The arms are then extended outward, next inward at the height of the body.

"X. Each knee is first raised as far as possible to the body, and then the leg is extended.

"XI. This movement is the same as IX, but with the fists pronated.

"XII. Each leg is bent backward from the knee and then straightened.

"XIII. Each arm is bent and straightened from the elbow.

"XIV. The arms are brought from the sides forward and upward, then downward and back as far as they will go, the elbows and the hands being straight.

"XV. The arms are put at a level with the shoulder, and then bent from the elbow inward and again extended.

"XVI. With the arms in front at the level of the shoulder and the hands stretched, the arms are opened out sideways and then brought together.

"XVII. The arms are bent from the elbow outward and extended.

"The movements should be slow and regular, each one being gently resisted by the nurse or attendant or by the patient himself, putting into action the muscles opposing the movement.

"There should be a pause of half a minute between each movement of the same class and a pause of one or two minutes between movements of an entirely different kind, as I and II."

#### ATROPHY OF THE HEART—BROWN ATROPHY.

**Definition.**—Atrophy of the heart is the opposite state to hypertrophy—viz., a reduction in the muscular substance, with a corresponding reduction in the size of the cavities. It is associated with pigmentation, hence the term brown atrophy. It is limited clinically, being confined to the subjects of wasting diseases, like phthisis pulmonalis and carcinoma. It is the special result of senile marasmus. It is occasionally associated with chronic valvular disease. The muscular fasciculi undergo molecular death, the organ wastes, and is symmetrically reduced. It is dark red-brown in color and firm in consistence. By the microscope is recognized a peculiar ar-

range of pigment granules about the nuclei and between the primitive fibrillæ. The source of the pigment is not precisely known. It may be the coloring matter of the muscle, or directly derived from the blood.

The **diagnosis** of such condition can only be based on a diminution in the normal area of cardiac percussion dullness associated with feeble pulse, and the long-continued presence of the causal disease. Reduced area of cardiac dullness must be unassociated with emphysema of the lungs or other causes which may diminish cardiac dullness by covering up the heart.

The **treatment** is that of the causal disease.

## DEGENERATIONS OF THE CARDIAC MUSCLE.

The heart muscle is subject to parenchymatous degeneration, to fatty degeneration, to fatty infiltration (yellow atrophy), to amyloid degeneration, to the hyaline transformation of Zenker, to calcareous degeneration, and to the changes known as brown atrophy described above and yellow atrophy.

**PARENCHYMATOUS OR ALBUMINOID DEGENERATION (CLOUDY SWELLING).**—This is a change in which the sarcofibrillar substance is converted into granular matter of albuminoid composition, which produces also more or less indistinctness in the striated appearance of the fasciculi. The albuminoid composition of the product is attested by its solubility in acetic acid, and its insolubility in ether. The general effect is one of softening and flaccidity.

It is ascribed to some toxic agency, and occurs most frequently in the infectious fevers—typhoid fever, scarlet fever, diphtheria, and the like. It was at one time considered a consequence of high temperature, but this view is no longer held. It is believed also to be, at times, at least, the first stage of fatty degeneration, or to precede fatty degeneration. It is certainly at times associated with it. Cloudy swelling may disappear and the muscle resume its natural histology.

**FATTY DEGENERATION OR FATTY METAMORPHOSIS.**—In this change, also sometimes known as *yellow atrophy*, the sarcofibrillar substance of the muscular fasciculi is directly converted into globular fat, as contrasted with the condition of fatty infiltration, in which the fat is deposited between the fasciculi. The little fat drops—and they are very minute, as a rule—are seen in rows parallel to the fibrillæ of the fasciculus, and all transverse striation has disappeared. As intimated, the cause of such degeneration is an interference with the proper nutrition of the heart muscle.

It may be *general*, when it has its most frequent expression in the dilated heart which succeeds upon hypertrophy, involving the walls of one or more cavities. It is also a result of the impaired nutrition of old age, of the grave infectious diseases, and of cachectic states generally—such, for example, as pernicious anemia. In the infective diseases and cachexias it may be associated with parenchymatous degeneration or succeed upon it. It is also a result of the action of certain poisons, as phosphorus and arsenic, the effects of which may extend to other muscular organs. Under these

circumstances, the heart is generally enlarged (dilated), flabby, and relaxed, of a light yellow or yellowish-brown color, and very friable, permitting the finger to be easily poked through it. The papillary muscles and the trabeculæ in the left ventricle may be the seat of circumscribed fatty degeneration, and be dotted and streaked with yellow, fatty matter. Unlike parenchymatous degeneration, fatty degeneration, when once established, is considered irremediable.

Fatty degeneration of the heart may also be *circumscribed* in small foci variously distributed. Thus, it may be confined to the superficial or sub-pericardial layers, when it is especially the result of pericarditis. Or there may be numerous pinhead-sized foci in the subendocardial layer in cases of extreme dilatation.

Finally, there may be a single focus in the substance of the left ventricle or the septum, due to total obstruction of one of the branches of the coronary artery, usually the anterior, by a thrombus or embolus. The product is an area of fatty degeneration known also as *anemic necrosis*, or *white infarct*. In the early stage the infarction is brownish-yellow or hemorrhagic. Minutely examined, the muscular fasciculi are without nuclei, and later they break up into a cheesy detritus. The infarct is not always thus made of fatty débris, but may present a hyaline appearance. It may be the seat of rupture, and thus cause hemorrhage into pericardium, and immediate death.

**Diagnosis.**—The diagnosis of fatty degeneration, so far as recognizable, is that of dilatation, slight degrees and circumscribed fatty degeneration being unrecognizable, while considerable areas of partial degeneration may also exist without exhibiting symptoms. In fact, the presence of some dilatation of the cardiac cavities seems to be necessary to the production of symptoms—the feeble pulse, palpitation, and dyspnea being symptoms of the dilatation, rather than the fatty degeneration.

**Prognosis.**—This is grave. It is impossible to restore the degenerated muscular substance to its natural structure. With degeneration established death is liable to occur suddenly, and remedies which avail with an integral organ are useless here.

**Treatment.**—This embraces that of cardiac dilatation. Acute attacks should be met by stimulants, of which alcohol, aromatic spirit of ammonia, and digitalis are the type. Strychnin is also indicated, and may be used hypodermically.

**FATTY INFILTRATION OR FATTY OVERGROWTH.**—Strictly speaking, this condition is not a degeneration of the heart muscle, though it leads ultimately to fatty metamorphosis. It is the *cor adiposum* of the older authors, and differs from fatty metamorphosis in that the fat is infiltrated *between* the muscular fasciculi. In the true *cor adiposum*, the fat extends deep into the substance of the muscle, sometimes as far as the endocardium. It covers also the outside of the heart, at times so completely that the true muscular structure is invisible. This infiltration sooner or later interferes with the proper nutrition of the muscular substance, a true fatty degeneration results, with its symptoms, so far as any are manifested, and becomes ultimately also a cause of death.

The fatty infiltrated heart is commonly a part of general obesity, and occurs, therefore, at a time of life when this is usual—that is, between the ages of 40 and 70 years—and is more than twice as frequent in men as in women.

The condition is inferred from the presence of extreme obesity associated with signs of cardiac weakness.

The **treatment** is that of obesity.

AMYLOID INFILTRATION invades the heart as it does other organs, attacking the blood-vessels and intermuscular connective tissue. *Zenker's hyaline transformation* attacks, on the other hand, the muscular fasciculi, causing them to appear swollen and transparent, and the striæ to be indistinct or absent.

CALCAREOUS INFILTRATION is a rare condition, in which the muscular fasciculi are infiltrated with lime salts.

## MYOCARDITIS.

### CHRONIC MYOCARDITIS OR FIBROMYOCARDITIS.

SYNONYMS.—*Fibroid Degeneration of the Myocardium; Fibroid Heart; Fibrous Myocarditis; Interstitial Myocarditis; Indurated Degeneration; Myodegeneration; Sclerosis of the Coronary Arteries.*

**Definition.**—A chronic disease of the cardiac muscle in which there is more or less substitution of the normal substance by fibroid or cicatricial tissue, either localized in patches or diffused throughout the organ.

**Etiology and Pathology.**—The condition is not, strictly speaking, inflammatory, the patches representing transformed areas of anemic necrosis, due to obstructive disease of the coronary arteries and branches. The disease in the coronary arteries is endarteritis, resulting in arterio-sclerosis. Through a diminished blood-supply, it causes degeneration of the muscular fasciculi, and their substitution by fibrous tissue. Only in the event of such diminished supply do the changes occur. Hence it is that arterio-sclerosis of the coronary arteries is not always followed by fibroid change. The causes of arterio-sclerosis of the coronary arteries are those of endarteritis elsewhere. They include all the causes which produce idiopathic hypertrophy (p. 647). The tendency to arterio-sclerosis is often hereditary. It is a disease also which seldom occurs prior to middle life, though sometimes seen surprisingly early. It might be said that it is natural to old age—one of its evolutionary terminations. In pure, uncomplicated cases of myocarditis the valves are normal, while the muscle, on examination, is found dotted with *white, shining areas* present in varying numbers. Minutely examined, these are found made up of pure or partly fibroid tissue, the muscular substance being correspondingly destroyed. They are seated for the most part in the *left ventricle toward the apex* and in the *anterior wall*, though they may be found elsewhere. They may often be seen from the endocardial or pericardial

surface as *cicatricial-like depressions*. Sometimes there is a single large patch known as a *fibroid patch*. The papillary muscles may exhibit the same fibroid change. Another cause of fibrosis is pericarditis which produces small and larger areas of degeneration in the shape of the milk-white fibroid patch on the surface of the heart and extending more or less into its substance. Mural endocarditis may produce similar patches on the inner surface of the heart.

The fibroid change may also be associated with valvular disease, the mechanical impediment to the movement of blood in this condition being the cause of a chronic venous congestion, which results in a fibroid infiltration; or the valvulitis may give rise to embolism of the coronary arteries or branches, thus cutting off nutrition. From the cardiac thrombosis which sometimes results there may arise cerebral, renal, and pulmonary embolism. Long-standing emphysema of the lungs results in similar congestion; so does obstruction of the pulmonary artery from any cause.

A further result of the fibroid change is dilatation of a part or of the whole of one of the heart cavities, producing in the former instance what is known as *cardiac aneurysm*. Fibrosis may also be associated with hypertrophy without valvular disease, though the recognition of such combination before death must be a matter of inference, based on the presence of arterio-sclerosis elsewhere and of the causes of such hypertrophy.

Recently the term myocarditis has been extended to include fatty as well as fibroid change since the same symptoms may result from both.

**Symptoms.**—Slight degrees of fibroid change occasion no symptoms, while autopsies even disclose advanced stages of indurative myocarditis which were not suspected. In consequence of the frequent association, too, of endocarditis and pericarditis, the symptoms of these diseases are often combined and mask the distinctive symptoms of the fibroid change. Unmasked, the symptoms are, in a word, those of dilatation of the heart, including *dyspnea*, often so severe that the patient cannot lie down. With this may be associated *Cheyne-Stokes* breathing, commonly occurring during sleep. There may be *palpitation*, with *small, frequent, and irregular pulse*, or the pulse may be persistently *slow*. There is *precordial oppression*, with *attacks of faintness*, and, finally, *venous stasis* with *cyanosis, general edema, congestion of the liver, stomach, and kidneys, feeble digestion, scanty urine, and albuminuria*. These symptoms may set in gradually or suddenly. On such a heart, digitalis and other heart tonics are often without effect. *Angina pectoris* is also a symptom of indurative myocarditis, though it also occurs in other cardiac diseases, especially aortic stenosis. It will be described when treating of neuroses of the heart.

A very interesting train of nervous symptoms may arise, due to changed local distribution of blood in the brain, partly due to feeble cardiac action and partly to stenosis of the basilar vessels. They may include brief unconsciousness and various degrees of paralysis and anesthesia resembling the symptoms of cerebral embolism; also modified breathing rhythm including *Cheyne-Stokes* breathing.

A peculiar sallow, or lead hued complexion may develop as the disease progresses.

**Physical Signs.**—Physical examination recognizes a *feeble impulse* which

may be displaced to the left, often scarcely appreciable, and, on percussion, enlargement of the cardiac area. The first sound lacks its muscular element, and is more like the second—more purely valvular, and therefore short. Both sounds maintain for a time considerable distinctness, but ultimately grow feeble. Occasionally there may be a mitral murmur, which may be functional and transitory or permanent. Such murmur is explained by the experiments of Ludwig and Hesse, already alluded to, and more recently confirmed by Krehl. These go to show that a certain integrity of the muscles about the mitral orifice or of the papillary muscles is necessary to a complete closure of the latter. Such integrity is impaired by myocarditis, and the resulting murmur increases the difficulty of diagnosis. The murmur is systolic, soft, low pitched, heard at the fourth rib. There is, however, usually absence of accentuation of the pulmonic second sound characteristic of mitral regurgitation, though this may also be relatively present if the right ventricle happen to be less severely involved than the left. There may be systolic shock greater than would be expected from the feebleness of the cardiac impulse. The second sound is also sometimes reduplicated, or there may be gallop rhythm sometimes early. The mitral murmur in the fibroid heart is more variable and more subject to intermissions than that of mitral regurgitation. The sudden addition of a mitral systolic murmur in a fibroid heart previously without murmur may also indicate a lacerated valve.

**Diagnosis.**—This is often difficult, requiring the opportunity of prolonged study of the case. For the most part, we are compelled to rely on the absence of the symptoms and signs of valvular disease, and the presence of the symptoms of dilatation, the evidences of arterio-sclerosis elsewhere, a persistently slow pulse, angina pectoris, the history of syphilis and of other causes, together with the age of the patient. When the fibroid condition is associated with murmurs, the diagnosis is still more difficult, and must, indeed, be a matter of probability, if even suggested, so much more likely are the signs to be interpreted as those of valvular disease, with which, however, the myocarditis may be associated. The presence of radial sclerosis is strongly confirmatory, but not essential.

**Prognosis.**—This is grave, or, to say the least, uncertain. Associated as it is with sclerosis and narrowing of the coronary arteries or branches, complete obstruction is liable to occur at any time, producing sudden death. On the other hand, the patient may live for many years with the heart the seat of considerable fibroid change.

**Treatment.**—This must mainly consist in treating the causes, and in a proper hygienic management. Habits of overeating and excessive drinking should be overcome. The avoidance of overexertion, associated with just sufficient exercise to develop the heart healthfully, should be observed. Outdoor life and a proper hygiene of the skin and body by bathing and massage are important.

Drugs which will remove the diseased condition of the coronary arteries and fibroid overgrowth probably do not exist. Still, the reputation of iodid of potassium as a remover of fibroid overgrowth and for the cure of syphilitic disease should be availed of. The iodid is also serviceable in producing vascular dilatation and facilitating the movement of the blood.

For the symptoms of stasis and heart weakness, of dyspnea and of angina pectoris, the treatment is the same as that for these conditions under other circumstances. The judicious use of digitalis is indicated, and may accomplish much. Nitroglycerin may be associated with advantage or used alone.

#### ACUTE SUPPURATIVE MYOCARDITIS.

SYNONYM.—*Abscess of the Heart.*

This is a rare condition. It is always metastatic or pyemic in origin, in association with puerperal fever, malignant endocarditis, or other septic processes. It may occur in the septum, as well as the outer ventricular walls.

As such it is not recognizable before death, and is commonly discovered at autopsies. It may, however, rupture into the heart cavities, causing other metastatic abscesses, or into the pericardium, causing septic pericarditis and early fatal termination.

#### ANEURYSM OF THE HEART.

This is a term given to two conditions:

1. A saccular projection from the ventricular surface of a sigmoid or cuspid leaflet, where the valve is weakened by ulceration through one of the lamellæ, the intravascular or intracardiac pressure furnishing the distending force. It is much more common in the aortic segments. The sacculus may ultimately perforate, causing laceration of the valve.

2. Projection outward of a circumscribed portion of the muscular wall, which has been weakened by the fibroid patch or by an injury to the wall. Here, naturally, the left ventricle, too, suffers, and near the apex in more than half the cases. The resulting pullulation varies in size from  $\frac{2}{5}$  inch (1 cm.) or less to dimensions equal to those of the heart itself. The aneurysm may be sacculated or partitioned and even multiple.

There are no symptoms by which the condition may be recognized with any degree of probability. It may also terminate fatally by rupture into the pericardium.

#### RUPTURE OF THE HEART.

Rupture of the normally integral heart muscle does not occur. It is only when weakened by disease that such an event is possible. Fatty metamorphosis furnishes the most frequent predisposing condition, in 77 out of 100 cases collected by Quain. The softening due to obstruction of a branch of the coronary artery, as already described on page 658, and known as *massive softening*, is the most frequent cause of heart rupture, but the fibroid change, abscess, or ulceration are all conditions which at times precede rupture. Morbid growths in the heart-wall, such as gummy tumor,

cysts, and carcinoma, are also possible causes. Segmentation and fragmentation of the muscle has been observed but this condition is by some considered as of doubtful occurrence.

These preliminary conditions presupposed, any unusual strain, physical or mental, is sufficient to produce rupture, though this is not always necessary, especially in the case of the white infarct, where the degeneration is so great as to admit rupture with the ordinary pressure. It is naturally an event of the second and third half-centuries of life. It has occurred among the insane when perfectly quiet.

The anterior portion of the left ventricular-wall near the septum is the favorite seat. Rupture is rarely recognized before death, which usually follows in the course of a few hours.

The symptoms are precordial pain, a sense of oppression, dyspnea, pallor, pulselessness, and collapse. There may be enlargement of the cardiac area of dullness, owing to filling up of the pericardial sac, associated with feeble or absent apex-beat.

## NEUROSES OF THE HEART.

### NERVOUS PALPITATION.

**Definition.**—By this is meant an unnaturally frequent, regular, or irregular beating of the heart, of which the patient is uncomfortably conscious, but which is unattended by any physical evidence of organic disease of the organ. This does not mean that there may not be functional or accidental murmurs, because these are especially prone to be present in the different varieties of anemia which are commonly associated with palpitation. *Such murmurs are always, however, systolic, a diastolic murmur always indicating organic disease.* Palpitation, or uncomfortable heart beating, also occurs in connection with organic disease, but this is not nervous palpitation.

**Etiology.**—There are numerous causes of palpitation. In the first place, it is much more frequent in women than in men. Again, it is prone to occur at the time of puberty in girls, and at the menstrual period and climacteric in women. Anemia is at once a predisposing and an exciting cause; indigestion is a very frequent causal agent. Mental emotion, including fright, anxiety, and grief, diseases of the uterus and stomach, the exhaustion of protracted illness, sexual excesses, overwork, the abuse of alcohol, tobacco, tea, and coffee, are all active etiological elements. The "irritable heart" described by Da Costa, based on observations made on soldiers in the late Civil War in America, has for its most striking symptoms palpitation; yet this dare not be called nervous palpitation, as dilatation of the heart was probably here present. Overwork and excitement were its chief causes, abetted by exhaustion from illness.

**Symptoms.**—The "beating" referred to is, of course, the chief symptom. It varies greatly, however, in degree and duration. At times there is a mere fluttering, lasting for a few minutes. At other times the pulse-rate may reach 160 or more and be scarcely countable. When the character last

described is attained, and continues for a variable time of hours to days, but finally ceasing, the term *paroxysmal tachycardia* is applied. The rapid heart-action is sometimes associated with a sense of *weakness* or "*goneness*" in the epigastrium, and sometimes with *nausea*. The face is usually pale, but is sometimes flushed. The physical signs usually add nothing to the undue beating noted on auscultation, though, as already mentioned, there may be functional murmurs systolic in time at the base of the heart, more rarely at the apex. The normal heart-sounds may be somewhat sharper and clearer, or they may be more blurred.

**Diagnosis.**—The only two conditions with which nervous palpitation may be confounded are *myocarditis* and *fatty degeneration of the heart and dilatation*, the symptoms of which, it will be remembered, are similar. The nervous affection is, however, a less serious one, characterized by intermissions during which the heart is quiet. Its subjects are also of the anemic nervous type, whose history greatly aids the diagnosis, and they are commonly younger.

**Treatment.**—This is by rest, nerve sedatives, and a suitable moral treatment of encouraging words and a confident manner. A few drops of tincture of digitalis, with a few more grains of sodium bromid, repeated every hour, may be useful. When the patient is weak and anemic, he should be built up and strengthened by iron, quinin, and strychnin.

## TACHYCARDIA AND BRADYCARDIA.

*Paroxysmal Tachycardia.*—This term is applied to conditions of the heart in which, without evident cause, there appears paroxysmally an inordinate increase in the number of heart-beats of which also the patient is conscious. The number of beats may reach 200 or more a minute. The paroxysm may last for a few minutes only, or for hours. The intervals between two attacks vary greatly, and their recurrence may extend over many years. It is a nonfebrile condition.

James Barr, of Liverpool, believes that paroxysmal tachycardia may be due to distention of the right heart associated with a relatively high blood pressure in the arteries and veins. Under these conditions only a small volume of blood is thrown into the pulmonary artery resulting in an accumulation of blood in the right ventricle. The life of the patient is kept up with the heart beating at 200 to 300 times in a minute, by a relatively high arterial pressure, by which the coronary circulation is maintained. As soon as this fails the patient dies. This higher arterial pressure which seems at first unlikely in view of the small amount of blood admitted to the arteries, is maintained by peripheral resistance, itself due to the small amount of blood discharged from the systemic arterioles. A sound cardiac musculature is therefore necessary, without which the arterial resistance necessary could not be kept up.

*Bradycardia; Brachycardia; Slow Heart.*—The term bradycardia is applied to unnatural slowness of pulse. It is to be remembered, however, that some healthy persons naturally have a slow pulse, as others have one whose rate is more rapid than the typical 72. A rate of from 50 to 60 in

health is not unusual. Of abnormally infrequent rates, cases with 20 beats are reported, some even at 12, 9, and 7. These instances of extremely slow rate are apt to be associated with fibroid heart, and there can be no doubt that the nervous condition is often confounded with the organic one.

In the study of an apparently slow pulse, care must be taken that the actual count is based on a corresponding heart-rate, for it sometimes happens that in consequence of the weakness of an alternate systole the heart-beat does not reach the wrist.

**Explanation of Tachycardia and Bradycardia.**—The rationale of the production of tachycardia and bradycardia has excited much discussion and cannot be said to be settled. The heart's action is accelerated by stimulating the accelerator branch of the sympathetic or by paralysis of the inhibitory root of the vagus, and slowed by excitation of the vagus center, directly or reflexly. Direct stimulation of the latter is caused by pressure on its root, which may be exerted through the cerebrospinal fluid, which in turn may be excited by brain tumor, hemorrhage, and meningitis of the dura or pia. Such irritation may be caused by toxic constituents of the blood, as in uremia. Diminished contractility of the heart muscle would also produce bradycardia.

Increased arterial pressure—such, for example, as occurs in *acute* nephritis—may produce cerebral vagus irritation. On the other hand, such slowing is not maintained if the arterial tension be kept up, seen in *chronic* Bright's disease and arterial sclerosis. Under such circumstances the excitability of the pneumogastric center may be said to be exhausted. Deficient nourishment to the heart substance, such as is caused by atheroma and obstruction of the coronary artery, leads also to a slow pulse. Reflexly, the pneumogastric may be stimulated by diseases of the abdominal organs—as, for example, the stomach, bowels, and peritoneum. The effect of disease of the muscular substance of the heart in reducing its rate has often been mentioned in the foregoing section. On the other hand, poisons and high temperature increase the pulse-rate. In this way the infectious diseases may produce acceleration. Other poisons slow the pulse, possibly by acting on the nerve endings in the heart. Such are the salts of the biliary acids and the uremic poison, whatever it may be.

It is well known that in the course of acute infectious diseases, especially typhoid fever, slowing of the pulse occurs at times very strikingly. This is not uncommon in the beginning of convalescence. It has been observed also in typhus fever, in croupous pneumonia, erysipelas, diphtheria and measles. I have met it as slow as 18 in typhoid fever. In explanation of this phenomenon one may suppose a lesion of the cardiac ganglia by the toxic substances circulating with the blood, or a consequent weakness of the heart muscle due to the long continued fever.<sup>1</sup>

His and Romberg, in their studies on the innervation of the heart, were led to believe that the cardiac ganglia are sensory in function and that they share the increased sensitiveness of the entire nervous system, variously caused, and thence reflexly may excite the violent cardiac action of tachycardia. Not unlike this is the explanation of H. C. Wood, who suggests that

<sup>1</sup> See a very full paper "Ueber Bradycardie," by F. Grob, "Deutsches Archiv für klinische Medicin," vol. xxii., 1888, p. 574.

the paroxysms of tachycardia are due to "discharging lesions" affecting the centers of the accelerator nerves. In some one of these views, perhaps, must be sought the required explanation. On the other hand, anesthesia of the cardiac ganglia, however, induced, would be expected to have the opposite effect of a bradycardia. By recalling these facts many of the cases of bradycardia may be explained.

**Summary of conditions in which Bradycardia Occurs.**—Bradycardia occurs in a variety of conditions, which have been carefully collected by Riegel. They include the following:

1. Convalescence from acute fevers, such as typhoid, pneumonia, diphtheria, acute rheumatism, and the like.
2. Diseases of the digestive apparatus, especially dyspepsia, but also ulcer and cancer of the stomach.
3. Rarely in diseases of the respiratory system.
4. Diseases of the circulatory system, more frequently those involving the muscular structure of the heart and associated with deficient nutritive supply, especially conditions succeeding obstruction to the coronary artery.
5. In acute nephritis.
6. From the action of toxic agents, including the uremic poison, lead, alcohol, coffee, and digitalis.
7. Certain diseases of the nervous system, including apoplexy, brain tumors, especially those involving the medulla and cervical cord. (To these may be added epilepsy and catalepsy.—*Author.*)
8. Finally, affections of the skin and sexual organs.

## IRREGULAR PULSE.

SYNONYM.—*Arrhythmia*.

### Description of the Different Varieties, Peculiarities, and Explanation.—

The simplest form of irregular pulse is the *intermittent pulse* in which there is an occasional drop or intermission in the beat, while the pulse in the intervals is perfectly regular. This may occur once only in 20 or more beats, and from this rate the intermissions may increase until they happen once in six or four beats, or it may be every second or third beat; or the pulse may be altogether irregular—*arrhythmical*. A striking feature of even the simplest form of intermittent pulse or heart is that the omitted beat is commonly recognized by the patient himself, and often it becomes a matter of intense annoyance to him. Here, again, it is quite important to decide whether the dropped beat at the wrist is the consequence of an omitted systole recognized by absence of the first sound in the auscultated heart, or whether it is a simple weak systole which does not send the pulse to the radial artery at the wrist. The former is called true intermission, the latter false. The true intermission is more apt to be noticed by the patient.

It may be constant, occur at regular intervals, or only occasionally. In the latter event it may be associated with some such disturbing cause as dyspepsia, especially flatulence. It follows the use of tea, coffee, or tobacco, and is rather frequently associated with chronic gout. It follows also

mental shock, and is especially prone to occur in nervous, hysterical persons. The intermittent pulse thus occurring is vaguely ascribed to nervous influence, and nothing more definite can at present be confidently suggested for its causation. It may be due to some influence of the causes named on the cardiac ganglia of the sympathetic nerve. It is probably at times directly due to organic changes in the heart muscle, especially in fatty degeneration, in which event it is a more serious symptom. It is characteristic of the more purely functional variety of intermittent pulse that it may be removed by exercise or excitement, while it often disappears during pyrexia. On the other hand, the effect of exertion on the intermittent pulse of fatty heart is to increase the intermission or convert it into an irregularity.

The *irregular pulse* is indicated by its name. It is associated with a corresponding degree of irregularity of the *heart's* action, the highest degree of which is known as *delirium cordis*. Irregularity may be constant or occasional, and be produced by the same causes as intermission. More frequently it is associated with muscular or valvular disease. Such irregularity is a distinctive symptom of mitral insufficiency, and to a less degree of mitral stenosis.

The *pulsus bigeminus* and *trigeminus* are also common in mitral disease, more especially mitral stenosis. In these, two and three beats follow each other in rapid succession, followed by a longer interval. In the *pulsus paradoxus* of Kussmaul, the beats during inspiration are more frequent, but less full than during expiration. The explanation of irregular pulse is not the same for all varieties, and it must be admitted that there are difficulties in explaining some of these. It will be remembered that cardiac rhythm is inherent in the cardiac muscle, but that the nervous system exercises an important controlling influence which has been briefly considered when treating of tachycardia and bradycardia. It would appear that most of the irregularities above enumerated are the result of physical causes operating to interfere with the normal rhythm. Thus the irregularity of the pulse so frequently associated with mitral insufficiency may be ascribed not to a modification of the normal nervous regulation, but to variations in pressure caused by traction of the lungs during the inspiratory act on the cavities of the heart as suggested by W. H. Broadbent. This is favored by the thin, flabby, and feebly resisting walls of a dilated auricle, incapable of resisting variations of external pressure. In mitral stenosis, though the auricle is dilated, the narrow auriculo-ventricular orifice prevents the disturbing effect of the varying pressure of the respiratory movements. In mitral stenosis the imperfect pulsations may also be due at times to feeble contractions of the ventricle, these being in turn due to insufficient stimulus of the ventricle by the small quantity of blood injected into it from the auricle. The smallness of the beat is further intensified by the small quantity of blood sent into the aorta and branches from the ventricle.

The *pulsus bigeminus* and *pulsus trigeminus* may be similarly accounted for. The *pulsus paradoxus* has been already explained when treating of pericarditis with effusion and chronic adhesive pericarditis.

The *dicrotic pulse* is a double beat, and is found in every normal sphygmogram. It is the effect of the elastic recoil of the overdistended aorta on the contained blood immediately succeeding the closure of the aortic valve,

and is shown at *f* in the catacrotic or descending portion of the normal sphygmogram appended. It is preceded by the aortic notch *e*; this by the tidal wave *d* and the percussion wave *b*, the apex of the curve. Only when exaggerated is it felt by the fingers. It may occur abnormally wherever there is a forcible systole and unobstructed arterioles, especially in aortic regurgitation, and although here the incompetent aortic valves do not furnish the required resistance, this is furnished by the full ventricle behind them, so that while the dicrotic factor may be delayed, it is marked when it occurs.

FIG. 59.—Showing Normal Pulse-tracing.

This is seen in the sphygmogram on page 628. It occurs also in anemia after venesection, the necessary atony of the arterial system being thus produced; after the administration of amyl nitrite and nitroglycerin; also in uncompensated mitral regurgitation, when the emptiness of the arterial system is produced in a different way—that is, by diminishing the amount of blood which enters the aorta with each systole. It is well shown in the appended drawing from Broadbent. (Fig. 60.)

FIG. 60.—Dicrotism (Broadbent).

Another variety of double beat is the *pulsus bisferiens*, most frequently noticed in aortic stenosis, but also in senile degeneration of the arteries. This resembles the dicrotic pulse, though quite different in its etiology. In it, the second beat is a reinforcement near its close of a prolonged systole. Under these circumstances the dicrotic wave may be small or absent. (Fig. 61.)

Mention should be made of the *anacrotic pulse* though this is not appreciable to the finger. It is similar to the *pulsus bisferiens*. An anacrotic pulse-wave is one in which a more or less marked notch occurs in the ascending limb, as in Fig. 62. It is the pulse of high arterial tension, and

occurs when the arteries are rigid and do not expand promptly to receive the contents of the ventricle during systole. The walls yield slowly, the pressure is prolonged, broadens the top of the sphygmogram, and throws the highest part of the tracing toward the end of the systole and nearer the dicrotic wave, which is usually ill developed. So, too, the percussion wave is practically abolished and the tidal wave forms the apex of the curve. The pulse of prolonged arterial tension is produced by anything which resists the motion of the blood through the capillaries and arterioles, and such causes

FIG. 61.—Pulsus Bisferiens (*Broadbent*).

are numerous. Chronic renal disease, especially interstitial nephritis, is one of them; so are gout, lead-poisoning, constipation, atheroma, or calcification of the arterial walls. The anacrotic pulse is also produced in aortic stenosis, where it is of diagnostic value.

Other modifications of the cardiac rhythm are the *gallop rhythm* and *embryocardia*. The former consists of three sounds, and is so called because it resembles the footfall of a horse in canter. It occurs especially in the hypertrophy which accompanies interstitial nephritis with arterio-sclerosis, and in fatty dilated heart. It is variously ascribed to an (1) abnormal

FIG. 62.—Anacrotic Pulse Curves—Pulse of High Arterial Tension. (*Landois and Sterling*).

“clacking,” produced by the contraction of a hypertrophied auricle, preceding the ventricular shock (*Charcelay*); (2) to a presystolic impulse which immediately precedes the precordial shock; (3) to the contraction of a hypertrophied auricle and powerful tension of the ventricular wall produced by the rushing of the column of blood into the ventricles in connection with the elastic resistance due to the muscular tonicity of the hypertrophied wall (*Potain*); (4) *Cuffer and Barbillion* suggest, in explanation

of the variety occurring in the feeble myocardium of ataxic fevers and dilatation, that the ventricular contraction and consequently the first sound is broken into two parts succeeding the precordial shock.<sup>1</sup> *Embryocardia*, first described by Stokes, is a condition in which the first sound is shortened, and therefore more like the second, the resultant being a sound similar to that of the fetal heart. It occurs especially in the latter stages of dilated heart, in which the muscular element of the first sound has become lost because of weakness and the sound is purely valvular.

TREATMENT OF PALPITATION, TACHYCARDIA, AND ARRHYTHMIA.—It is of the greatest importance that the cause of nervous *palpitation* should be ascertained, for with its removal recovery may be expected. Indigestion, distant causes of reflex irritation, such as uterine and ovarian disease in women, anemia, chlorosis, and the like should be carefully sought and eliminated by a proper treatment. During an attack the strictest quiet should be enjoined, and the patient should be kept in the recumbent posture. It is much more important that this should be done than that heart tonics or heart sedatives should be administered. Yet at this time it may be helpful to give small doses of digitalis, frequently repeated, say 3 to 5 minims (0.18 to 0.3 c.c.), or 5 to 10 drops, every hour, combined with the bromids in 10 to 15 grain (0.66 to 1 gm.) doses, or aconite and veratrum viride in 1 minim (0.06 c.c.) doses as often. When the palpitation is prolonged, a belladonna plaster may be applied to the heart, or cold may be applied over the cardiac region.

The treatment of an attack of *tachycardia* is similar. Every conceivable remedy has been tried by those subject to these attacks and their advisers, with results apparently satisfactory at one time and totally disappointing at another. In one remarkable case, a dear medical friend of my own, a glass of ice-water rapidly drunk almost always stopped a paroxysm. I have seen this effect in his case follow in a few minutes. This remedy he hit upon after 50 years' trial of everything he could think of.

Barr, consistently with his theory of tachycardia, recommends the free use of amyl nitrite, and nitroglycerin to lessen peripheral resistance and equalize the amount of blood in the two sides of the heart. He also encourages the patient to take long, deep breaths so as to aspirate the blood from the right side of the heart into the lungs, and thus give a better supply to the left ventricle. He suggests that counterirritation might call into play the reflex cardiac contraction of Abrams. If, after the preceding measures have been carried out, the hyperdistended right ventricle does not properly contract, then the addition of digitalis and strychnin is required, aided by a good, brisk purgative to clear the portal circulation. The diet should be as dry as possible, to avoid the addition of fluid to the over-repleted veins and right side of the heart.

*Bradycardia* is perhaps best left alone, unless some evident, easily removable cause be found.

As to treatment between attacks, the continuous use of strychnin may be expected to be useful. It may be combined with iron and quinin in moderate doses if there is anemia. A very elegant and convenient prepara-

<sup>1</sup>For an elaboration of these and further explanations see Barth and Roger, "Traité Pratique d'Auscultation," thirteenth edition, Paris, 1898.

tion is the elixir of iron, quinin, and strychnin of the U. S. P. On the other hand, strychnin sometimes causes nervousness. The dose must be regulated to avoid this. The tincture of nux vomica has been commended as especially suitable in these cases, given in ascending doses until 30 minims (2 c.c.) or more are reached. Outdoor life and exercise, mild gymnastics, walking, riding, cycling if not too violent, and mountain-climbing, all contribute to improve the general health and strengthen the heart at the same time. Cold bathing is one of the best measures for the same purpose, either at home or at the seaside.

The same principles of treatment apply to *intermittent heart and arrhythmia*. When these are the result of organic cardiac disease, their treatment is that of the disease. In the treatment of the simple slow pulse any cause of pneumogastric irritation should be sought for and removed, such as dyspeptic states, torpor of the liver, poisoning with retained bile salts, and the like. In the absence, however, of positive knowledge of the presence of such cause, the condition is best left alone, as treatment under such circumstances may do more harm than good.

Cardiac arrhythmia may be present without serious or indeed any interference with the essential function of the organ. Too much stress therefore should not be laid on such irregularity in the absence of other evidence of organic disease.

### HEART BLOCK. STOKES-ADAMS SYNDROME.

**Definition.**—A condition characterized by permanent slow pulse, becoming paroxysmally slower, associated at times with dizziness, dyspnea and syncopal, apoplectic or epileptic seizures.

**History.**—The syndrome constituting the Stokes-Adams disease was first described by Robert Adams,<sup>1</sup> of Dublin, in 1827; in 1846 William Stokes<sup>2</sup> described two cases, enlarging upon the symptoms. Other English physicians continued its study, while in Germany His, Hoffman and Jaquet<sup>3</sup> have published noteworthy papers. In France, Charcot and Huchard have studied the disease, the former ascribing it to lesions in the medulla, the latter to arterial sclerosis, especially of the coronary artery. Lately, in America, Prentiss, Edes, Osler, Erlanger, Stengel and Thomas Ashton have studied and reported cases.

**Etiology.**—This disease has heretofore been ascribed to some myocardial change, either fatty or fibroid; to injury or disease of the pneumogastric nerve or medulla oblongata; of the cardiac plexus and to sclerosis of the coronary arteries. Recent experimental studies by Joseph Erlanger go to show that the syndrome is due to disease, probably fatty degeneration, of the auriculoventricular bundle of His, a small muscle 18 mm. long, 2.5 mm. broad and 1.5 mm. thick, connecting the auricles with the ventricles. Through this muscle pass the auriculoventricular impulses which, starting in the auricles, pass over into the ventricles, causing the latter to contract. Both auricles and ventricles have their own automatic rhythmicity, but the auricles contract much more rapidly than the ventricles. If the muscle of His is destroyed in the dog the impulses are cut off or blocked and the

<sup>1</sup> Adams, Dublin Hospital Reports, vol. IV., 1827.

<sup>2</sup> Stokes, "Some observations on cases of permanently slow pulse," "Dublin Quarterly Journal," 1846.

<sup>3</sup> Jaquet, "Deutsches Archiv. für Klin. Med.," Bd. lxxii.

ventricles assume their own slow rate of beating. Erlanger has contrived an instrument by which he can gradually compress the muscle and produce various stages of the condition, thus one ventricular silence to 2, to 3, to 4 auricular beats. Complete blocks cut all impulses off from auricles to the ventricles, leaving the latter at its own inherent rate of 23 to 28 beats to the minute in man. Thus may be explained the slow pulse of the Stokes-Adams syndrome in the presence of some degenerative change in the muscle. It was also observed by Erlanger, while compressing the auriculoventricular bundle in the dog, that the ventricle alone stopped beating for a time—as long as 20 seconds. This it was thought explained the syncopal attacks of the Stokes-Adams disease.

The conclusions as drawn from Erlanger's experiments have been confirmed by studies of a case of Stokes-Adams disease in the wards of my colleague Alfred Stengel at the Hospital of the University of Pennsylvania. Adams' case was 68 years of age; Stokes' were 56 and 68; whence it was thought that the disease was confined to persons well on in years, but more recent studies have found cases anywhere between 30 and 70, although it is of course more frequent in the aged.

**Symptoms.**—The first of these is *slow pulse*, habitually slow and regular, although it may be irregular. It becomes much slower during the paroxysms, falling to 40, 30, 20, and even 10 and 5. At times between the notable beats there is nothing noticeable, even with the stethoscope applied to the heart. At others it is said there are numerous auricular and feeble tones not accompanied by a perceptible impulse. These have been regarded by some as auricular contractions and by others as ventricular contractions, but the recent observations by Erlanger would seem to show they are primary auricular contractions, which are blocked off by disease of the muscle of His. In addition to this may be noted also between the strong beats, feeble pulsations in the right internal jugular vein just below the clavicle described by Stokes. These are synchronous with the above noted cardiac sounds. Babcock regards the feeble tones as feeble ventricular contractions and says he cannot conceive of auricular systoles being powerful enough to cause preceptible though imperfect apex beat. It is further characteristic of the slow heart beats that they cannot be accelerated by any of the causes which usually accelerate the heart's action, as walking or exertion of any kind.

*Vertigo* is the most constant symptom, being present in a greater or less degree in all cases and independent of position. It has been ascribed to cerebral anemia.

Another symptom generally but not always present is a momentary *syncope* lasting a few seconds or a minute, and ushered in by an *ashen pallor* to be replaced by a sudden rush of blood to the head, with flushing of the face and feeling of distention of the brain and subsequent headache. During this time no pulse is appreciable. The patient may not be aware of what is transpiring or may revive with a consciousness of having fainted. *Mild epileptiform convulsions* may appear during the syncope, amounting to a mere twitch of the mouth, though they may extend also to the extremities, arm or leg. Biting of the tongue has occurred with involuntary evacuation of urine. *Disturbance of breathing is much less common*; it

is said to be of the Cheyne-Stokes type. The syndrome occurs at varying intervals, but rarely daily or more than once a day. *Cardiac murmurs* due to aortic obstruction and relative insufficiency of both mitral and tricuspid valves are rarely present.

**Diagnosis.**—This depends upon the presence of a sufficient number of the distinctive symptoms, since if unaccompanied by vertigo and an increase in an already slow pulse, it may be due to other causes. In common with all cardiac muscular derangements this syndrome usually occurs in those past middle life but they may occur under 40 when they have been mistaken for mild epileptiform attacks, typical *petit mal*.

The **prognosis** is grave, the cases generally terminating fatally.

**Treatment.**—This is mainly symptomatic. Gastrointestinal derangements should be corrected. Stimulating measures in general are suggested, such as brandy, camphor and injections of ether. Hypodermic injections of morphin and inhalations of nitrite of amyl and oxygen may be useful. One of Stokes' patients found relief by supporting himself on his hands and knees and allowing the head to hang low.

### ANGINA PECTORIS, OR STENOCARDIA.

**Definition.**—An affection of the heart characterized by intense paroxysmal pain, at first usually substernal, extending thence down the arms, especially the left, and up into the neck. It is a symptom rather than a disease, as it is commonly associated with some recognizable organic change in the heart or great vessels, though not always the same change. Often, however, such change cannot be found, and it may be that in rare instances it is a purely functional state.

**Etiology.**—The immediate cause of angina pectoris is deficient cardiac nutrition, however induced. It may be on account of obstructive disease of the coronary arteries, aortic stenosis or insufficiency, pressure by a tumor or other cause, dilatation or enlargement of the heart beyond the capacity of the coronary arteries to nourish, or any cause which produces cardiac ischemia. Adhesive pericarditis may act in this way. It may be that the excessive use of tobacco, which has been accredited with the direct effect of causing angina, may operate thus. The exciting cause of the attack is usually some overexertion or mental emotion calling for some additional effort from an already crippled ischemic heart. These events are more apt to produce this effect after a meal because a full stomach encroaches on the heart. The taking of food alone, even in moderate amount, may excite an attack. Still more, excessive eating and indigestion, however caused, become exciting causes.

It must be admitted that all explanations of the pain are purely speculative, for though total obstruction of the coronary arteries experimentally produced is followed by death, pain has not been found an associated symptom. On the other hand, the pain which succeeds the obstruction of an artery, leading to gangrene of a part, as the leg, is precisely analogous to the anginous pain which succeeds obstruction of the coronary arteries, while the results of experimental closure of these arteries have their parallel in recog-

nized cases of *angina sine dolore*. Again, neuralgic pain of the ordinary kind occurs in a nerve which is badly nourished. May one not explain the pain of angina in the same way, since a defective nutrition is the one acknowledged condition of angina? Mention should be made of the view recently announced by Clifford Allbutt<sup>1</sup> that the agonizing pain and dread characteristic of angina pectoris may be produced by an acute aortitis.

Angina pectoris is a disease of adults, and of men rather than women, and though it may happen in early life, 80 per cent. of all cases occur after the 40th year.

**Morbid Anatomy.**—Atheroma of the coronary arteries is the most constant anatomical change found associated with angina pectoris. It is well known, also, that experimental obstruction of these arteries results fatally, though such death is not attended by the pain of angina. On the other hand, many cases of advanced sclerosis of the coronary arteries occur without angina. In these it must be concluded that the nutrition of the heart has not seriously suffered. The other associated conditions named in considering the etiology must also be regarded as a part of the morbid anatomy. A fair estimate of the frequency of such associations may be obtained from W. H. Walshe's statement that in every one of 24 cases he examined during life distinct signs of changes in the heart, the aorta or in both coexisted. The testimony of G. W. Balfour and P. W. Latham is similar. Acute aortitis has been found. (See Clifford Allbutt's paper previously mentioned.)

**Symptoms.**—The cardinal symptom is agonizing *pain*—pain beginning beneath the sternum in the the region of the heart, extending up into the neck, sometimes the jaws, and down the arms, especially the left following the distribution of the ulnar nerve. Associated with this are *shortness of breath*, *precordial oppression*, and a *sense of impending dissolution*. The pulse is often strikingly natural, though it is also at times unnaturally small, frequent, and irregular. The pain is often associated with a *numbness or tingling in the fingers or over the cardiac region*. There are usually *extreme pallor* and an *agony of expression* which are not soon forgotten. The *skin is pale or ashen gray*, and often the *perspiration* stands out in huge beads. This ashen-gray color of the skin is not confined to the period of the paroxysm. It is, in my experience, quite a characteristic symptom, and when associated with atheromatous arteries, is of diagnostic value. The duration of the paroxysm varies from a few seconds to a half hour. At the end of this time, or earlier, the patient either passes out of the attack or dies in it. The paroxysms occur at widely different intervals, sometimes once in a few months, sometimes oftener, and sometimes at intervals of a year or more. Neither are they always so painful as described, and it is more than likely that the slighter attacks of cardiac pain associated with aortic stenosis and sometimes with aneurysm are of the same nature.

**Diagnosis.**—The only condition with which true angina pectoris is liable to be confounded is the hysterical form known as *pseudo-angina*. It is not often, however, that practical difficulty occurs in separating the two conditions. The hysterical form is more common in younger women, in

<sup>1</sup> "Angina Pectoris," by Clifford Allbutt, M. D., "Philadelphia Med. Jour.," vol. v., June 30, 1890, p. 1464.

nervous and hysterical persons, than the true form, and is associated with other nervous symptoms. In all instances careful examination should be made of the vascular system with a view to detecting alterations in it, such as arterial sclerosis and enlargement of the heart. These will generally be found in some one of their modes of manifestation in true angina. In false angina, as in other manifestations of hysteria, there is something indescribable which will guide the experienced physician aright. In cases of doubt the patient should have the benefit of it.

*Intercostal neuralgia* in the neighborhood of the heart resembles the pain of angina somewhat. It is, however, more circumscribed. It does not radiate into the neck and arms, and the heart and blood-vessels are normal. The pain is not so severe, and the anxious expression of the face is wanting.

**Prognosis.**—True angina is a very grave condition because, although fully three-fourths of all persons attacked recover from the first paroxysm, sooner or later a fatal ending may be expected, and no one knows what attack is going to be the last. In some instances paroxysms recur at intervals of considerable length throughout a lifetime, while in others the first proves fatal. G. W. Balfour mentions the case of an old gentleman who had a final fatal attack after an interval of ten years, in which he had enjoyed excellent health. Many instances of death in the first paroxysms are reported.

**Treatment.**—Treatment naturally resolves itself into that of the paroxysm and that for prevention or cure. For the first, morphin is the most efficient remedy, and if at hand, should be used hypodermically in not less than  $\frac{1}{4}$  grain (0.016 gm.) doses for an adult, combined with atropin. Nitrite of amyl has come to be an acknowledged remedy, first suggested by Sir Lauder Brunton. A few drops may be placed upon a handkerchief or on cotton and inhaled, or, more conveniently, pearls of glass filled with the nitrite are crushed in a handkerchief. The pearls recommend themselves further because they can be conveniently carried, and it is desirable that persons subject to angina pectoris should always have the drug at hand. Chloroform may also be used instead of nitrite of amyl, if more convenient. Nitroglycerin is used for the same purpose in doses of  $\frac{1}{100}$  to  $\frac{1}{50}$  grain (0.00065 to 0.0013 gm.) at short intervals, say 15 minutes. Counter-irritation should be simultaneously applied. The ordinary mustard plaster is a most convenient and efficient measure for the purpose.

Prophylaxis is exceedingly important, and is best accomplished by avoiding the exciting causes commonly responsible for the paroxysms—overexertion, overeating, and mental excitement. The patient subject to angina should never hurry or get into a passion or become excited in any way. The use of all indigestible articles of food should be carefully avoided. Nitroglycerin is sometimes efficient as a prophylactic as well as for the paroxysm in the same doses once in four hours or oftener. The alcoholic solution, of such strength that 1 minim represents  $\frac{1}{100}$  grain (0.0006 gm.), is the best preparation. Nitrite of sodium may be used in from 3 to 5 grain (0.1944 to 0.32 gm.) doses. Other remedies recommended with a view to averting the attack are arsenic, nitrate of silver, the bromids, and especially iodid of potassium, the long-continued use of full doses of which

has apparently sufficed to prevent recurrence. Its effect in this disease is comparable to that produced by it in aneurysm and arterio-sclerosis. As heart tonics, arsenic and strychnin in doses of  $1/50$  to  $1/25$  grain (0.0012 to 0.024 gm.) should be given. While sudden exertion and overexertion are to be avoided, carefully graduated exercise is to be recommended, for like all organs, the heart is strengthened and invigorated by exercise properly regulated. When moderate exertion, if borne at all, brings on an attack, even this should be avoided.

Could we correct the faulty nutrition of the heart we could hope for a cure, and though this may be impossible, we may do that which promotes it. Angina pectoris is one of the conditions in which the Nauheim hot bath may be expected to be beneficial. So it might, so far as the hot baths are used, but the cold bath in any form is harmful.

The treatment of *hysterical* or *pseudo-angina* is that of hysteria under other circumstances.

## DISEASES OF THE BLOOD-VESSELS.

### ARTERIO-SCLEROSIS.

SYNONYMS.—*Angio-sclerosis*; *Endarteritis chronica deformans*; *Atheroma of the Blood-vessels*; *Arterio-capillary Fibrosis*.

**Definition.**—An inflammatory thickening of the walls of blood-vessels, chiefly of arteries, beginning in the intima, but extending also to the media and adventitia, associated also, more or less, with degenerative changes.

*Endarteritis obliterans* is an inflammation of the endarterium which, partly by its immediate product and partly by thrombosis and the organization of the resulting clot, produces complete obliteration of the artery with resulting gangrene.

**Etiology.**—There is a tendency to atheroma in the arteries of the old, as an evolution process quite independent of exciting causes. This tendency also varies greatly in different families, being very strong in some and absent in others. Men are more frequent subjects than women. There are, many exciting causes, among which are especially overeating and drinking, with consequent accumulation of irritating matters in the blood, syphilis, the gouty poison, and lead. Chronic Bright's disease and diabetes mellitus are especially frequently succeeded by it; more rarely acute articular rheumatism. In the latter the rheumatic poison, whatever that may be, is probably the responsible agent, and in Bright's disease it may be retained excrementitious matter. In diabetes it is the sugar in the blood. Two classes of cases may, however, be associated with Bright's disease, in one of which the arterio sclerosis is general and primary, causing interstitial nephritis, and in the other it is secondary, the result of Bright's disease. One set of observers regard all cases of interstitial nephritis as secondary. Among these Sir William Gull and Henry D. Sutton, of England, and Arthur V. Meigs, of Philadelphia, have been conspicuous by their writings. Still another cause of arterio-sclerosis is increased arterial tension due to

prolonged muscular exertion. The toxins in the blood of the various acute infectious diseases may also cause endarteritis and sclerosis.

**Morbid Anatomy.**—The aorta is the most frequent and conspicuous seat of the changes ascribed to chronic endarteritis, but the carotids, subclavians, brachials, radials, and ulnars, the iliacs, femorals, and especially the arteries of the brain and coronary arteries of the heart, are frequently involved. The arteries to viscera, like the stomach and liver, are rarely affected, while the pulmonary arteries take an intermediate place. On the other hand, the latter are sometimes invaded to the exclusion of the aorta. Whatever invites high tension in the lesser circulation tends to produce sclerosis in these vessels. The portal vein may also be invaded.

Appearances differ in arteries of different sizes. Those in arteries of moderate size are best studied in the superficial vessels. They are tortuous, stand out conspicuously, and feel hard to the finger, under which they may be made to roll. These features are often recognizable in the temporals and less plainly in the radials. The smaller arteries and veins with transparent walls, especially in the brain, exhibit to the naked eye white patches which are the seat of the atheroma. On slitting them open, the inner surface of these and other arteries will be found to have lost its natural smoothness, to be rough and uneven, while the lumen is more or less encroached upon.

Minutely examined, the appearances vary with the stage. The first stage is that of cellular infiltration, represented by the translucent yellowish areas of intima thickened to three or four times its natural thickness. Later these young cells are in part converted into connective tissue, causing the primary hardness of the vessel-walls. In the second stage the cells of the connective tissue and the surface cells of the intima undergo fatty degeneration, and the intercellular substance liquefies. In the third stage, which is not reached in the smaller arteries, or, indeed, usually in those below the aorta, there occurs a further liquefaction with the formation of the so-called atheromatous abscess, whose contents are not pus, but the well-known atherom-pulp, representing the débris of fattily degenerated cells, including fat drops and cholesterin crystals. Alongside of the atheromatous patches appear also plates or scales of calcareous infiltration of the intima, produced by a deposit of lime salts in the intercellular substance of the deeper layers. The atheromatous abscess sometimes undermines the intima, forming sinuous cavities, and after evacuation there results the atheromatous ulcer. Both the limy plates and ulcers furnish inequalities which favor thrombosis. In the later stages of the more diffuse form of arterio-sclerosis, especially studied by Councilman, the media or muscular coat and the adventitia are also invaded, the former mainly by atrophic changes, alongside of which, at times, is a homogeneous hyaline infiltration. In this form the capillary walls are also thickened, especially those of the glomeruli of the kidneys, in some of which the vessels become obliterated.

A *calcareous* infiltration of the *muscular* coat without previous inflammation may be found in old age in arteries like the radial, crural, and temporal. Still another primary degeneration is the *fatty crossin* of Virchow, extending through the intima and media as a transverse fissure thought to be the starting-point at times of dissecting aneurysm.

The effect of these changes is to produce rigidity and narrowing of the

vessel, a loss of the propulsive power residing in the elastic coat, a slowing of the current, and increased intravascular resistance. These events tax the compensating power of the left ventricle, which therefore hypertrophies. This hypertrophy keeps up so long as its nutrition is maintained.

But another effect of obstructed circulation is defective local nutrition, some of the consequences of which have already been considered in the study of the fibroid heart. Similar interstitial overgrowth and contraction may be met in the kidney and have been referred to. Localized softening of the brain also succeeds upon atheroma, though this event is usually preceded by thrombotic obstruction favored by the sclerosis. A more frequent accident to the brain is rupture of one of these atheromatous vessels, succeeded by the symptoms of apoplexy and hemiplegia. Such rupture may be preceded by an aneurysmal dilatation. Finally, aneurysm of the larger vessels has for its almost indispensable condition, except in traumatic cases, atheroma of the dilated vessel. Both events—the primary atheroma and the subsequent dilatation—are favored by the increased intravascular pressure.

**Symptoms.**—Superficial vessels in a state of atheroma are easily detected as for example in the temples, by their *dilated, tortuous* outline in which pulsation is sometimes apparent; in other situations, as at the wrist, antebraclial and popliteal spaces, they may be recognized more or less by the touch. Distinction should be made between simple increase of tension and thickening of vessel-walls, though the two are constantly associated. The vessel in both instances is hard and requires some force to compress it, and between beats it is still full and can be rolled under the finger, but the artery with the thickened wall, if firmly enough compressed to obliterate the blood current, can still be felt beyond the seat of compression. In many instances, on the other hand, the changes escape detection until a fatal apoplexy gives notice of their presence. In most of these cases, however, if attention had been directed to the patient, the previously described condition of the arteries would probably have been recognized, while a certain degree of hypertrophy of the left ventricle would also, perhaps, have been detected. It does not follow, however, that the absence of atheroma in one place implies its absence in another, since fatal rupture of an artery in the brain has occurred when there has been no sign of sclerosis in the radials. It should not be forgotten that prolonged hypertrophy and the increased tension incident to it may produce atheroma, or the two may be the result of the same cause—as, for example, contracted kidney.

*Cardiac hypertrophy* is not always demonstrable to percussion, as the enlarged heart may be covered by an emphysematous lung, also often present in the aged, in whom atheroma is most prone to occur. On the other hand, the usual sharp accentuation of the aortic second sound is present if the hypertrophy has not given way to dilatation or fibroid induration. Cardiac murmurs do not occur unless the atheroma invades the valves to produce insufficiency, stenosis, or roughening of the aortic orifice or aorta near the orifice. This is not so very rare in old persons, apart from the relative insufficiency due to aortic dilatation.

For the reasons mentioned, the pulse is prolonged, hard, and tense—the *pulsus tardus* (Fig. 63)—while its sphygmogram is very characteristic: a slow,

oblique ascent, a broad top; a slow descent and absence of the dicrotic rise, which in the normal state depends on an elasticity absent in the diseased vessel. Owing to the same slow transmission of the pulse-wave the pulse is sometimes retarded at the wrist, while the rate is also slow. At other times it is frequent and irregular, especially toward the end of life when the heart begins to fail. On the other hand as measured by the sphygmometer the blood pressure is commonly low, 140 to 160 m.m., or less.

The *arcus senilis* is often an associate of arterio-sclerosis, and strongly confirmatory of its presence.

One of the most annoying consequences of atheroma of the blood-vessels of the brain is *dizziness* or vertigo, and this symptom, when present in the aged, is very apt to be caused by it.

The consequences of atheroma of vessels of the lower extremities include *muscular weakness*, *stiffness*, and a *tottering* gait. In extreme cases gangrene of the lower extremities may result from obstruction to their arteries due to thrombosis invited by the atheroma. Such termination is not very rare in contracted kidney.

FIG. 63.—Sphygmogram of an Atheromatous Vessel—The Pulsus Tardus.

With the supervention of cardiac dilatation and heart failure there appear paralysis, precordial oppression on slight exertion, dyspnea, edema, pulmonary congestion, scanty urine, aggravated vertigo, angina pectoris—in a word, all the symptoms of chronic heart disease. Finally, other symptoms are those of the morbid states it causes—*i. e.*, apoplexy, contracted or senile kidney, atheroma of the coronary artery and its consequences.

**Treatment.**—Treatment is mainly the removal of conditions causing it, such as too free living, gout, lead-poisoning, and syphilis; together with rest and quiet, the avoidance of excitement, also aperients to lower the arterial tension, a slight increase of which is often the last straw required to produce an apoplexy. The iodid of potassium has received general endorsement, though from different points of view. Thus Vierordt gave the iodids on the assumption that they promote resolution of the sclerotic product; Huchard and Balfour on the ground that they dilate the arterioles and thus lower the blood pressure.

More recent studies by Boehm, Prévost, Corin, Stockman, James Burnet and Rolleston, go to show that the iodids do not reduce blood pressure, yet they admit that the drug is useful in arterio-sclerosis. Burnet claims that a further effect of the iodids is to increase elimination, thus removing certain irritant constituents of the blood.

As such, it ought to be useful in arterial sclerosis and probably is. Moderate doses should be continued a long time. In conjunction with this the usual cardiac tonics should be employed with a view to promoting a proper circulation of the blood.

## ANEURYSM.

**Definition.**—An aneurysm is a more or less circumscribed dilatation of a blood-vessel. Aneurysm is known as true or false. A *true* aneurysm is one in which, at the outset, all three coats of the blood-vessel share in the dilatation, though one or two may disappear later in the course of its growth. A *false* aneurysm, on the other hand, starts at the outset with a laceration of one of the coats.

1. True aneurysm may be saccular, fusiform or spindle-shaped, cylindrical and cirroid. The “cirroid” or varicose aneurysm is one in which a blood-vessel of medium size and its branches are irregularly dilated and contorted like a varicose vein, whence the name “varix,” a dilated vein. The “invaginating” aneurysm is a rare form of cylindrical aneurysm, in which the cylindrical sac overlaps at either or both ends the main trunk of the artery involved. Saccular and fusiform aneurysms are the more frequent. The “neck” of an aneurysm is a constricted portion by which a saccular aneurysm is attached to the main trunk.

2. False aneurysm includes two varieties, traumatic and dissecting.

(a) Traumatic aneurysm. In traumatic aneurysm the initial event is some injury from without to one or more of the coats of the vessels, as the result of which the resistance to intravascular pressure is diminished and a protrusion of the intima through the yielding media takes place, the latter being the most passive of all the coats. The simplest illustration of this form of aneurysm is the antebrachial aneurysm caused by accidental wounding of the brachial artery in venesection of the median vein. The blood pushes out the intima and antebrachial fascia and forms a sac communicating with the artery through the wound.

A second form of traumatic aneurysm is the aneurysmal varix or anastomotic aneurysm, in which the blood from the wounded artery passes directly into the adjacent vein through the wound made at the same time, causing a dilatation of the vein. This is resisted by the valves, which, however, give way to the extent of two, three, and even more pairs before the current is successfully resisted.

(b) Dissecting aneurysm. This involves the aorta, in which, in consequence of a perforation through the intima and media, the blood dissects between them and the adventitia. The initial slit is found most frequently in the inner and posterior portion, about one inch (2.5 cm.) above the semi-lunar valves. The blood may dissect from this point around the arch of the aorta, even as low as the diaphragm, before it returns to the lumen of the vessel. Even the visceral pericardium has been thus separated by an aneurysm which projects into the pericardium, rupturing finally into the pericardial sac.

**Etiology.**—The aneurysm most frequently encountered by the physician is the saccular and fusiform form. Its most frequent essential cause is endarteritis and its consequences, including the more acute stage of cellular infiltration, as well as atheroma. The coats thus weakened yield to the intravascular pressure. The intima is capable of a considerable degree of expansion without rupture, while the media is entirely passive

and yields very soon to the distending force. The adventitia alone seeks to guard the sac against rupture by reactive overgrowth. The causes of endarteritis, already discussed, such as syphilis, alcohol, and other toxic substances variously introduced into the blood, are responsible for the more usual forms of arterio-sclerosis which furnish the initial lesion of aneurysm. But weakening of the coats is caused also in the smaller vessels by emboli, after the lodgment of which the proximal part of the vessel often becomes dilated. Such embolus may excite an endarteritis, or may occasion direct violence to the vessel-walls if it be hard or sharp, as is often the case with a fragment of a calcified valve. Muscular compression exerted by muscles in certain situations may also produce it. Such may be the origin of popliteal aneurysms so frequent in footmen, who maintain a rigidly erect position. Finally, disturbances of innervation are considered capable of causing dilatation, and to such influence are ascribed the varicose aneurysms of the arteries of the scalp, of the temporal, and of the popliteal.

Aneurysm is a disease of men rather than women. It is rarely seen until after the 40th year of life.

#### ANEURYSM OF THE THORACIC AORTA.

Thoracic aneurysm occurs in the arch of the aorta, in its ascending, transverse and descending portions, and in the thoracic aorta below the arch. Such aneurysm may but slightly exceed the normal caliber of the vessel, or it may be six inches (12 cm.) or more in diameter.

The greater frequency of aneurysm in the male sex and during early middle life is recognized. To the preexisting conditions of atheroma there may be added the effect of extreme exertion in lifting, or muscular strain of any kind, the effect of which is always to increase intravascular pressure. Partly because they are points of least resistance, and partly because they are in the line of successive impingement of the whirling blood stream, there are certain points of selection in the aorta which are quite constant seats for beginning aneurysm. These are shown in the appended illustration, Fig. 64.

The first point (1) of election is the beginning of the aorta directly behind the trunk of the pulmonary artery. Aneurysm originating there may produce early hypertrophy of the right ventricle because of the resistance to the outward flow of the blood through this vessel, a basic murmur in the pulmonary area, relative insufficiency of the tricuspid valve and venous pulse, with a possible ultimate perforation into the pericardium or pulmonary artery. The second point (2) is the favorite seat of aneurysm of the ascending limb of the arch, behind the sternum, at the manubrio-gladiolar junction, at which place it often bores its way through the sternum as a sacculated aneurysm, which may finally burst through the external integument. The third seat (3) is at the convexity of the arch toward the apex of the right lung. The pleural cavity at this point is soon obliterated by adhesive inflammation, through which the aneurysm bores its way, rupturing into the bronchioles of the apex of the lung, producing fatal hemoptysis. The fourth (4) is between the innominate and left

carotid at the apex of the arch in front of the trachea. It may perforate into the trachea before attaining very large size. The fifth position (5) is posterior in the descending limb of the arch, between the left subclavian and the isthmus of the aorta to the left of the vertebral column. The aneurysm here is more commonly a cylindrical dilatation. It may also rupture into the larynx. The remaining aneurysms of the aorta all point more or less toward the vertebræ, but the greater resistance to their formation in that direction favors lateral development. Ultimately they rupture with hemorrhage into the pleural or abdominal cavity. As much as seven pounds (3.17 kilos.) of blood have been found in the pleural cavity after a fatal hemorrhage. Aneurysms of the thoracic aorta lying close upon the

diaphragm may bore their way between the trunk muscles behind, attaining often large size without perforation.

**Symptoms of Thoracic Aneurysm.**—Apart from the physical signs, the most important of the symptoms due to thoracic aneurysm are the result of pressure of the growing aneurysm, hence they are called *pressure symptoms*.

The first of these is *pain*, which may be sharp and acute when nerves are directly involved, or dull and boring when the result of pressure on bone. In the latter case, too, it is localized; in the former it may extend all over the chest and down the arms, simulating angina pectoris. It may be unilateral. It may occur in aneurysm of any part of the arch, but is more frequent in that of the ascending limb.

*Shortness of breath*, especially on exertion, is a frequent symptom. It may be due to pressure of the aneurysm on the trachea, or on a bronchus, especially the left. Dyspnea may be increased on changing position. *Dysphagia* from pressure of the tumor on the esophagus is a frequent symptom, especially in aneurysm of the descending aorta, anywhere in the thorax. Such pressure may be strikingly demonstrated by Schnell's<sup>1</sup> method of introducing into the esophagus a stomach-tube, of which the lower end is closed, attaching to the outer end a glass tube, and filling the whole with water, and watching the rise and fall of the water in the glass tube, corresponding to the pulsation. Dysphagia is sometimes associated with *broncho-esophageal fistula*.

*Cough and alterations in the voice* are important symptoms. The latter include hoarseness, aphonia, and stridor. Some of these symptoms may be produced by direct pressure on the trachea itself, others by pressure upon the left recurrent laryngeal nerve. A stridulous voice, unaccompanied by dysphagia or aphonia, was early pointed out by Thomas Jolliffe Tufnell as indicating that the pressure is on the right side of the trachea and does not affect the esophagus or recurrent laryngeal nerve. Cough may be caused by tracheal pressure or by a resulting tracheo-bronchitis with copious thin or mucous expectoration, sometimes bloody. The cough is often brassy in character.

On the other hand, hoarseness, aphonia and various degrees of paralysis of the vocal cord are due to paralysis of the recurrent laryngeal nerve, commonly the left, which passes around the arch of the aorta and is, therefore, more likely to be involved than the right. The paralytic phenomena may be present without other laryngeal symptoms, hence any alteration of voice in a person exhibiting palpitation or dyspnea calls for a laryngoscopic examination. When paralysis is total on the left side, such examination may show little alteration in the position of the vocal cords in *ordinary* breathing, or the left may be a little nearer the median line. On *deep inspiration* the right vocal cord is well abducted, the left remaining quiescent in the so-called cadaveric position, midway between that of inspiration and phonation. The attempt at *phonation* is more or less abortive. During it, the right vocal cord may go to the median line, leaving a small opening between it and the motionless left cord, or it may even cross the line to its paralyzed neighbor.

Partial recurrent paralysis results if only the twigs distributed to the *abductor* muscle—*i. e.*, the posterior cricoarytenoid—are involved in the pressure. There ensues gradually a permanent shortening or "paralytic contracture" of the antagonistic adductors of the same side, and the affected cord is drawn by this into a position of constant phonation—that is, to the median line. The result is that the voice may be entirely natural, the paralyzed cord being in the position of adduction, while its tension is mainly regulated by the external branch of the superior laryngeal nerve, the sensory nerve of the larynx which is uninfluenced in aortic aneurysm.<sup>2</sup> In these cases quiet breathing is also unimpeded.

These phenomena imply, of course, a destructive lesion of the nerve,

<sup>1</sup> Ferdinand Schnell "Der Diagnose des Aneurysma der Aorta descendens," "Münch. med. Woch.," xxxvi., pp. 526 and 609, 1889.

<sup>2</sup>For the muscles involved see Diseases of the Larynx.

the result of pressure, which may be preceded by a primary neuritis. Such neuritis and resulting irritation of the entire pneumogastric may account for certain attacks of extreme *dyspnea* sometimes experienced by subjects of aortic aneurysm. Associated with the neural degeneration is also found *atrophy* of the left posterior cricoarytenoid or abductor muscle while the adductors, the lateral cricoarytenoids and the arytenoid remain nearly intact. Constant dyspnea is more likely to be due to direct compression of the trachea.

Other *nerves* may also be *compressed*, especially the intercostal, vagus, and sympathetic. By compression of the intercostal nerves, pain may be caused; of the vagus, vomiting; and of the sympathetic, inequality of the pupils and unilateral sweating. I remember well a very stubborn case of seeming intercostal neuralgia in my own practice which turned out to be caused by aneurysm of the descending aorta, confirmed by autopsy.

Then, there is the *tracheal tugging* of aneurysm first described by Surgeon-Major Oliver, and further studied by Ross and McDonnell, in Canada.<sup>1</sup> It is generally indorsed by English clinicians as a valuable sign, while Fränkel, from the German side, confirms the importance of this symptom.<sup>2</sup> This is a dragging downward of the larynx with each systole of the heart. In Ewart's method the patient sits with his mouth closed, his head well bent backward, steadied against the chest of the examiner, standing behind him. The trachea is drawn up gently by inserting the ends of the fingers under the edge of the cricoid cartilage, when with each impulse the larynx is felt to be pulled downward. Oliver directs, with the patient in the upright position, the mouth closed, and chin elevated, grasping the cricoid cartilage between the fingers and the thumb pressing it steadily upward, when, if aneurysm exists, the pulsation of the aorta will be distinctly felt. It is said that it may be the sole sign of aneurysm, and a sign, also, that the position of the aneurysm is such as to involve the posterior aspect of the arch—4 in Fig. 64. It should be a distinct tug downward, as light degrees of tracheal tugging are found in healthy persons. Cardarelli's sign of *lateral* movement of the larynx is similar, with an obvious difference. It is said never to be present in aneurysm of the innominate.

J. N. Hall called attention<sup>3</sup> to a sign of aneurysm not previously described, which he calls *tracheal shock*, consisting in a distinct sharp impulse, diastolic in time, transmitted through the aneurysm *to the trachea just after the tracheal tug*, when the latter is present.

*Alteration in the pulse* in distal arteries is also a sign of considerable diagnostic value. The pulse-beat may be simply delayed as compared with the heart-beat. This is the natural result of the intervening sac which may receive temporarily a considerable amount of the blood required to produce the pulse wave. Or the pulse in one radial may be smaller than that in the other. It is chiefly when the aneurysm involves the origin of blood-vessels leading to the radials, as the innominate on the right and the carotid or subclavian on the left. If the right radial pulse is enfeebled or delayed, the aneurysm will be on the right, involving the origin of the

<sup>3</sup>"Tracheal diastolic Shock in the Diagnosis of Aortic Aneurysm," "Amer. Journ. of the Medical Sciences," vol. cxix., 1900, p. 10.

innominate; if the left radial is influenced, the aneurysm is probably in the neighborhood of the left subclavian. Great care should be taken in the examination, and it should be made from the center to the periphery—that is, the carotids, the subclavians, the brachials, and the radials should be successively examined, as recommended by Sansom. These effects are variously produced. Thus, the aneurysm may narrow or distort the orifice of the blood-vessel by traction on it; or there may be atheromatous change in the branch vessel analogous to that in the aorta itself, which may cause narrowing of the orifice, while the possibility of this, in the absence of aneurysm, is also to be remembered; or the aneurysmal sac may act as the elastic air-chamber in a pump, diminishing thus the pulsatile force in the vessel and branches beyond. It is particularly in the arteries of the lower extremities, by aneurysm of the descending thoracic and abdominal aorta, that this air-chamber effect is seen, and the pulse, even in the abdominal aorta and its branches, has been thus obliterated by a large thoracic aneurysm. *Capillary pulse* is occasionally present, and is probably favored by the recoil of the blood into the aneurysmal sac.

*Pressure of the aneurysm on a bronchus* may lead to retention of secretion and fetid bronchitis and bronchiectasis, and favor the inoculation of tubercular phthisis, thus accounting for the frequent association of tuberculosis of the lungs and aneurysm.

*Spitting of blood* is an occasional symptom, which may be the forerunner of larger and more dangerous hemorrhage.

Still rarer is pressure on the thoracic duct, causing emaciation. Though this symptom is more frequently due to mediastinal tumor.

*Physical Signs.*—*Inspection* does not always discover changes, but if the sac grows outwardly, sooner or later a swelling makes its appearance, to the right of the sternum if in the ascending limb, possibly raising a rib or the end of the clavicle; above and behind the sternum if in the transverse portion, raising the manubrium or boring its way through it; and to the left of the sternum if in the descending limb of the arch. As the tumor protrudes, the skin becomes smooth, shining, and tense over it, and may become gangrenous previous to rupture. Such a tumor may pulsate or not. The aneurysm is, as it were, a rudimental heart, dilating in all directions with every jet of blood that is shot into it, and contracting on the withdrawal of the intravascular pressure so long as any elasticity remains. Should this property be lost, either as the result of calcification or the lining of the sac with successive layers of coagulum, such dilatation becomes impossible, and pulsation does not occur. The pulsation is, however, of great importance to the diagnosis. When present, it is synchronous with the systole of the ventricles. The heart itself is sometimes displaced downward, as seen from the lowering of the apex sometimes as low as the sixth interspace and outside the mammillary line. Less frequent is hypertrophy of the left ventricle, and when present, not so extreme as in aortic valve disease.

If the aneurysmal tumor press upon the great veins of the neck, there may be venous engorgement and edema on one side of the neck or both, according as the innominate vein of one side only is compressed or the descending cava itself. The aneurysm may rarely rupture into the descend-

ing cava, resulting in a form of varicose aneurysm, producing, in addition to the ordinary signs of aneurysm, sudden distention of the veins in the upper half of the body, edema of the face, hands, and arms, cyanosis, systolic venous pulse, and purring thrill.

*Palpation* also recognizes the impulse of the aneurysm if it is visible, and sometimes when it is not visible. This beating is peculiar, being *expansile*, and differs thus from the rising of a tumor over a pulsating blood-vessel. Sometimes there is a double beat, the second and weaker being the usual recoil following closure of the aortic valves. A *thrill* is also often felt, a vibration in the walls of the sac caused by the whirl of the blood in it. It is by no means, however, invariable, and it may come and go. Very great *tenderness* is sometimes present over the seat of the protruding aneurysm. Palpation may also recognize the "diastolic shock," or recoil blow of the aneurysm on the closed aortic valve, if this be competent—to be again referred to.

*Percussion* over the swelling of an aneurysm invariably elicits impaired resonance, varying greatly in degree and extent. On the other hand, the adjacent lung may be compressed, producing an area of dullness beyond the tumor itself. The dullness is usually in the right upper intercostal spaces, especially if the aneurysm is in the ascending limb of the arch. Aneurysms in the transverse portion produce dullness in the middle line under the manubrium and toward the left of the sternum, while aneurysms of the descending part may produce dullness in the left interscapular and scapular regions posteriorly. Sometimes the impairment of resonance precedes the pulsation, though such dullness is of uncertain significance.

*Auscultation* is no exception, as compared with the other modes of physical investigation, as to the inconstancy of its information, sometimes furnishing the most distinctive signs, while at other times it is totally negative.

The murmur or bruit heard over an aneurysm varies. Sometimes but one murmur is produced—systolic, corresponding with the first sound over the ventricles, but more intense; more rarely it is diastolic only. Not infrequently there is a combined or double murmur, both systolic and diastolic, the first intense and prolonged, the second fainter and shorter. It varies greatly, being sometimes rough, sometimes soft, and sometimes musical. The murmur is not infrequently absent. The mechanism of these sounds is not settled. The systolic is the most easily explained. There can be little doubt that it is produced by the inequalities which meet the entrance of the blood into the sac. The diastolic murmur, when the aneurysm is at the beginning of the aorta, will probably be an aortic regurgitant murmur, due to relative insufficiency of the aortic valve. When the aneurysm is distant from the aortic orifice, the diastolic murmur may be due to the recoil of the distended sac, propelling the blood through the outlet with additional force, or the whirling of the blood through the sac. Rarely in these distant situations there is a diastolic murmur only, probably thus caused.

A much more constant symptom is an accentuated aortic second sound, which is, in fact, rarely absent in aneurysm of the arch where the aortic valves are intact and which constitutes the so-called *diastolic shock*. It is an exaggeration of the second sound, recognizable by the ear and due to

the elastic recoil of the aneurysmal sac. "It is the shock of the second sound that is heard and the recoil is felt." It is not always present, and requires a sound aortic valve to produce it in its most marked degree. Sir Douglas Powell holds that it is best studied with the wooden stethoscope, and that the binaural fails to observe it. Ernest Sansom considers it best investigated by the ear direct, with only a slight intervening chest covering. It may be accompanied by or replaced by the diastolic murmur referred to. It is rarely, if ever, present with mediastinal growths, even when they perforate the sternum and produce pulsation.

Occasionally a peculiar *whiffing interruption of the breath-sounds* may be heard by the stethoscope or ear placed near the open mouth, due to the expansile pulsation of the aneurysm. Similarly caused is *Drummond's sign*, produced by having the patient take a full inspiration and allowing the air to pass out slowly through one nostril, the other being compressed by the finger, while the clinician listens with the stethoscope over the manubrium. *Perez's sign* is a creaking sound heard when auscultating over the sternum when the patient raises and lowers the arm. It is caused by traction on adhesions, which may have formed in the anterior mediastinum in cases of aneurysm of the first and second parts of the aorta. *Glasgow's sign* is a systolic thud audible by the stethoscope in the brachial or similar large artery like that heard in aortic regurgitation. *Scheele's sign* is a momentary disappearance of the systolic murmur, accompanied by severe pain, produced by pressing over the crural arteries of the two sides. It is an experiment not altogether without danger, as death occurred in one instance on practicing it. Enlargement of the tumor mass may also arise by the pressure on the crurals.<sup>1</sup>

But any one or all of these signs may be wanting. Particularly is this the case where the aneurysm occurs just after the aorta has left the heart. The most valuable is the pulsation distinct and separate from that of the heart, or, as graphically put by Da Costa, "what is more essential is to find two points of pulsation in the chest—two hearts, apparently each with its own distinct beat, its own distinct sounds."<sup>2</sup>

The X-ray has been brought to bear on the diagnosis of aneurysm, and commonly a distinct demonstration of the tumor can be made, both by the fluoroscope and skiagraphy, but it is scarcely available to the practicing physician, because of the costliness of the apparatus.

Is it possible to determine the portion of the aorta involved by aneurysm? Yes, with a certain degree of probability:

In aneurysm of the ASCENDING AORTA there is more apt to be pain like that of angina pectoris, dyspnea, dullness to the *right* of the manubrium sterni from the second intercostal space upward, pulsation in the same region, displacement of the heart downward and to the left, delayed pulse in the peripheral arteries as contrasted with the heart's impulse, compression symptoms involving the sympathetic and the area of the superior cava, pressure upon the pulmonary artery producing a pulmonic systolic murmur, with hypertrophy and dilatation of the right ventricle if the aneurysm compress the pulmonary artery.

<sup>2</sup> Da Costa, "Medical Diagnosis," eighth ed., 1895, p. 507.

Aneurysm of the TRANSVERSE PART OF THE ARCH furnishes more particularly pulsation in the *fossa jugularis*; tracheal tug; dullness on percussion over the manubrium and to its *left* in the first intercostal space; narrowing of the orifices of the innominate, the left carotid, or left subclavian, and resulting inequality of the pulse in the head and arm; pressure on the *left* innominate vein, with resulting congestion and edema of the *left* half of the neck and head. It is when in this situation that aneurysm compresses the left recurrent laryngeal nerve and causes paralysis of the left vocal cord, presses on the trachea, with resulting stridor and cough, and on the left bronchus, producing inspiratory dyspnea.

In aneurysm of the DESCENDING LIMB OF THE ARCH OF THE AORTA<sup>1</sup> we look for the pulsation behind to the left of the vertebral column opposite the angle of the scapula or below. The bruit is faint or absent. In the *thoracic aorta below the arch*, in consequence of the air-chamber effect, we may find smallness of the crural pulse as contrasted with the radial, and symptoms of pressure upon the left lower azygos or hemiazygos vein—*i. e.*, edema of the upper part of the abdomen and pleuritic effusion; also pressure on the esophagus and left bronchus. The intercostal nerves may be compressed, producing intense pain in the course of their distribution, the vertebral column may also be eroded, the spinal canal opened, and the cord compressed, with resulting paraplegia. If the aneurysm project forward, which is rarely the case, it may press upon and displace the heart, causing palpitation, or it may also compress the esophagus, causing painful deglutition. It sometimes ulcerates and breaks into the esophagus. Obscure symptoms of this variety of aneurysm may exist for a long time before a tumor shows itself posteriorly between the shoulders, which is unmistakable at this late stage.

Aneurysm of the ABDOMINAL AORTA furnishes a pulsating tumor to the left of the vertebral column, to the left and above the umbilicus. The bifurcation of the aorta takes place on the fourth lumbar vertebra, which point corresponds to the umbilicus. Sometimes a thrill may be felt and a systolic murmur heard, rarely a double murmur. Here, too, the smallness of the crural pulses, as contrasted with the heart's impulse and the radial pulse, may be observed, while in some cases the crural pulses disappear altogether. The symptoms vary somewhat, according as the aneurysm grows backward or toward the front. In backward pressure pain is also a striking symptom, and may be of two kinds, a fixed and constant pain in the back, caused by the pressure of the tumor on the solar plexus and splanchnic nerves, or a sharp lancinating pain radiating along the branches of the compressed lumbar nerves, whence pain in the loins, testes, hypogastrium, and in the lower limbs, usually on the left side. If the sac grows anteriorly, gastrointestinal symptoms may be present, such as vomiting, gastralgia, diarrhea, and even symptoms of obstruction of the bowel. Pain is also present, but is more likely to be fixed in the loins, epigastrium, or some part of the abdomen.

Erosion of the spine is much rarer in abdominal aneurysm than in

<sup>1</sup> The *descending part of the arch* of the aorta is somewhat arbitrarily terminated by anatomists at the lower end of the fifth dorsal vertebra, below which it is called the *descending thoracic aorta*, which terminates at the opening of the diaphragm in front of the last dorsal vertebra, below which it is the abdominal aorta. The symptoms of aneurysm of the descending part of the arch and the descending thoracic aorta do not differ widely.

thoracic. In emaciated persons the abdominal aorta sometimes pulsates so plainly that one is strongly reminded of aneurysm, and I have myself been misled by such pulsation, but under these circumstances there is absence of the systolic murmur and of the alterations in the pulse of the arteries of the lower extremity, and none of the pain described. Indeed, evident abdominal pulsation occurs far more frequently without aneurysm than with it.

ANEURYSM OF THE BRANCHES OF THE ABDOMINAL AORTA.—Of these, aneurysm of the *celiac axis* is most often mentioned and diagnosed, though not always correctly. The symptoms may be said to be a pulsating epigastric tumor, associated with pain in the same neighborhood, and often with vomiting. The pain and vomiting may precede the pulsation and tumor by some months. These aneurysms are sometimes traumatic, and have been referred to railroad accidents in which sudden and powerful compression has been exerted upon the abdomen. As intimated, their diagnosis is not always easy. Two illustrative cases have come to my knowledge. In one, an aneurysm diagnosed as being of the celiac axis was at the autopsy proved to be in the abdominal aorta. In another case of supposed aneurysm the celiac axis was excluded, and the necropsy disclosed an aneurysm of that vessel.

Aneurysm of the SPLENIC ARTERY is sometimes met. Ten cases were collected by Lebert out of 39 involving various branches of the abdominal aorta. Osler reports, in his book, one in a patient aged 30. The aneurysm was as large as a cocoanut, and was found at autopsy between the stomach above and the transverse colon below. The sac contained densely laminated fibrin and had perforated the colon. The symptoms were a deep-seated tumor in the left hypochondriac region, with dullness, which merged into that of the spleen. There was no pulsation, but a bruit was *thought* once to have been heard. The symptoms were vomiting, epigastric pain, occasional hematemesis, and, finally, hemorrhage from the bowels.

Aneurysm of the HEPATIC ARTERY is a rare lesion, some ten or twelve cases having been recorded. These aneurysms are not usually large, while the liver has been found greatly enlarged.

Aneurysms of the SUPERIOR MESENTERIC ARTERY have been found at necropsies.

Aneurysms of the RENAL ARTERY are more numerous. They are generally small, but may terminate in rupture and retroperitoneal hemorrhage.

Aneurysm of the INNOMINATE is especially indicated by its murmur, thrill, and impulse in the vicinity of the inner end of the right clavicle, which is sometimes raised by the resulting tumor; also by the comparative absence of signs of pressure on the larynx or esophagus. The differences in the right radial pulse alluded to are especially present here. Compression of the right subclavian and right carotid diminishes the force of the beat of the innominate aneurysm, but is without effect in aortic aneurysm. Nor are there percussion signs of enlargement of the aorta.

If the SUBCLAVIAN is involved, the signs are further outward, on the outer side of the sterno-cleido-mastoid, while in aneurysm of the innominate they are found on the inner or tracheal side. To those named may be

added symptoms of pressure upon the subclavian vein, producing swelling of the arm and neck; upon the right recurrent laryngeal, producing defective speech and dyspnea; on the sympathetic, producing contraction of the pupil, and on the brachial plexus of nerves, pain. Especially would these signs point to aneurysm of the subclavian if the pulse of the carotids is uninfluenced while the right or left radial pulse is influenced.

The very rare condition of aneurysm of the PULMONARY ARTERY may produce a swelling, with the other local symptoms described, to the left of the sternum, in the second interspace. A murmur is less constant and is not conducted into the vessels of the neck, while the superficial pressure signs are more conspicuous. There is lividity of the face, with dropsy, and the dyspnea is naturally very great. There is no cough or voice alteration. It is to be remembered, however, that the swelling of an aneurysm of the arch of the aorta *may* extend to the left of the sternum. Such an aortic aneurysm may break into the pulmonary artery.

An aneurysm of the HEART is not recognizable, though it may be suspected if there is bulging succeeding signs of fibroid disease of the organ.

**Differential Diagnosis of Aneurysm of the Arch.**—Further diagnosis distinguishes aneurysm of the aorta mainly from *mediastinal tumor*. There may be the same percussion signs, though percussion dullness is usually more irregular in mediastinal tumor. There is often similar pain; there may also be pulsation, but instead of the expansile pulsation extending in all directions, it is more upheaving. Murmurs are not usual in the mediastinal tumor. The ringing, or accentuated second sound—diastolic shock—which may be present in aneurysm when the aortic valves are intact, or substituted by the diastolic murmur when the valves are incompetent, is absent in mediastinal tumor. Tracheal tugging does not occur in mediastinal tumor, nor do differences in the pulse or changes in the voice. The state of the blood-vessels usually associated with aneurysm must be ascertained. Fever is often present in mediastinal tumor; very rarely in aneurysm. A differential diagnosis is often impossible, and experts have held opposite opinions on the same case. Should the patient develop a cachectic state and secondary glandular enlargements appear, presumption is in favor of mediastinal disease.

Allusion was made on p. 682 to Schnell's sign produced by the compression exerted by the expansile pulsation of an adjacent aneurysm of the descending aorta on a rubber sound introduced into the esophagus. A like effect may be caused by a mediastinal tumor pressing the aorta against the esophagus. But the murmur of the rushing blood in the suddenly dilated aorta is said to be quite different from that produced in the suddenly narrowed aorta. This difference may be recognized by a microphone brought in connection with the esophageal sound and thus a differential diagnosis between the two conditions facilitated.<sup>1</sup>

The resemblance of some of the symptoms of aneurysm of the ascending aorta to some of those of *aortic incompetency* is very close. The same pulsating aorta, the same double basic murmur with impaired resonance at the right of the sternum, may be present. I have seen a case diagnosed as aortic regurgitation with stenosis, in which the autopsy disclosed perfect

<sup>1</sup>"Münchener medicinische Wochenschrift," No. 35, Aug. 27, 1889.

semilunar valves with, however, aneurysm and relative insufficiency, which caused the diastolic murmur. In aneurysm there is less hypertrophy of the heart than in aortic valvular disease. The age of the patient, if under 40, especially the history of heart disease in early life, the history of rheumatism, and the absence of the causes of atheromatous vessels, point to valvular disease. Though there may be pulsation at the root of the neck in both, in aortic incompetency the same strong pulse-beat extends to the wrists. Traube's double sound in the femorals and popliteals, though possibly otherwise caused, is still more frequently associated with aortic incompetency than any other lesion. Simple dilatation may, indeed, be present in aortic incompetency, but the pressure signs are wanting.

A *pulsating empyema* on either side of the upper sternum sometimes closely resembles a pulsating aneurysm, and the illusion is more complete because the pulsation is expansile. I well remember a case in which the pulsation to the left of the sternum was so like that of an aneurysm that I hesitated to use the exploring needle. Pulsating empyemas are generally further to the left of the sternum than aneurysmal pulsation. Other signs of aneurysm are also wanting, unless it be tenderness, which may be present. A rare condition is a *narrowing of the aorta* below the remains of the ductus arteriosus at the junction of the arch with the thoracic aorta, which produces small delayed pulse in the femorals, a thrill and murmur over the upper part of the sternum, but the extraordinary enlargement of the collateral vessels, especially the mammary and epigastric arteries, should set the question at rest.

How shall the symptoms, which also so much resemble those of a *laryngitis*, be recognized as due to aneurysm instead of the latter affection in the absence of the physical signs of aneurysm?

In acute laryngitis we have often the cause—exposure to cold—to help us, though in the chronic form we have not. In laryngitis there is usually more huskiness and less stridor in the voice, nor is the cough so brassy, or the voice so uniformly changed; it is more likely to alternate with normal voice. In aneurysm the voice grows progressively weak until aphonia results. The dyspnea in aneurysm is more often attended with wheezing, and is sometimes relieved for a time by coughing. Stokes called attention to the fact that in aneurysm the stridor of the voice seems to come from the notch of the sternum, rather than from the larynx itself. In aneurysm the breathing sounds are more likely to differ in the two lungs. Then we have the laryngoscopic picture. There is no swelling of the cords in aneurysm, while there may be the paralytic phenomena detailed. Finally, in laryngitis there may be fever.

**Prognosis.**—Aneurysm is not infrequently found at necropsy without having been suspected. In other cases the fatal termination is the first notification of its presence. When an aneurysm of the aorta is so developed as to exhibit its usual signs plainly, it is sooner or later fatal in some one of the modes already described. To foretell in which of the directions pointed out perforation will occur depends upon the accuracy with which diagnosis of its position can be made, and such diagnosis is at best a matter of probability. Only in cases in which aneurysm slowly erodes the anterior wall of the chest is there a gradual termination. Then there are sometimes

repeated small hemorrhages, which gradually reduce the strength of the patient, who finally dies of exhaustion or of an ultimately fatal large hemorrhage. Perforation into the vena cava, pulmonary artery, and right side of the heart is a rare termination. The course of the disease may, however, be prolonged many months, and if treatment is instituted early, it may contribute to such prolongation. When death does not occur from sudden hemorrhage, the symptoms may assume the type of chronic heart disease, for which, indeed, the condition is sometimes mistaken by the untrained observer. With failing heart come dyspnea, palpitation, dropsy, and death.

**Treatment.**—We seek in the treatment of aneurysm to *diminish intravascular pressure* and *restore the integrity of the vessel*. The former may be accomplished in a degree by placing the patient under conditions which will avert the causes of such increased intravascular pressure, which is constantly cooperating with the disease of the artery to produce further dilatation and ultimate rupture of the blood-vessel. This is, of course, best accomplished by absolute rest. It is plain the less frequently the heart beats and throws the weight of its blood against the weak blood-vessel, the longer will that blood-vessel last, while it is known to every student that the heart beats less frequently in the sitting than in the standing posture, and less in the recumbent than in the sitting position. On the other hand, it is evident that absolute rest is an impossibility. Yet it may be approximated in various degrees. It is impossible also to restore the integrity of the vessel, but to this end also measures are suggested which have for their immediate purpose coagulation of the blood in the vessel and obliteration of the sac. That this sometimes occurs numerous autopsies also attest.

The method which has met most favor is that now known as Tufnell's treatment, though Valsalva originally suggested a restricted diet and practiced frequent venesections. Bellingham advised starvation without bleeding. It was, however, revived by the late T. Jolliffe Tufnell and modified by G. W. Balfour who added the iodid of potassium. Tufnell's treatment consists in absolute mental and physical rest in the recumbent position, together with a moderate dry diet. The object of this is to diminish the blood-pressure and volume of blood, to increase the proportion of fibrin in the latter, and to promote its coagulation. The diet is as follows:

For breakfast, two ounces of bread and butter and two ounces of milk; for dinner, two or three ounces of meat and three or four ounces of milk or claret; for supper, two ounces of bread and two ounces of milk. Thus it is hoped to diminish the blood volume and reduce the pressure within the sac, to render the blood more fibrinous and to favor coagulation. The proper dose of the iodid of potassium is 5 to 20 grains (0.33 to 1.3 gm.) three times a day. It is supposed to act by increasing secretions, thus thickening the blood. To its efficiency in this direction I may add my testimony. Balfour also claims that it lowers the blood pressure by promoting the flow of blood through the arterioles. Boehm, Prévost, Corin, Stockman, James Burnet and Rolleston deny that the iodids lower blood-pressure, though they admit that the drug is useful. It may be expected, also, that cases of syphilitic origin will be those especially benefited, but it is said that experience does not confirm such expectation. Occasional small bleedings amounting to a few ounces are said to contribute to a favorable

result including relief of pain. Evidences of improvement are reduction in the size of the tumor, diminished force of pulsation, and relief of pain. The Tufnell treatment should be kept up for several months, or as long as the patient will submit to it. It is said to be useful more particularly in saccular aneurysm communicating by a small orifice with the aorta. It is doubtful whether it is worth while to subject a patient with large aneurysm communicating with the aorta by a large orifice to the inconvenience of such a treatment, and whether it may not be better to advise him to live a life as quiet as possible and to await the inevitable, while we relieve symptoms as they arise, and remember especially that iodid of potassium is often one of the best remedies for pain.

Another remedy said to favor coagulation of blood in an aneurysm is chlorid of calcium of which 10 grains (0.66 gm.) may be given four times a day. Acupuncture as a means of securing coagulation and contraction of the clot was suggested by Velpeau. It consists in placing an iron wire or needle into the aneurysm with the hope that the blood will coagulate on it. Filling the aneurysm with *horseshair* or *fine wire* has been suggested for the same purpose. The wire is introduced through a hypodermic needle. Galvano-puncture, suggested by Loretta, furnishes perhaps the most satisfactory results. Two needles are introduced into the sac, and a mild current of electricity is passed through them. In this way a combined electrolytic and mechanical effect is obtained. The introduction of astringent substances, as solution of acetate of lead or persulphate of iron, into the aneurysm may be mentioned only to be discouraged, since the danger of producing embolism far exceeds the chance of benefit. Ligation of the carotid or subclavian, or both, has also been done for aneurysm of the aorta with satisfactory results. It is, however, a formidable operation.

The latest method of inducing coagulation for the cure of aneurysm is by the subcutaneous injection of gelatin, suggested by Lancereaux.<sup>1</sup> Two hundred and fifty cubic centimeters of a solution of 2 grams of gelatin in 100 grams of saline solution are injected under the skin of the thigh. This is renewed at varying intervals from every two to 15 days. It has been claimed that, as a rule, 10, 15, or 20 injections produce complete cure. They act by increasing the coagulability of the blood. Recently, Professor Shoycesco, of Bucharest, reported<sup>2</sup> six cases treated in this way with good results in five cases. On the other hand, Osler treated ten cases at Johns Hopkins Hospital without a single cure.

No other internal treatment for aneurysm other than that suggested—by iodid of potassium—has ever been of any use. As a part of the medicinal treatment of thoracic aneurysm it should be added that where there is violent action of the heart, *cardiac sedatives* are sometimes indicated to allay this, in addition, of course, to the enjoined rest. Among these sedatives we include aconite and veratrum viride in extreme cases, also cold to the seat of the swelling and to the cardiac region.

The treatment of *peripheral aneurysm*, as of the popliteal and femoral, is usually relegated to the surgeon, who will treat it by ligation or compression. The *injection of ergotin* in the vicinity of the aneurysm, as suggested by Langenbeck, may be tried. From two to five grains (0.132 to 0.33 gm.)

<sup>1</sup> "The Lancet," October 22, 1899.

<sup>2</sup> "Journal de Médecine Interne," July 1, 1899.

of the aqueous extract dissolved in water or glycerin are injected every two days. Tufnell's method is also applied to peripheral aneurysm, for which indeed, it was originally recommended.

The treatment of peripheral aneurysm by *compression* has long been an acknowledged method for the purpose, and though looked upon as a surgical procedure, is as medical as it is surgical. The method adopted which has been most successful is digital compression, which is exerted by relays of students or others available for the purpose. The effect is that in the course of 48 hours coagulation has taken place and the aneurysm is cured. Failing in these measures, ligation is practiced in case of the smaller arteries, but all details of this operation belong to the province of surgery.

## SECTION V.

### DISEASES OF THE BLOOD AND BLOOD-MAKING ORGANS.

#### DISEASES OF THE BLOOD.

##### THE MINUTE STRUCTURE OF THE BLOOD.

An accurate knowledge of the histology of the blood has become so important to an intelligent study of its diseases that a brief statement of its minute constitution seems justified. It is more especially since the practice of staining blood preparations has come into use that our present more intimate knowledge has been acquired.

The *red blood disk* needs these aids least, but it is nevertheless a more interesting object thus studied. Thus, when stained with a solution of orange G, contained in the Ehrlich triple stain, it assumes a beautiful yellow or pale-orange color. With Wright's modification of Leishman's stain the hemoglobin becomes pink or yellow, according to amount of discoloration by water.<sup>1</sup> By means of these stains the expert observer may even measure a diminution in the amount of hemoglobin, indicated by a diminished intensity of the central coloring. Only in high degrees of loss of hemoglobin do the edges of the cell become paler. Eosin solutions stain the red disk a brilliant red. (See F in plate opposite p. 712.) The average number of red disks in a cubic millimeter in the male is 5,000,000, in the adult female 4,500,000; previous to menstruation, the number is somewhat larger.

The *blood-plaques*, though a constituent of normal blood, are not rendered visible by Ehrlich's stain. With Wright's stain they are colored dark purple or red and Wright claims they may be so stained as to be recognizable in sections of fixed tissues and organs. They are small bodies generally

<sup>1</sup>The student is referred to works on diagnosis for technical methods, but it may not be amiss to add directions for making and using Ehrlich's triple stain. The formula is as follows:

Saturated aqueous solution orange G, . . . . .	120-135 c.c.
Saturated aqueous solution acid fuchsin, . . . . .	80-105 c.c.
Saturated aqueous solution methyl-green, . . . . .	125 c.c.

Add—	
Water, . . . . .	300 c.c.
Absolute alcohol, . . . . .	200 c.c.
Glycerin, . . . . .	100 c.c.

Or the colors previously mixed, constituting the Ehrlich-Biondi or Ehrlich-Biondi-Heidenheim powder, may be used as follows:

Ehrlich-Biondi powder, . . . . .	1.70 gm.
Acid fuchsin, . . . . .	0.05 gm.
Absolute alcohol, . . . . .	2.00 c.c.
Distilled water, . . . . .	18.00 c.c.

*To Stain.*—After cleansing the finger thoroughly with soap and water and alcohol, it is pricked with a clean needle and a clean cover-slip touched to the blood as it flows from the puncture. Drop this cover-slip on another, draw the two apart and dry in the air. At any time within a few days fix by heating at 230° F. (110° C.) for ten minutes, or by placing in absolute alcohol or alcohol and ether. Then place for four minutes in the Ehrlich tricolor mixture. Dry and mount.

Ehrlich's method has been largely superseded by Wright's modification of Leishman's stain. It is done as follows:

1. Drop on the blood film with a medicine dropper as much of the stain as it will hold without spilling and leave it there one minute, the object being chiefly to fix the film.
2. Add to the fluid on the cover-glass or slide sufficient water, drop by drop, to make visible a greenish metallic scum on the surface. For a 7/8 in. square cover-glass 6 to 8 drops are usually needed. Let the stain thus diluted remain for about two minutes on the film.
3. Wash the film by running water and let stand in water for one or two minutes more or until the thinner portions of the film are yellowish pink. Water washes out part of the blue dye and differentiates the stain.
4. Dry cautiously with blotting- or filter-paper and mount in balsam. The whole process should not consume more than five minutes. This stain also answers well for malarial parasites and basophilic granules of red cells and all the purposes of a blood stain.

circular in outline, of variable diameter, but usually smaller than a red blood-cell. A striking feature is the presence in the center of each plate of an aggregation of more or less closely packed granules forming at times a sharply defined opaque homogenous mass suggesting a nucleus. Wright holds that they are detached portions of the cytoplasm of those giant cells of the bone-marrow and spleen named megakaryocytes to distinguish them from the multinuclear giant cells of the marrow, the so-called osteoclasts or polykaryocytes. They are readily demonstrated unstained by placing a drop of fresh blood at the edge of a cover-glass laid on a slide, whence the blood is drawn in by capillary attraction.

*Fibrin* is not stainable, but its delicate threads may be seen after a time in specimens prepared as directed.

It is the study of the *colorless corpuscle* which is most facilitated by the staining process. By it are differentiated first the different varieties of white cells. They include the following:

1. *The Small Lymphocyte* (C, plate opposite p. 712).—This consists of a greenish blue nucleus as stained by the acid fuchsin of Ehrlich's triple solution. With Wright's it assumes a deep purplish blue. It is about as large as a red disk, surrounded by a thin, slightly stained, scarcely visible or even invisible ring of protoplasm. The small lymphocyte is from 5 to 10 micromillimeters in diameter.

2. *The Large Lymphocyte or Large Mononuclear Cell* (B, plate, Fig. 1).—This presents the same characters as the small lymphocyte, but is larger and paler. Both nucleus and protoplasm have increased in size, but the former more than the latter. The protoplasm continues free of granules, as a rule, but fine and pale granules may be brought out by intense basic stain like methylene-blue. Between the small and large lymphocyte are intermediate forms. These cells have a common origin and represent different stages of development. It was formerly erroneously supposed that the large mononuclear cell arose from the spleen and the small one from the lymph glands. The large lymphocyte may have a diameter of 13 to 15 micromillimeters. Both large and small cells sometimes show a disposition to division of the nucleus.

3. *Transitional Leukocytes* (B. Plate, Fig. 2, at right).—These differ from the large mononuclear cells only in the fact that the nucleus is indented or horseshoe-shaped, and are a still more mature cell than the large lymphocyte. Its protoplasm is like that of the large mononuclear leukocyte, but neutrophilic. The protoplasm of the three varieties described is therefore quite similar.

4. *Polymorphonuclear or Polynuclear Cells*.—These include three subdivisions:

- (a) *Polymorphonuclear Neutrophiles* (B, plate opposite p. 705).—These are regarded as matured leukocytes. They make up the majority of the white cells of the blood and of pus. They are large, possessed of an irregular nucleus, often bent or twisted into fantastic shapes, which stain a light blue in Ehrlich's tricolor fluid. With Wright's stain the nucleus takes an intense navy-blue color. Different parts of the nucleus are variously distinct, according to the distance of such parts from the surface, and thus the impression of a polynuclear cell is often produced, though a multiple

The total mean number of leukocytes in health is about 8000 per cubic millimeter.

*Cell Forms Rarely or not at all Found in Normal Blood.*—(a) *Myelocytes.*—The *myelocyte* of Ehrlich, or *marrow cell*; Cornil's "*cellules medullaires*" (A, Fig. 1, plate opposite p. 705).—Certain large leukocytes twice or three times as large as a red blood-disk and corresponding in all respects to the large granular cells of the bone-marrow are thus named. They are the variety of leukocyte most numerous in the bone-marrow, in which lymphocytes, polymorphonuclear cells, as well as eosinophiles, are also found. Their protoplasmic granules are commonly neutrophilic, but occasionally eosinophilic. They are recognizable only by the Ehrlich staining methods. The nucleus stains pale in the Ehrlich-Biondi stain, is large, single, at times smooth, at others irregular, and sometimes showing a tendency to degeneration. Smaller cells exhibiting all the characteristic features of true myelocytes are sometimes met associated with the large variety. Myelocytes resemble the large lymphocytes, differing, however, in the presence of granules. They differ also from the polymorphonuclear cells only in the shape of the nucleus. They may be an intermediate stage between the large lymphocytes and polymorphonuclear cells. Their granules are usually exactly like those of the latter, although at times these granules are also eosinophilic.<sup>1</sup> Rarely if at all found in normal blood, these cells are numerous in certain varieties of leukemia and occur also in pernicious anemia and in some infectious diseases. There is every reason to believe they are the cells originally described by Cornil as "*cellules medullaires*."

Degenerate forms of leukocytes are found in leukemia and occasionally in other conditions.

The commonest forms of degenerated leukocytes are thus described by Cabot.

1. "A homogeneously stained mass looking like a washed-out, structureless nucleus that has lost its protoplasm and become ragged at the edges (karyolysis).

2. "The same intensely stained.

3. "Vacuolization of the nucleus or of the protoplasm.

All these forms of degeneration affect chiefly the lymphocytes and large mononuclear forms. In the granular leukocytes we see all stages of breaking up; the granules are scattered about the field and the nucleus is pale, structureless, and deformed."

(b) *Nucleated Red Corpuscles* (D, plate opposite p. 712).—These are red cells possessed of a nucleus. They are usually divided into three classes: (a) *Normoblasts*, about the size of a normal red corpuscle; (b) *megalo-blasts*, large and irregular cells; (c) *microblasts*, very small cells, smaller than a normal corpuscle. These cells are variously regarded as regenerate and degenerate. The *normoblast*, representing an immature red corpuscle, is found normally in the bone-marrow, or "nursery" of red cells whence it may pass out prematurely before it has expelled its nucleus. Its nucleus stains deep blue, almost black with the Ehrlich-Biondi fluid. The nucleus is sometimes nearly or wholly separated into two parts. The cell is

<sup>1</sup> There is always a wide variation in the staining affinities of different granules, some assuming a much deeper color than others.

found in severe anemias, occasionally in large numbers. The *megaloblast* is very large, with a large nucleus, staining pale green or a robin's-egg blue with Ehrlich-Biondi fluid, and some shade of blue with Wright's stain while the protoplasm often stains abnormally (polychromatophilia). It is found nowhere in the normal adult body, but it does occur in *fetal* marrow and in grave forms of anemia along with the normoblast. Ehrlich regarded it as degenerate, and the normoblast regenerate. The *microblast* is still smaller than the normoblast. It is variously regarded as degenerate and as a younger normoblast. Its nucleus is like that of the normoblast. It is found in the blood in anemias. Irregular or atypical forms are also met. The smaller forms of nucleated cells appear in the earlier stages of anemia, the megaloblasts and irregular forms in the more advanced stages.

Muller's<sup>1</sup> "*blood dust*" (hemoconien) is the latest discovered constituent of normal and pathological blood. It consists of small, round colorless granules resembling the smallest fat drops, about  $\frac{1}{4}$  to one micromillimeter in diameter, highly refracting and characterized by molecular movement. According to Stokes and Weyforth<sup>2</sup> they may be the extruded granules of neutrophilic and eosinophilic leukocytes.

### THE ANEMIAS.

Broadly defined, anemia means "bad blood." It is further subdivided into *local* and *general*. The former is known also as *ischemia*. Its special consideration requires but brief treatment in a text-book of medicine. It is illustrated by the pallor of the fainting person, and by that interesting disease known as Raynaud's disease, which will be considered with diseases of the nervous system.

By *general anemia* is meant any state of the blood in which there is a diminution of its total bulk, its red corpuscles, its hemoglobin—any one or all of these. The first is the condition which ensues from a large hemorrhage of any kind, as from the rupturing of an aneurysm, erosion of a blood-vessel, such as sometimes happens in ulcer of the stomach or in tuberculosis of the lung, or from a blood-vessel wounded in any way. In all instances, however, where the hemorrhage is not fatal the original bulk of the blood is rapidly restored by the absorption of water and salts from the tissues, while the hemoglobin and albumin remain deficient until they can be restored by suitable nourishment. Practically, therefore, anemias resolve themselves for study into conditions in which there is a reduction in the amount of hemoglobin through a diminution in the total number of red corpuscles or in the proportion of coloring-matter in each corpuscle, or both.

Anemias are further divided into *primary* or *essential*, and *secondary* anemias. The former, strictly speaking, should include only those which are the direct result of a defect in the blood-making apparatus, while secondary anemias are those due to loss of blood, or some one of its important constituents, or from a defective supply of blood-making material. Richard C. Cabot defines primary anemia as an anemia "in which the causal factors

<sup>1</sup>"Centralblatt f. allg. Path.," viii., 1896.

<sup>2</sup>"Johns Hopkins Hospital Bulletin," December, 1897.

are entirely unknown or are insufficient to cause so severe a disease." That such a definition has some foundation will appear from the facts to be adduced as our study proceeds.

Among primary anemias are commonly included chlorosis, pernicious anemia, leukocythemia, lymphatic anemia or Hodgkin's disease, and splenic anemia. It is not conceded by all observers that pernicious anemia is the result of a defect in blood-making. In fact, each year adds more evidence to show that the conclusion of Quinke and William Hunter that it is a hemolysis, or disintegration of the red blood-corpuscles in the circulation or certain parts of it, especially in the liver, is the correct one. Particularly noteworthy are the studies of J. P. C. Griffith and C. W. Burr,<sup>1</sup> favoring such view. As the chain of evidence is not, however, complete, I shall for the present consider it among the essential anemias.

The secondary anemias are numerous, including those due to hemorrhage and other drains of various kinds on the economy, inadequate food, and defects in the digestive apparatus; also those due to the action of poisons on the blood—the toxanemias, including lead-poisoning and uremia.

## SECONDARY OR SYMPTOMATIC ANEMIA—SIMPLE ANEMIA

This form of anemia is the direct result of trauma, accidental hemorrhage, chronic disease, or toxic agents. I may again refer to the fact mentioned in the preliminary remarks on the anemias, that reasons are being found to show that some, at least, of the so-called essential anemias may be due to agencies tending to destroy the corpuscles, rather than to disease of the blood-making apparatus. The secondary anemias include:

1. *Anemias Due to Hemorrhage, however caused.*—Traumatic hemorrhage, post-partum hemorrhage, lung hemorrhage, and gastric and intestinal hemorrhages comprise most of these; ruptured aneurysms, purpura, and the bleeding habit furnish others. Parasites invading the intestinal canal may be causes of hemorrhage and consequent anemia. So may parasites elsewhere, as the *distoma hæmatobium* in the kidney.

In nonfatal hemorrhages from these causes the immediate loss of blood in bulk is rapidly made up by the absorption of water from the gastrointestinal tract, but a long time is required, even under favorable circumstances, before the corpuscles and hemoglobin are restored. At other times regeneration is quite rapid, restoration being complete in ten days. The hemoglobin is always rather more reduced than the corpuscles, but both increase for a time *pari passu*, as shown in the appended chart. The albuminous constituents are more rapidly restored.

2. *Anemias Due to the Drain of Chronic Disease.*—Such are chronic Bright's disease, suppurative processes, cancer, or prolonged lactation, or chronic diarrhea. In this group belong the anemias of acute malaria, in which the corpuscle is directly consumed by the plasmodium.

3. *Anemia from Inanition.*—This results from starvation, which may be the practical consequence of diseases which interfere with the successful ingestion and assimilation of food, such as obstruction of the esophagus

<sup>1</sup> "Pathology of Pernicious Anemia," "Transactions of the Association of American Physicians," vol. vi., 1891.

by cancer or otherwise, or chronic and prolonged dyspepsia. Carcinoma of the stomach may also be included in this group. The last two groups (2 and 3) overlap.

4. *Toxic Anemias*.—Finally, there remain the toxic anemias. These are the result of the presence in the blood of such substances as lead, acquired by painters or workers in lead-paint factories, type-setters, and type-founders; also arsenic from dress fabrics, wallpaper, and furniture coverings; mercury, and certain disease poisons, among which that of chronic malaria is the most conspicuous. The same is true of other infec-

cases. Yet a total reliance dare not be placed on it, for it sometimes happens that the skin and even the lips are pale, and yet no anemia is found when the blood is examined. On the other hand, the skin and lips may have a good color, and yet anemia be actually present. Weakness, faintness, vertigo and palpitation are also symptoms.

In addition to these are the blood changes, which vary with the degree of anemia. Both corpuscles and hemoglobin are reduced, not always *pari passu*, the hemoglobin commonly in somewhat larger proportion. The disproportionate lowering of the hemoglobin is explained by a more than natural paleness of the red corpuscles. Their average size is reduced, while there is also a moderate poikilocytosis. Nucleated red corpuscles also make their appearance soon after a hemorrhage. The normoblasts and microblasts are the prevailing forms. They exhibit, after staining with hematoxylin, a deep-blue nucleus, while free nuclei are occasionally found. Microcytes, megalocytes, and poikilocytes are present in advanced cases.

The colorless corpuscles are moderately increased, such increase being represented by the multinuclear neutrophiles, while the small mononuclear lymphocytes are diminished. The leukocytosis gradually disappears with the return of the blood to its normal state. The presence of leukocytes as well as of the nucleated red corpuscles is evidence of regenerative activity. The proportion of the different varieties is nearly normal. In severe cases the lymphocytes may be in excess and the polymorphous leukocytes be reduced. Myelocytes are exceptionally present.

**Diagnosis.**—In addition to the blood changes more or less common to all of these causes of anemia, the same general symptoms of pallor, lassitude, debility, and faintness which characterize the essential anemias are also present in less degree.

While a feature of simple anemia is the nearly coequal reduction of the hemoglobin and corpuscles this is not true of all forms. Thus in lead-poisoning, as a rule, the hemoglobin is reduced in larger proportion than the red cells, resembling in this respect chlorotic anemia. Lead-poisoning is further characterized by a higher grade of leukocytosis than the other forms of symptomatic anemia. The history of the case in the presence of one of the causes named is of itself sufficient to determine the diagnosis in many cases. The simple anemias are not always, however, sudden or rapid in their occurrence, and a study of the blood is often necessary to clear up a doubtful case.

**Treatment.**—The treatment of simple anemia is eminently satisfactory. The administration of nourishing food with rest is followed by a very rapid coequal rise in the hemoglobin and corpuscles, as is beautifully shown in the foregoing chart (Fig. 65) made from one of my cases in the Philadelphia Hospital. And when to the treatment by nourishing food we add the use of iron, there is nothing more to be desired. Full doses of iron are well borne in these cases, and we have the choice of almost any of the preparations, including Bland's pills of the carbonate, reduced iron, tincture of the chlorid, Basham's mixture, and the vegetable salts. Though full doses are here indicated, it is still unnecessary to give the massive doses recommended by some, as they are not absorbed and produce constipation. The rapidity of the cure in some of these is surprising.

## THE PRIMARY OR ESSENTIAL ANEMIAS.

These include chlorosis, *for the present* pernicious anemia, leukocythemia, lymphatic anemia, or Hodgkin's disease, or pseudoleukemia, and splenic anemia.

## I. CHLOROSIS.

SYNONYMS.—*Morbus virginicus; Green Sickness; Chloremia; Chloranemia.*

**Definition.**—An essential anemia most frequently met in young women, characterized by a very marked relative reduction in the hemoglobin of the blood.

**Etiology.**—As stated in the definition, it is a disease of women, and especially of young women. Yet its occurrence is not impossible in men having the habits and occupations of women, among whom Hermann Eichhorst especially instances tailors. Moreover, while it is especially a disease of young women from about the age of puberty to 24 years, it is also possible in those who are older, as well as those who are younger. In the former it is known as *chlorosis tarda*, and as such is met in women between 30 and 40. Rather more frequent is its occurrence in children who have not reached the age of puberty. Niemeyer held that girls who menstruated at 13 or 14, in whom there was, as yet, no development of pubes or breasts, most invariably become chlorotic. The disease occurs the world over, and is apt to be recurrent in the same individual. It is more common in blondes than in brunettes, in the weak and delicate, rather than the strong and vigorous. Yet this general truth is not without exception.

Among predisposing causes are overwork, especially in closely confined and ill-ventilated rooms, insufficient nourishment, exhausting drains, such as prolonged lactation and profuse menstruation. Menstrual derangement is, however, also a consequence as well as a cause. Sustained or repeated emotion, especially such as arise from sexual excitement and masturbation, is a cause. Homesickness and grief are included among causes.

The frequent association of constipation with chlorosis led Sir Andrew Clark to suggest that it might really be a copremia, or poisoned blood due to absorption from the large bowel of poisons of the nature of ptomains and leukomains. Such poisons may readily interfere with the proper development of the hemoglobin of the blood-disk, without in a great degree causing its destruction. Similar is the hypothesis of Bunge that intestinal putrefaction due to imperfect stomach digestion is the cause of chlorosis, through sulphur generated in fermentations interfering with the digestion and assimilation of iron. These views explain what seems to me a closer relation between chlorosis and pernicious anemia than has commonly been admitted, a relation consistent with the newer etiology of pernicious anemia, as well as with features in its clinical course, and with the results of treatment, to which attention will be called when considering the latter affection.

**Morbid Anatomy.**—Other than the changes in the blood, to be considered under symptoms, there is no essential morbid anatomy in chlorosis.

Many years ago Virchow pointed out an imperfect development of the circulatory apparatus as more or less characteristic—that the heart was small, the right ventricle sometimes dilated, the aorta and its larger branches were poorly developed and thin-walled. Such a condition, when present, is probably an accidental coincidence. There is no enlargement of the spleen or lymphatic glands. Imperfect development of the uterus and other genitalia has been noticed. The rarity of fatal termination in chlorosis may limit our knowledge of the morbid anatomy, uncertain at best.

**Symptoms.**—Of these, the *blood changes* may be regarded as fundamental, though not absolutely constant. They consist in a decided reduction in the hemoglobin, with a moderate reduction in the size and number of the red corpuscles—microcytosis and oligocythemia. Thus, the hemoglobin value of each red disk is diminished. The usual range may be put at from 3,500,000 to little less than normal. Thus, Thayer, in 63 consecutive cases in Osler's clinic, found the average 4,096,544, or over 80 per cent., and Lembeck found the maximum in one of 15 cases to be but 3,600,000. In a few instances, however, in cases of acknowledged chlorosis, there has been found a more decided reduction in the erythrocytes. One has been reported in which they were reduced as low as 1,190,000 in a cubic millimeter.

The hemoglobin, on the other hand, is much reduced, the average of Thayer's cases referred to being 42.3 per cent., which may be regarded as a fair average. This disproportionate fall in the hemoglobin, while not invariable, remains, however, a tolerably constant feature, producing sometimes a recognizable diminished intensity of color when the blood is seen *en masse*. Along with the lowering of hemoglobin the iron of the blood falls, as would be expected, since it is a constituent of the hemoglobin.

An increase of alkalescence, announced by Graeber<sup>1</sup> as a constant symptom, has not been found by Kraus<sup>2</sup> in his more exact methods of testing. Increased coagulability of the blood has been observed.

As to remaining changes, the red corpuscles may be *undersized*. This may be said to be a more or less characteristic change and with the diminished coloring-matter may be the only change. The red disks are sometimes appreciably paler than in health. They may be larger than in health (megalocytes). They may be altered in shape, constituting a small degree of poikilocytosis, a term suggested by Quincke. A very *slight* degree of *leukocytosis* may be rarely present, an average of 8467 in Thayer's counts, as contrasted with a mean normal of 6000 in the cubic millimeter, while the *blood plaques* in severe cases may also be increased. *Nucleated red corpuscles* are sometimes met, especially in the later stages, represented by the smaller forms (microblasts) which sometimes appear in crops. In this stage the corpuscles may assume irregular shapes. Myelocytes have rarely been met.

While the blood alterations in chlorosis are scarcely distinctive enough to be considered diagnostic, the *other symptoms* help greatly to the formation of a correct conclusion. The patient is almost invariably a girl, generally between 16 and 20, who, although she may have been over-worked, does not seem badly nourished; certainly she is not emaciated.

<sup>1</sup>"Zur. klin. Diagnostik d. Blutkrankheiten," Leipsic, 1888.

<sup>2</sup>"Zeitschrift f. Heilkunde," Bd. ii.

There is often derangement of menstruation, and sometimes the girl is hysterical.

Most striking, though not invariable, is a peculiar pallor, often exhibiting a yellowish-green tinge, extending to the lips, and especially the mucous membranes, and which is responsible for one of the names of the affection—*green sickness*. The patient is extremely weak, especially on

Red Corpuscles—Black.

Hemoglobin—Red.

Colorless Corpuscles—Blue.

FIG. 66.—Blood in Chlorosis.

exertion, and short of breath. She is subject to vertigo, palpitation of the heart, and even irregularity of the heart's action. Physical examination will sometimes discover functional cardiac murmurs; also a systolic murmur at the apex, ascribed by Balfour to a relative insufficiency of the mitral valve due to dilatation of the left ventricle. Rarely, a compensatory hypertrophy of the left ventricle has been noticed, but never actual valvular

disease. Sometimes a *bruit de diable*, or humming-top murmur, may be heard over the right jugular. Epigastric pain is also a symptom at times. It must not be forgotten that a chlorosis late in life, or *chlorosis tarda*, does sometimes occur. Fever is not rarely present. On the other hand, the hands and feet are often cold.

**Diagnosis.**—The diagnosis is based chiefly upon the age and sex of the patient, the peculiar greenish-yellow color, the paleness of the lips, and the decidedly diminished hemoglobin, unaccompanied, as a rule, with a proportionate reduction in the number of erythrocytes. The same lost normal ratio between the hemoglobin and the corpuscles is also a characteristic of *lead-poisoning*, which has, however, superadded its own characteristic symptoms, and is almost restricted to adult males.

The epigastric pain mentioned as occurring in chlorosis resembles that more common in *ulcer of the stomach*. The anemia which so constantly attends ulcer of the stomach, often in a high degree, is, however, different from that of chlorosis, there being a corresponding decline in the number of the erythrocytes and their coloring-matter. At least, the reduction is not so widely disproportionate as in chlorosis. Subacidity of the gastric juice is not as common in chlorosis as was at one time supposed, nor is there motor deficiency. This aid to diagnosis is therefore wanting.

A not infrequent error of diagnosis in connection with chlorosis is the mistaking of it for a "decline," a *pulmonary consumption*, which it resembles in the pallor, the feebleness, and shortness of breath of the patient. The absence of emaciation, of cough, and of the physical signs of consumption exclude that disease. On the other hand, evidences of tuberculosis should always be sought where the symptoms of chlorosis prevail. Latent *cancer* is also sometimes responsible for similar symptoms.

Most frequently chlorosis is confounded with *secondary anemia*, and with reason. Close observation will recognize in chlorosis the yellowish tinge of the skin and mucous membranes, while the sclerotic coat remains white or bluish. The most constant difference is in the reduction of hemoglobin, which is disproportionately large in chlorosis. Leukocytosis is less frequent in chlorosis; so are nucleated red cells. In advanced degrees of chlorosis the blood approaches nearer that of *pernicious anemia*, in which, however, the blood coagulates more slowly. The question whether a chlorosis will be transformed into that more serious variety of anemia known as pernicious anemia has been raised. This seems not impossible. If the view of Sir Andrew Clark be accepted, that chlorosis may result from the absorption of poisonous substances from the larger bowel, and if pernicious anemia be due to the absorption of more intense poisons from the small intestine, the difference is only one of degree. Both are characterized by defects in the cellular constituents of the blood. In the one, chlorosis, the coloring-matter is chiefly wanting, although associated with this is usually found a small degree of morphological defect. In pernicious anemia both cell-shapes and coloring-matter are defective. In both diseases the oxygen-carrying office of the blood is interfered with, and thus important vital processes are embarrassed, the total suspension of which must be fatal.

**Prognosis.**—The prognosis is nearly always favorable when the disease is recognized and the proper treatment instituted. There are few results

more satisfactory in therapeutics than those of a properly treated case of chlorosis. Time is, however, necessary, and too rapid a cure must not be promised, several months and even longer being sometimes required.

**Treatment.**—The treatment is preeminently by iron, and it matters not very much what preparation is used. The tincture of the chlorid well diluted is probably the most easily assimilable, but the carbonate, in the shape of Blaud's pill, made by a double decomposition between the carbonate of potassium and the sulphate of iron, maintains its popularity, 1 to 5 grains (0.06 to 0.2 gm.) being given at a dose three times a day. Much larger doses are sometimes given, as much as 45 grains (3 gms.) a day. I repeat that iron is given in too large doses in the majority of cases for which it is prescribed. Most of it is unabsorbed, and therefore wasted. Nay, worse, that which is unabsorbed locks up the intestinal secretions by its astringency, produces headache, and makes the patient otherwise uncomfortable. But chlorosis is one of the few diseases in which large doses of iron are well borne. The reason is plain. It is the iron-holding constituent of the blood which is wanting, and the iron is needed to replace it. The blood is, as it were, hungry for it. Reduced iron or one of the vegetable salts of iron may be given. Next to iron comes arsenic. The efficiency of iron is greatly aided by union with arsenic, which should be given in increasing doses, but short of toxic effect.

Hydrochloric acid in full doses, originally suggested by Zander on the ground of supposed deficiency of this acid in the digestive fluid in chlorosis, is useful also in promoting the solubility of iron, as well as for its tonic and antiseptic properties.

But to give these drugs alone is not sufficient. *Rest* in bed, at first continuous, is imperative to secure a rapid result, and this must be associated with an abundance of good food. Daily massage, except during menstruation, is also a useful adjuvant. There is no condition in which the so-called "rest cure" is more efficient than in chlorosis. With a return of color to the lips, or, better, with the growing increase in the hemoglobin as measured by the hemoglobinometer, the patient should be permitted to be out of bed at first from a half-hour to an hour only, but this should be gradually increased until she is up most of the day. For a long time, however, fatigue should be avoided. To those who can afford it, a residence at the seaside materially aids convalescence. Indeed, I know of no condition so rapidly improved at the proper time by sea air as chlorosis. To the poor, a well-regulated hospital treatment is a boon for which there is scarcely a substitute.

## II. PROGRESSIVE PERNICIOUS ANEMIA.

SYNONYMS.—*Idiopathic Anemia; Pernicious Anemia.*

A second variety of essential anemia is *pernicious* or idiopathic anemia, originally described by Addison in 1855 in his celebrated paper on "Diseases of the Suprarenal Capsules." Interest in the subject was revived by Biermer in 1868, and since then it has been thoroughly studied anatomically and clinically. It is, however, still the least understood of all the anemias.

**Definition.**—Pernicious anemia is an anemia in which the red corpuscles and hemoglobin are both reduced, the former in larger proportion, so that the hemoglobin appears in relative excess.

*Aplastic anemia* is a grave form of pernicious anemia characterized by a rapidly fatal course, and an "aplastic" bone-marrow, by which is meant a bone marrow lacking development, and which is pale yellow instead of dark red as in pernicious anemia.<sup>1</sup>

**Etiology.**—The etiology of pernicious anemia is very obscure. Evidence is accumulating in favor of a toxic hemolytic origin, the toxins being the result of some one of the associated conditions. Pregnancy seems to be in some way responsible for a certain number of cases. Such a condition, associated with the puerperal state and with functional disease of the uterus, was first described by Walter Channing<sup>2</sup> in 1842. The symptoms described by him are evidently those of pernicious anemia, though he called the condition simply "anemia." A. Gusserow<sup>3</sup> published, in 1871, a

FIG. 67.—Liver Lobules in a Case of Pernicious Anemia, Showing Distribution of Iron Pigment—(after Griffith and Burr).

number of cases in pregnant women. It has also followed lactation. Other causes are cited, such as atrophy of the stomach, early noted by Flint and Fenwick, profound and long-continued gastrointestinal disease, and intestinal parasites, especially the *anchylostomum duodenale* and *bothriocephalus latus*, which undoubtedly produce symptoms clinically indistinguishable from the general anemia which Addison characterized as "occurring without any discoverable cause whatever—cases in which there had been no previous loss of blood, no exhausting diarrhea, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous, or malignant disease." I have already expressed my partiality toward the view of Quincke and others, who ascribe the state of the blood to a hemolysis, in proof of which they point to the enormous accumulation of iron in the liver noted by Quincke in 1876 and confirmed by Rosenstein in 1877. To these, William Hunter added a pathological increase of the urobilin in the urine.

<sup>1</sup> For an admirable paper by R. S. Lavenson on "The Nature of Aplastic Anemia and its Relations to Other Anemias," see "American Jour. of Med. Sciences," Jan., 1907.

<sup>2</sup> "New England Quarterly Jour. of Medicine and Surgery," Boston, 1842-43.

<sup>3</sup> "Ueber hochgradigste Anämie bei Schwangerer," "Archiv für Gynäkologie," Berlin, 1871.

In a noteworthy paper, Griffith and Burr take the same view.<sup>1</sup> Figs. 67 and 68 are from Griffith and Burr's paper, and show the deposit of iron in the liver cells demonstrated by ferrocyamid of potassium. Such a hemolysis is most satisfactorily explained on the supposition of absorption from the intestine or elsewhere of poisonous products engendered under any of the circumstances named. Among these may be included the products of imperfect digestion, such as may be expected to arise when there is atrophy of the gastric tubules.

The disease is widespread, and not rare in this country. It affects mostly those past middle age, but children also have it, and Griffith mentions ten cases occurring under 12. It is more frequent in males.

**Symptoms.**—The approach of pernicious anemia is most insidious, beginning with a gradual *progressive weakness*. What is first interpreted

FIG. 68.—Cells from Liver in Pernicious Anemia, More Highly Magnified, Showing Position of the Iron Pigment within them—(after Griffith and Burr).

as a causeless weariness or languor grows slowly into an extreme debility, with faintness on the slightest exertion, and thence into a state of thorough muscular weakness, which ultimately prostrates the patient, and he is too weak to rise from bed. To this succeeds a state of mental hebetude and bodily torpor. *Yet there is no emaciation.* The body bulk is well preserved. The skin acquires gradually a *lemon-yellow* hue, and sometimes an actual jaundice, whence the disease has been mistaken for the slower form of yellow atrophy of the liver, a mistake not altogether unsustained by other symptoms. In fact, the jaundice is similarly caused. It is probably a hemato-genous jaundice, a matter of blood disintegration, although it has also been ascribed to defective cell action on the part of the liver. The mucous membranes, on the other hand, are blanched, as may be noticed in the lips, gums, and mouth.

<sup>1</sup>*Loc. cit.*

*Cardiovascular symptoms* are especially conspicuous in progressive pernicious anemia. Heemic murmurs, visibly pulsating and throbbing arteries, even pulsating veins, have been noticed. The large, but soft, jerky pulse, resembling that of aortic regurgitation, was mentioned by Addison. The capillary pulse is also frequently seen, and hemorrhages, cutaneous and retinal, occur.

*Digestive derangements* form an important part of the symptomatology of pernicious anemia. Indisposition to take food or, rather, a disgust for food, nausea, vomiting, and diarrhea are often troublesome symptoms. Sore mouth and sore tongue are often present. *Hydrochloric acid* is constantly deficient in gastric digestion (achylia gastrica). *Moderate* elevation of *temperature*, irregular and intermittent, is also noticed, while *nervous symptoms*, including numbness, languor, and even paralysis, are some-

FIG. 69.—Blood in Pernicious Anemia.

times present. Paresthesia is especially emphasized as an early symptom, even the earliest.

The *urine* exhibits no constant changes, being sometimes pale and sometimes dark-hued. The dark color is ascribed by Mott and Hunter to an excess of urobilin.

*Blood Changes.*—The changes in the blood are more distinctive than in chlorosis, although it is true also that there is no single constant characteristic feature. It may be pale and watery. The most constant feature is a very decided oligocythemia, without a corresponding reduction in the hemoglobin, *in toto*, is much reduced. Rarely it has been found increased. Quincke found as few as 143,000 corpuscles in a cubic millimeter of blood, while it is not uncommon to find less than half a million. Frederick P. Henry found 315,000 a few hours before death,

and Laache 360,000. In a case under my own care at the Philadelphia Hospital, in 1898, the red disks fell to 437,000, and the hemoglobin to nine per cent., death taking place two days after the count was made. The inevitable conclusion from the average of cases observed is that either the hemoglobin value of each corpuscle must be increased, or there is a hemoglobinemia, which has its seat in the plasma. This latter view Silbermann has adopted, because he has been able to produce, by the administration of blood-corpuscle-dissolving substance, as pyrogallol, to animals, a complex of symptoms like those of pernicious anemia. If pernicious anemia be a hemolysis, as seems likely, rather than a defective hematogenesis, we would expect such a hemoglobinemia to result.

The changes in the red cells point preeminently to degeneration of these bodies. Among these changes is an *increase in the size of the red corpuscles*. They become *megalocytes*, from ten to fifteen micromillimeters in diameter, as compared with a normal of from 6.5 to 9.4. The majority may be so enlarged. They are often also ovoid in form. Their abundant presence marks severity in the disease, but they are not essential to diagnosis. On the other hand, there are also *microcytes*—cells smaller than normal—and *poikilocytes*—corpuscles characterized by great irregularity in shape. While these irregular shapes were first demonstrated in connection with pernicious anemia, and although they are more or less characteristic, cases of the disease have been described by Grainger Stewart, Lepine, Hermann Müller, and others, in which poikilocytosis was altogether absent. Neither megalocytosis, microcytosis, nor poikilocytosis is therefore a pathognomonic feature. *Polychromatophilia*.—A condition in which the erythrocytes stain irregularly and unevenly is always present and accompanies the enlargement of the cell. Basic granulation or granular degeneration of the red cell, a variety of polychromatophilia, is very frequent.

*Nucleated red corpuscles* are a constant constituent of the blood of pernicious anemia, and have also been regarded by their discoverer, Ehrlich, as almost pathognomonic. Two kinds are found—first, the small, normal-sized corpuscle with its deeply stained nucleus (normoblasts), and certain large forms with pale nuclei (megaloblasts). They are not confined to this disease. Blood plaques are either absent or very scanty. Karyokinesis is rarely found in these larger cells, but when present in connection with the other changes it is regarded by some as almost pathognomonic. *Leukocytes* are usually slightly diminished in number due to a decrease in the polymorphonuclear leukocytes, while there is a tendency to an increase of the mononuclear white cells, as compared with health. F. P. Henry<sup>1</sup> has called attention to a fact which condenses the peculiarities of the blood changes, by saying that in this disease the red corpuscles "approach those of the lower animals in many, if not all, of their chief characteristics—namely, in their number, their size, their shape, and the amount of hemoglobin they carry."

There are also sometimes found in the blood numerous minute highly colored spherical bodies, called *Eichhorst's corpuscles*. Eichhorst regarded them as pathognomonic, but they, too, are sometimes absent. When present they contribute to the hemoglobin in the blood, but as they are not

BONE MARROWS.—1. Normal. 2. Typical progressive pernicious anemia. 3. Scattered areas of megaloblastic degeneration in progressive pernicious anemia. 4. Aplastic anemia —(From Lvenson's paper on *Aplastic Anemia* *Transac. Assoc. American Physicians*, vol. xxi, 1906.)

(To face page 711)

included in the blood-count, they get no credit for their effect. The relative excess of the hemoglobin may, in a measure, be thus accounted for.

**Morbid Anatomy.**—Various tissues have been studied in the effort to find a morbid anatomy for pernicious anemia. In the absence of lymphatic involvement or enlargement of the spleen, except sometimes in small degree, the *marrow of bones* has claimed close study. H. C. Wood described the red condition of the marrow of long bones in 1871. It was further studied in this country by William Pepper<sup>1</sup> and myself,<sup>2</sup> and abroad especially by Cohnheim.<sup>3</sup>

Although the appearances described by these observers are not identical, they are sufficiently constant to justify their association as more than accidental. *Summed up*, they amount to this: Marrow dark red; consistence less soft; fat vesicles absent; specific lymphoid cells increased, including marrow cells of various sizes, containing one or more nuclei; numerous nucleated red corpuscles present, especially the larger forms, the giganto-blasts of Ehrlich. These studies were made before the days of differential staining and counting. More recent studies add neutrophiles and eosinophiles. These appearances are now commonly interpreted as due to an effort of the blood-making apparatus to reproduce the disintegrated erythrocytes. They are not, however, constant, as the marrow is sometimes pale or yellow. It is a compensatory process, an irregular attempt at regeneration as contrasted with "aplastic."

The appended illustrations from Lavenson's paper shows well the contrast between normal and diseased bone-marrow.

The deposition of *iron in the liver cells* has already been alluded to. It is found in the outer and middle zones of the lobules, and may be so distributed as to outline the bile capillaries. It is regarded by Hunter as characteristic. I have myself examined the preparations of Griffith and Burr, and they are striking and seem unmistakable. The liver itself is often fatty and is sometimes enlarged. The iron is, in like manner, sometimes increased in the kidney, and spleen, and these organs are not otherwise essentially changed, though the spleen has been found reduced in size.

The *heart muscle* is fatty, while the other muscles are unusually red. Other *morbid changes* are described, but they cannot be regarded as essential. Such are changes in the ganglion cells of the sympathetic, and sclerosis of the posterior columns of the cord, first studied by Lichtheim.<sup>4</sup> Softening of the upper part of the lumbar cord has also been reported by Sir Dyce Duckworth.<sup>5</sup> While the associated changes in the posterior columns are so constant that they cannot be regarded as accidental, experimental studies by Burr and Griffith intended to determine this relation to pernicious anemia resulted in nothing definite. Complete atrophy of the secreting tubules of the *stomach* has been described by Fenwick, and by William Osler and F. P. Henry in one case studied jointly by them.

**Diagnosis.**—The diagnosis of pernicious anemia may be uncertain at

<sup>1</sup> "Progressive Pernicious Anemia," "American Journal of the Medical Sciences," October, 1895.

<sup>4</sup> "Congress für innere Medicin," 1887.

<sup>5</sup> "British Medical Journal," November 10, 1900.

first, but the true nature of the disease soon declares itself. The intense anemia, extreme weakness, digestive derangements, and cardiovascular symptoms, in connection with blood-count of 1,000,000 or below, with a relative increase, or at least no proportionate diminution, in the hemoglobin, and an admixture of megalocytes, microcytes, and poikilocytes, point to a condition scarcely mistakable. It may be said, moreover, that almost never in the case of a pernicious anemia do the number of corpuscles fail to fall below 1,000,000. The large forms of nucleated red corpuscles have been regarded as characteristic, but are also found in leukemia (see also diagnosis of Cancer of the Stomach, p. 398).

**Prognosis.**—The prognosis is to-day regarded as less unfavorable than it was a few years ago, since recent experience has developed the fact that temporary improvement is not uncommon, and it is said that recovery sometimes takes place. Still, Addison's original prognosis, of a termination sooner or later fatal, is seldom astray.

**Treatment.**—Treatment of this form of anemia is, moreover, not fruitless. The same measures which are almost a specific for chlorosis are not without effect in pernicious anemia. Accordingly, arsenic, to a less degree iron, good food, and favorable hygienic surroundings, are to be adopted. The arsenic treatment has been followed by results which justify the words "temporary cure," and it is said that permanent cure has followed. Such temporary cures have covered a period of three years. The best preparation appears to be Fowler's solution, in gradually increasing doses, until 20 and even 30 minims (1.3 to 2 c.c.) are reached, and this three times a day. It should be continued for a long time, for weeks or months, with intermissions of a few days if unpleasant results appear, to be again resumed. Arsenic is not a specific for pernicious anemia, but the results of its use are often surprisingly gratifying. Cakodylate of sodium has been recommended as less irritating than other preparations of arsenic, being suitable also for hypodermic use. The dose is  $\frac{1}{2}$  a grain (0.033 gm.), three times a day. Atoxyl is still another preparation of arsenic given in doses of  $\frac{1}{3}$  to  $\frac{1}{2}$  grain (0.022 to 0.033 gm.) hypodermically every other day. Inhalation of oxygen has also been recommended, as advised in leukemia. The relation between chlorosis and pernicious anemia, already referred to, is sustained by therapeutic results. Certain cases of chlorosis very closely resemble pernicious anemia, especially when not arrested by treatment. The arsenic, administered as directed, is wonderfully well borne, nausea and vomiting being rare. Rest in bed is indispensable, but should be supplemented with massage, if possible. Food should be in easily assimilable shape, such as beef-juice, beef-peptonoids, and peptonized milk. Pernicious anemia is one of the diseases in which much was expected from the use of *bone-marrow*, originally suggested by Thomas R. Fraser.<sup>1</sup> Fraser used 3 ounces (90 gm.) daily of beef-marrow, in addition to iron and arsenic, with apparent cure. At the present day the glycerids are used in doses of  $\frac{1}{2}$  an ounce (15 c.c.), three times a day. I have had some experience with it, but my results have not been very encouraging. Salol has been suggested as an intesti-

nal antiseptic, from the standpoint that the disease may be due to toxins absorbed from that canal. From the same point of view lavage of the large bowel through an opening into the cecum has been tried using peroxid of hydrogen and solutions of permanganate of potash. Recently, too, William Hunter has suggested the use of antistreptococcus serum to counteract possible general infection.

Transfusion of blood and of milk, which seemed at one time to give promise of favorable results, has been discontinued. At the present day, hypodermoclysis would probably answer the same purpose, and is much easier done.

### III. LEUKEMIA.

**Definition.**—A disease characterized by an enormous increase in the colorless corpuscles of the blood, by hyperplastic changes in the spleen, in the lymphatic glands, or bone-marrow, any one or more of these.

Pure splenic leukemias scarcely exist; pure lymphatic varieties are not very rare. Myelogenous leukemias were long denied, but their occasional occurrence is now admitted. Mixed splenic and medullary leukemias are the most common—called *lieno-medullary* or *lieno-myelogenic*.

The disease has been called *leukocythemia* as well as *leukemia*, the former of these words meaning white-cell blood, the latter simply white blood. From the etymological and histological standpoint, *leukocythemia*, suggested by Hughes Bennett, is the more accurate term, but Virchow's term, *leukemia*, has become the one in common use.

**Historical.**—The history of the development of our knowledge of leukemia possesses unusual interest. The older observers spoke of a purulent blood ascribed to an inflammation of this tissue, while Piorry and Rokitansky spoke of a hematitis as the cause of a literal pyemia. Craigie undoubtedly saw a case of the disease in Edinburg in 1841. He did not, however, publish the case until John Hughes-Bennett published his on October 1, 1845, in the "Edinburgh Monthly Journal of Medicine." Both Craigie and Bennett noted enlargement of the spleen. Rudolph Virchow published his case in Froriep's "*Notizen*" in the second or third week of November, 1845. The matter of priority between Bennett and Virchow has given rise to much discussion. There can be no doubt that Bennett's case was published first; also that he declared it unconnected with inflammation of any of the tissues, and especially unconnected with phlebitis, and that he attributed the condition to the development of white corpuscles in the blood. Craigie, on the other hand, ascribed it to the absorption of pus from an inflammatory lesion either in the mesenteric veins or the spleen. Virchow confirmed all the observations made by Bennett and published new cases, especially one of great importance, in which there was *enlargement of the lymphatic glands without enlargement of the spleen*. Virchow also said the blood changes consisted essentially in an increase of the colorless cells of the blood, and that these cells originated in the lymphatic glands. He also suggested the name *leukemia*, while Bennett did not suggest that of *leukocythemia* until 1851 in a series of papers, and again in 1852 in a separate work. It appears to me that Bennett is clearly entitled to priority, and was the first to interpret the condition as an increase in the colorless corpuscles of the blood, though he speaks of it as *pus*. Virchow's added point was ascribing the formation of the cells to the lymphatic glands.

Vogel first recognized a case during life in 1849. Virchow described two forms of the disease in his "Cellular Pathology," in one of which the smaller forms of leukocytes predominated and in which there was marked involvement of the lymph glands. In the second the larger white blood cells predominated, and there was marked enlargement of the spleen; hence he inferred that the lymphatic glands were at fault when the smaller cells predominated, and the spleen when larger cells prevailed. Varieties thus characterized do exist, but we dare not draw conclusions as to the organs involved as sharply as Virchow did. Large cells predominate in the *lieno-myelogenic* form, while small cells characterize the lymphatic variety. Inter-

mediate varieties, however, interfere with sharp distinctions. It was many years later that Neumann described a case in which the *bone-marrow* was markedly altered. Pure splenic forms scarcely exist, but a few myelogenic cases have been described. The pure *lymphatic form* does occur, but even this is rare. Most common is the mixed *lieno-myelogenous*. Seven cases of acute leukemia, in which more than the usual number of myelocytes were present, were published by Frank Billings, of Chicago, in 1903, under the title of acute myelogenous leukemia.

The extremely rapid course of certain cases of leukemia justifies its division into an *acute* and *chronic* form. Ebstein was the first to call attention to the acute forms reporting a fatal case in which the whole duration of the disease, including a prodromal stage, was but six weeks. Similar cases are reported by others.<sup>1</sup> Fraenkel collected all the cases to 1895, including ten of his own. M. H. Fussell<sup>2</sup> and A. E. Taylor collected 56 cases. Mina<sup>3</sup> in 1901, 69 cases. The duration of the chronic form may extend over years. Leukemic women have been repeatedly pregnant and have borne children at term.

Fraenkel concluded that all cases of acute leukemia are lymphatic in which the increase of white cells consists chiefly or almost exclusively of large or small lymphocytes. This statement has been apparently refuted by the authors just named to which must be added Frank Billings in the paper above mentioned (see history).

*Leukanemia* is a term applied by von Leube to a condition of combined leukemia and severe anemia. The disease lasts for from a few days to three months. It may begin suddenly with fever and severe tonsillitis to which are added weakness, hemorrhage, extreme pallor and rapid decline. There is often general glandular enlargement including the liver and spleen. The reduction of hemoglobin and erythrocytes with increase of lymphocytes usually the large form are conspicuous. The red cells may be as low as 1,500,000. The color index is high.

**Etiology.**—Nothing definite is known of the cause of leukemia. It occurs in all countries, in both sexes, and at all ages, although it is more common in middle life and in males. Cases have occurred in the eighth week and 70th year. It is sometimes hereditary, but leukemic women have borne nonleukemic children. It has succeeded upon exhausting illness. Malaria has been assigned as a cause, and certainly its association with this disease has been seemingly more than accidental. To a less degree this is true of syphilis. Pregnancy is said to favor it. It is said to have followed a blow or injury, and to have been found in the lower animals.

The idea of the infectious origin of leukemia, advanced by Klebs and supported by observations of Osterwold, Roux, Byrom Bramwell, Pawlowsky, Kelsch, Vaillard, and others, seems well founded, but no single microorganism has been found associated. A case has, however, been reported where an attendant on a case of leukemia contracted the disease and died. The frequent association of leukemia with stomatitis and intestinal ulceration was pointed out by Hunterberger.

**Morbid Anatomy.**—Leukemia has a definite morbid anatomy, consisting in alterations in the blood and in the hemogenic apparatus, including the spleen, the lymphatic glands, and the marrow of bones, and

<sup>1</sup>"Wiener klin. Wochenschrift," 1894.

<sup>2</sup>"American Medicine", March 5, 1904.

<sup>3</sup>"Wiener med. Rundschau", 1901, Nos. 37 and 38.

it is called, accordingly, splenic, lymphatic, myelogenic, while combined or mixed forms are indicated by suitable compound terms, such as lienomyelogenous. Most leukemias are mixed.

In the first place, the *spleen* is almost always enlarged. It may be adherent to the abdominal walls, the diaphragm, stomach, or other viscera. The splenic changes exhibit three stages in their development. In the first, the spleen is simply hyperemic, soft, and swollen, sometimes even ruptured. The Malpighian bodies share in the hyperemia, and may be slightly enlarged, but are overshadowed by the swollen pulp. In the second stage, hyperplastic changes make their appearance in the Malpighian bodies, and as these grow the pulp is intruded upon. They may reach such size as to be recognized by the naked eye as spherical gray nodules one to three lines in diameter, or they may be elongated or forked following the course of the blood-vessels. The third stage furnishes the granitic spleen, in which white dots are separated by dark streaks representing the destroyed pulp, pigmented by the disintegrated blood. The spleen is now hard, and is cut with resistance. Its size may be enormous, and the organ may weigh from two to 18 pounds (1 to 9 kilos.). It does not attain as large size in acute leukemia as in chronic, being palpable in but 65 per cent. of cases.

The *lymphatic enlargement* is a true hyperplasia. Not only do the glands enlarge, but new foci of lymphatic tissue appear in various organs, as the liver and kidneys. These are regarded by some as simple extravasations of leukemic blood from the capillaries. All the more prominent groups may share in the enlargement—the cervical, axillary, inguinal, and perineal glands. The individual glands remain, however, soft. The lymphatic follicles in the tonsils and in the tongue, pharynx, and mouth may enlarge. This is also occasionally the case with the solitary glands of the intestine and the agminated glands of Peyer.

The *marrow changes* may be described, in a word, as reversion to the embryonal type of medullary tissue. The fat of the adult marrow has disappeared, and a mass of lymph cells mingled with nucleated red corpuscles in all stages of development takes its place. The marrow is often *pyoid*. The lymph cells include numerous large mononuclear cells, many in the act of division, also multinuclear leukocytes. There are also numerous marrow-cells or myelocytes and eosinophiles, like those found in the blood.

The *liver* is often enlarged, and, according to von Jaksch,<sup>1</sup> *pari passu* with the spleen, and it has this further peculiarity, that its edges are rounded, while in what he describes as *pseudoleukemia infantum* the edges are sharp, and the enlargement does not go hand in hand with that of the spleen. The liver is also at times infiltrated with leukemic patches and nodules, not unlike miliary tubercles. The same is occasionally true of the kidney.

The thymus gland has been found enlarged in some cases of acute lymphatic leukemia, and even the skin, stomach, and gastrosplenic omentum have been the seat of growths, presumably lymphatic. In fact, there is no situation in which such growths may not make their appearance.

<sup>1</sup>See cases reported by J. Chalmers Camerson and Saenger, *Sajous*, "Annual" for 1891, E.

The possibility of their being blood extravasations, white in consequence of the large proportion of white cells, is always to be remembered.

The lungs and heart alone seem free from encroachment by the lymphatic tissue. The heart may, however, be dislocated by a large spleen.

The alterations in the *blood* constitute really a part of the morbid anatomy of leukemia, but are commonly treated under the head of symp-

FIG. 70.—The Blood in Leukemia.

tomatology, where I, too, will consider them. An increase in the mass of the blood may, however, here be mentioned. The heart and vessels are commonly found gorged with blood, usually coagulated, sometimes whitish or yellow in color.

**Symptoms.**—The early symptoms of leukemia are precisely those of the other anemias, viz.: *Insidious onset, pallor, rapid breathing amounting*

to *dyspnea* on exertion, *weakness* and *faintness*, *headache*, *indigestion*, and *loss of appetite*. The last two symptoms may precede all others. *Emaciation* is ultimately added. *Moderate fever*, with rapid pulse, is also present in the majority of cases, the temperature sometimes reaching  $103^{\circ}$  F. ( $39.4^{\circ}$  C.). Headache, more or less continuous, is a symptom. Enlargement of lymphatic glands or spleen or both are generally easily recognized. In a case recently under my care the first intimation of the presence of a *large spleen* was an attack of circumscribed *peritonitis*, favored, doubtless, by the presence of the splenic tumor and ascribed to exposure to cool air while perspiring. *Hemorrhages* from the nose and stomach are common, and dropsical swelling appears toward the close. *Nasal hemorrhages* are sometimes fatal. Thomas Oliver reported a case terminating fatally by sudden postperitoneal hemorrhage.<sup>1</sup> *Hematemesis* may be an early and almost initiatory fatal symptom. *Purpura hemorrhagica* sometimes presents itself as a manifestation of the same tendency, as may also cerebral hemorrhage, producing coma. *Priapism* is an occasional symptom; it is sometimes persistent, and in a case of Edes was the first symptom noticed.

The *urine* often contains a small quantity of albumin, is highly colored and scanty, and deposits a copious sediment of uric acid.

*Blood Changes*.—The blood exhibits a most marked and diagnostic change consisting in an *enormous leukocytosis*. The mean number in normal blood is about 8000 colorless corpuscles to the cubic millimeter, which, with the red disk at 4,500,000, makes the proportion 1 to 580; or with these at 5,000,000, to 1 to 625. There is a physiological leukocytosis which, after a full meal, may reach 1 to 150, and even 1 to 100, while there are pathological leukocytoses which quite equal those of many true leukemias. In leukemia, however, there may be 1 to 50, to 25, to 10, to 3, to 2, or the leukocytes may equal, and in rare cases even exceed, the red disks. The maximum proportion of colorless corpuscles impresses decidedly the color of the blood *en masse*, making it pink, or even the color of chocolate and milk, while aggregations of leukocytes may produce white streaks, and well justify the belief of the older pathologists that there was pus in the blood—a suppuration of the blood, as they called it.

There is also a reduction in the total number of blood-cells, including white and colored, the quantity in a cubic millimeter being sometimes reduced to between 2,000,000 and 3,000,000. This reduction may be even more positive, as in a case reported by Suchannek,<sup>2</sup> in which there were 301,600 red disks and 306,100 colorless corpuscles.

Numerous *nucleated red disks* are present, especially in the myeloid blood. Cabot says "the striking point is the presence of very numerous nucleated red cells even in the absence of any signs of anemia. With over 4,000,000 well-formed and well-colored red cells we may have hundreds of erythroblasts in every cover-glass. They are as numerous in this form of leukemia (myeloid) as in the worst forms of pernicious anemia, even though the patient be feeling very well." The hemoglobin falls below

<sup>1</sup>Sajous' "Annual" for 1890, vol. i., E, p. 12.

<sup>2</sup>Sajous' "Annual" for 1891, vol. ii., E, p. 18.

the normal proportion, so that the value of each disk is lowered. There is occasional poikilocytosis. The blood-plaques may be slightly increased. The beautiful plate opposite page 712 was made from the blood of a patient in the Hospital of the University of Pennsylvania. (See also Diagnosis.)

An early discovery in the study of leukemia was that of certain transparent octahedral crystals, known as Charcot's crystals, which form in blood which has been kept for some time on slides. Neumann referred these crystals to the bone-marrow, but they are commonly conceded to be the same as those sometimes found in the expectoration and in feces and in seminal fluid. There is reason to believe they are decomposition products, and that they hold no essential relation to leukemia.

That the alkalinity of the blood is sometimes diminished is true; that it is ever replaced by acidity is not true, as was at one time held. Its specific gravity is lowered to 1030 to 1050. Leukemic blood coagulates slowly, a feature which has been ascribed to the presence of albumoses.

*Chloroma*, formerly known as "green cancer" and regarded as belonging to the sarcomas, is a tumor-like hyperplasia of the parent cells of the leukocytes, primarily in the red marrow of bones, and secondary in the periosteum. It is now classed among the leukemias because it is the result of a leukoblastic hyperplasia resulting in the formation of atypical leukocytes or leukocytes corresponding to some one of the normal types. In certain cases the hyperplasia of the parent cells is such that the new forms do not get into the blood stream in such numbers as to give a picture of a leukemia. Chloroma differs from other forms of leukemia in its marked neoplastic type and in the green infiltrations and metastases. As a consequence of the diminution of red cell-formation and replacement of the erythrocytes by the hyperplastic white-cell product, the bone-marrow is paler in color and there results an intense anemia—an anemia of deficient hematopoiesis and not one of excessive hemolysis.

The blood picture is not, however, uniform. The etiology is unknown as is also the green color.<sup>1</sup> An infectious origin has been suggested.

**Diagnosis.**—The diagnosis of leukemia requires the aid of the microscope, but with it it becomes easy. (See Blood Changes.) A refinement of diagnosis, thus aided, attempts with partial success to separate the different varieties, which are known as simple or complex, according as one or more of the cytogenous organs are implicated. Most leukemias are, however, mixed. In his monograph Hermann Rieder says that, so far as he knows, *pure splenic* and *pure myelogenous* forms have never been observed, while the *pure lymphatic* form does occur.<sup>2</sup> As above shown, the occurrence of myelogenous leukemia can no longer be denied, several cases having been reported. On the other hand, Ehrlich prefers to call the most common form the splenomedullary, "myelogenous," because he thinks the spleen is purely passive.

<sup>1</sup>See an exhaustive paper, "Chloroma with Leukemia," by George Dock and Alfred Scott Warthin "Trans. Assoc. American Physicians," vol. xix., 1904.

<sup>2</sup>"Beiträge zur Kenntniss der Leukocytosis," von Hermann Rieder, 1892, S. 36. Recall Virchow's announcement in "Cellular Pathology," in 1849, alluded to on p. 644, last paragraph.

## I. White cells in lieno-medullary leukemia.

	Average.	Normal.
Lymphocytes, small and large,	10.6 p.c.	24 to 38
Polymorphonuclear (neutrophilic),	46	62 to 70
Myelocytes (neutrophilic),	20 to 60	none
Eosinophiles,	4	.5 to 4
Coarse granular basophilic or mast cells,	1 to 10	.25 to .5
Nucleated red disks,	numerous	none
Poikilocytes,	numerous	none

## II. Lymphatic leukemia.

Lymphocytes (all forms).	90	20 to 30
--------------------------	----	----------

I. For the present I shall retain the term *splénomedullary* or lieno-myelogenous for the most usual form. The spleen is very large, and the leukocytosis is intense, the ratio of white to red corpuscles being one to three, one to two, or one to one. The *lymphocytes*, while actually increased, are *relatively diminished*—that is, instead of representing 20 to 30 per cent. of all the leukocytes, they represent a smaller proportion, an average of 10.6 per cent. The *polymorphonuclear cells* are increased as to absolute number, but the percentage is also reduced, particularly toward the close, to an average of 46 per cent., normal being 62 to 70 per cent. *Eosinophiles* are increased, but not their percentage, and they are not now assigned any distinctive significance, because so numerous in other conditions. But the most characteristic feature of this variety is the presence of the large *neutrophilic myelocytes*, and the more of these, the more likely is it that the leukemia is myelogenous. These cells are not present in normal blood. In leukemia the percentage rises, sometimes as high as 60 per cent. and often above 20, with an average of 35 per cent. *Basophilic leukocytes*, including "mast" cells, are much more numerous than in normal blood.

The red corpuscles are those characteristic of anemic blood, and nucleated cells are numerous.

II. Pure *lymphatic leukemia* is less frequently met, probably less than 15 per cent. of all the cases. The external lymphatic glands are most involved. The leukocytosis is not nearly so marked, the colorless cells scarcely ever exceeding one in ten, often only one in 40. The lymphocytes predominate, equaling 90 per cent., including all forms, large, small and mixed. Myelocytes are infrequent. In a case reported by Uthemann, 93 per cent. of all the leukocytes were lymphocytes, as compared with 15 to 30 per cent. in normal blood; in one of Osler's, 98 per cent. Even in the combined form lymphatic involvement is found. The superficial groups of glands are usually involved, but never to the same degree as in Hodgkin's disease.

Caution should be observed, too, in basing the presence of leukemia solely on a *leukocytosis*, as some remarkable instances of this condition have been reported wherein leukemia did not supervene. Thus, von Jaksch, in his studies of the anemia of children, found such proportions as one white to 12 red corpuscles, one to 17, and one to 20; and in the case

of an adult, one to eight, and still no leukemia followed.<sup>1</sup> Eighty thousand white corpuscles in a cubic millimeter are not unusual in leukocytosis, while 170,000 have been produced experimentally in the dog. The association of lymphatic or splenic or myelogenous change with the leukocytosis is therefore essential to a diagnosis. Nay, more, we must look to the proportions of the varieties of leukocytes. It will be remembered that in the most frequent form of leukemia at least, myelocytes predominate over lymphocytes and polymorphonuclear cells. But in most cases of nonleukemic leukocytosis the adult polymorphonuclear cells are in relative as well as actual excess—90 per cent. being made up of this form in leukocytosis. Rieder is also inclined to regard the cases of so-called acute leukemia as really acute inflammatory leukocytoses rather than leukemia.

Allusion has already been made to an anemia described by von Jaksch as *anæmia infantum pseudoleukæmia*, further studied by Loos and Luzet, which is not to be confounded with leukemia. Its essential feature is an enormous falling off in the red cells of the blood, often as low as 820,000. The proportion of leukocytes is always increased, but never to the same degree as in leukemia, nor is it so rapidly brought about. They have been found to the number of 54,666. On the other hand, the leukocytes are characterized by their varied shape and unusual size. The red cells display a high degree of poikilocytosis, while white cells inclosing red cells and fragments of red cells are also found, together with occasional eosinophilic leukocytes and large multinuclear neutrophilic leukocytes and nucleated red cells. All of these modifications of the blood-corpuscles may occur in leukemia, but in the latter disease there is not so marked a reduction either in the hemoglobin or in the number of erythrocytes. The difference in the form of the liver and splenic enlargement in the two conditions has been referred to on page 715. It has been suggested that this is a form of disease intermediate between pseudoleukemia, or Hodgkin's disease, and true leukemia.

**Prognosis.**—The prognosis of leukemia is unfavorable, the best that can be expected from treatment being the deferring of the fatal end. Some rather remarkable fluctuations are noted, and cases of cure are even reported, especially of late, by inhalations of oxygen. Osler saw a case ten years after the original diagnosis was made by Wm. H. Draper. The lymphatic leukemias are the more acute and more intractable.

**Treatment.**—The treatment has heretofore been mainly with iron, quinin, and arsenic, fresh air, and good food. Large doses of arsenic—as much as 30 drops (0.92 c.c.) of Fowler's solution, reached by gradual increment have been especially recommended and certainly should be tried.

Inhalations of oxygen, suggested in 1887, were used by Sticker and Pletzer with temporary benefit, and Da Costa and Hershey report the apparent cure of one case, a boy of 13, and such marked improvement in a man of 35 that he was thought for a time to be cured. This treatment deserves, therefore, to be tried along with that first named. Thirty to 100 liters (about 4 to 12 gallons) of oxygen are to be inhaled daily.

<sup>1</sup>*Op. cit.*, p. 29.

I used it faithfully in one case without results. *Bone-marrow* has been extensively used, but the results have been disappointing. It should, however, be tried in 1 fluidram (4 c.c.) doses of the glycerin solution, increased to 1/2 an ounce (16 c.c.), three or four times a day.

**Treatment by X-ray.**—The Roentgen ray has been employed in the treatment of leukemia, and no less than 109 articles have been published in the last two years (up to July, 1906) on this treatment of leukemia and pseudoleukemia. The results have not been uniform, although on the whole they may be said to be sufficiently encouraging to justify a trial in every case. No cures have been reported, although frequent remissions, one in which there was no recurrences for three and a half years after the exposures. It must not be forgotten that marked remissions in the progress of leukemia occur under any treatment. Certainly a trial of the treatment should be made where possible. There is no satisfactory explanation as to the action of the rays.

#### IV. LYMPHATIC ANEMIA—HODGKIN'S DISEASE.

**SYNONYMS.**—*Hodgkin's Disease; Pseudoleukemia; Lymphadenosis; Lymphadenoma; Malignant Lymphoma (Billroth); Adénie and Lymphadénie.*

**Definition.**—The disease consists essentially in an anemia accompanied by a fibroadenic enlargement of the lymphatic glands and the formation of lymphatic foci in the spleen and occasionally in other glandular organs, but unassociated with an increase in the colorless corpuscles of the blood.

**Historical.**—Hodgkin's paper, to which we are indebted for our first definite knowledge of the disease, appeared in 1832.

**Etiology.**—Its etiology is as undetermined as that of leukemia. Depressing influences of all kinds are believed to favor it. Scrofulosis has sometimes preceded it and tuberculosis been associated with it, but the conclusion reached after much discussion, is that it is not tubercular. The presence of an irritating (infection?) substance in the blood has been suggested, and the necessity of local irritation, associated with a lymphatic diathesis, has been insisted upon by Trousseau. It may occur at any age, but is more common in adult life, and in males.

**Morbid Anatomy.**—Its morbid anatomy is, however, definite. There is both lymphatic and splenic involvement, the latter secondary to the former. The tonsils, intestinal lymphatic structures, and even the liver and kidneys may be invaded. There is, moreover, a deposition of new foci of lymphatic tissues decidedly more marked than in leukemia. The *lymphatic enlargement* usually begins first in the more superficial groups, as those of the anterior and posterior cervical triangles, the glands of the axilla, and the groin, but the entire lymphatic system may be involved, including the retroperitoneal glands, resulting sometimes in marked abdominal enlargement. Occasionally the overgrowth is limited to the deep-seated glands. Of the abdominal, the retroperitoneal are most frequently involved, producing tumors which have been mistaken for

myomata of the uterus. The bronchial glands may also be involved, and by their pressure produce dyspnea and suffocation.

The lymphatic enlargement is a hyperplastic one, shared by the cellular and trabecular tissue in varying degrees. When the former predominates, the product is soft and exudes a milky juice on section; when the latter, it is firm and resisting. The individual glands are not disposed to fuse nor to become adherent to adjacent tissue, differing in this respect greatly from glands enlarged by the tubercular process. The enlargement also exceeds that in leukemia.

Histologically,<sup>1</sup> the earliest changes as found in the smallest glands consist in increased vascularity with hyperplasia of the lymphoid cells and active proliferation at the germinal center, together with proliferation of the reticular endothelium. Mitotic figures are not infrequent in the reticular cells. The lymphoid sinuses contain many small and large mononuclear lymphocytes, epithelioid cells and a few eosinophiles. As the reticulum increases it grows coarser and the glands harden. In the last stages almost all traces of the normal structure are lost and only here and there are seen fragmentary remains of the lymphoid follicles and sinuses. In the spaces of the reticulum lie many small and large lymphocytes, plasma cells in large numbers, polymorphonuclear lymphocytes, eosinophiles in enormous numbers, epithelioid cells and large uninuclear and multinuclear giant cells. The giant cells, also often found in large numbers, are apparently traceable through the epithelioid cells to the endothelium of the reticulum. The various cell types are not equally distributed, lymphoid cells predominating in some parts, epithelioid cells in others, and giant cells and eosinophiles in others still.

After the lymph glands the *spleen* is more frequently involved. It is enlarged in various degrees, sometimes enormously. The changes in the enlarged spleen are quite different from those in Banti's disease or splenic anemia. On section, it is found filled with lymphomatous nodules composed of a tissue like that of the lymph glands. The earliest changes are seen in the Malpighian bodies. They consist in a hyperplasia of the lymphoid cells with early thickening of the reticular network and proliferation of the endothelial cells, forming grayish-white masses varying in size from a lentil to a walnut ( $1/4$  inch to an inch—.6 to 2.5 cm.), contrasting strongly with the dark red parenchyma. Typical uninuclear and multinuclear giant cells, eosinophiles and plasma cells are also present, sometimes abundantly. The connective tissue increases with the growth of the nodules in varying proportion. It is not reparative and represents an advanced stage of the disease.

The splenic enlargement is especially apt to be associated with enlargement of the retroperitoneal and bronchial lymph glands. It is more limited than in leukemia, the organ rarely exceeding ten inches (25 cm.) in length, as contrasted with the colossal size of the leukemic spleen. The spleen is not always involved, though Gowers found splenic enlarge-

---

<sup>1</sup>For a complete and thorough report of the histological changes in the organs and tissues in Hodgkin's disease, for which I am indebted for much contained in the text, the reader is referred to the excellent paper of W. T. Longcope, "On the Pathological Histology of Hodgkin's Disease with a Report of a Series of Cases," published in the Bulletin of the Ayer Clinical Laboratory of the Penna. Hospital, October, 1903.

ment in 75 per cent. of the cases collected and the organ contained lymphoid growths in 56 of these.

The *bone-marrow* is soft, very largely composed of cells, the fat being more or less replaced by lymphoid marrow. Myelocytes and large lymphocytes are the predominating cells, but myelocytes and polymorphonuclear leukocytes containing eosinophilic granules may also be numerous, though few of the typical bone-marrow giant cells are present, while the small lymphocytes are not relatively increased. Nucleated red blood-corpuscles are sometimes present in small numbers, usually of the normoblastic type. According to Longcope the most remarkable deviation from the normal consists in the great excess of the eosinophilic leukocytes and myelocytes, though he also says they may be absent.

The *liver* becomes the seat of secondary growths and is enlarged. The initial change is a deposit of small foci of lymphoid cells, in which take place the same changes as in the spleen and lymph glands. To this is added perilobular cirrhosis and fatty degeneration.

Similar changes may take place in the *thymus gland* and the kidney. Indeed, there is no organ in the body in which they may not occur, not excepting the nervous system. Paraplegia has resulted from pressure on the cord by growths in the spinal canal. The posterior nares may be occluded by invasion of the tonsils and the numerous lymphoid follicles in the pharynx. In like manner the intestinal walls may be invaded, producing thickening, while even serous surfaces do not escape.

The latest studies by Fischer, Reed, Longcope, Simons and Yanasaki go to show that the process is inflammatory and infectious, distinct from tuberculosis and Banti's disease, although tuberculosis may coexist.<sup>1</sup>

**Symptoms.**—The symptoms of Hodgkin's disease are, again, the *pallor, weakness, dyspnea, palpitation, dizziness*, and other signs of anemia, concurrent with or even sometimes in advance of the glandular enlargement. There is quite often *fever*, very irregular and variable in degree, and cases have been observed by Murchison and De Renzi in which there was *paroxysmal glandular enlargement* coinciding with fever, the enlargement subsiding with the decline of fever, but not reaching the degree present prior to the enlargement. In a case of Laache's the glands diminished in size during the fever. In a case under my care in the wards of the Hospital of the University of Pennsylvania in which the glandular enlargement was not conspicuous, there occurred an intermittent rise of temperature to a concurrent peritonitis, but the autopsy discovered this to be so limited that it is perhaps more reasonable to ascribe it to the febrile tendency characteristic of the disease.

The external glandular growths are variously conspicuous; occasionally, however, they are wholly absent. There is no fixed order of involvement, although the glands of the anterior and posterior cervical triangles commonly enlarge first, and with the acme of their growth produce a striking picture. The enlargement is not uniform, but at times remits and even ceases. It is said it may disappear altogether for a time. The glands are usually soft, sometimes there is even a sense of fluctuation.

<sup>1</sup>Reed, Dorothy M., on the "Pathological Changes in Hodgkins' Disease with especial reference to its relations to Tuberculosis, Johns Hopkins Hospital Reports," vol. x., 1902.

The glandular enlargements themselves contribute further to the symptoms by their effects. Thus, in the case of the bronchial glands, *dyspnea from pressure* on bronchi or trachea may occur, and may also be intermittent. Pressure elsewhere may lead to *pleuritic or abdominal effusions*, while the entanglement of nerves in the growth may cause *pain*. Erosion of bone may result. *Bronzing of the skin* has been found associated with enlargement of the abdominal glands. A *purpuric rash* is sometimes present in Hodgkin's disease, due perhaps to the hydremic state of the blood.

Macroscopically, the *blood* appears thin and pale. Minutely examined, the red corpuscles are diminished in number, although not always. Minimum counts make 960,000<sup>1</sup> to the cubic millimeter, while in a case reported by Henry,<sup>2</sup> that of a boy of five, with enormous enlargement of the right cervical glands, there were 5,462,000 to the cubic millimeter. Thus, the diminution is less than in pernicious anemia. The hemoglobin is, however, reduced to at least 60 per cent., furnishing thus one of the conditions essential to anemia. There are few nucleated red corpuscles and poikilocytes, and especially microcytes. The leukocytes may be slightly increased, occasionally decidedly so, but this is rare, and there is no approximation to the leukemic state of the blood, and the two states are distinct and separate. A combination of the two may be possible.

**Diagnosis.**—The diagnosis requires some care, as more than one condition is attended by similar glandular outgrowths. Chronic and even acute *adenitis* has been mistaken for the early manifestation of Hodgkin's disease, while the converse has obtained perhaps more frequently. Time is the arbiter of such uncertainty.

A group of *tubercular glands* resembles more closely the disease under consideration, but it is not usually difficult to distinguish between the two. Tubercular glands are adherent to each other and to adjacent tissues, while the lymphadenoid growths are loose and easily movable. Tuberculosis rarely involves more than one group of glands, is characterized by caseation and suppuration, while the lymphadenoid growths almost never suppurate. Yet the tubercular process is the slower. Tuberculosis is commonly found in young persons under 20. Hodgkin's disease may occur at any age, but the average age is greater. It is more common in males. In Gowers' 100 cases, 75 were males and 25 females; 30 were under 20, 34 between 20 and 40, and 36 above 40.

*Sarcoma* also involves groups of glands, and in the beginning the consistence of the glands is similar to that in Hodgkin's disease. But this disease rapidly invades surrounding tissues, fusing with them, and destructive ulceration soon makes its appearance.

*Carcinoma of lymphatic glands* should also be mentioned as producing a somewhat similar growth, associated also with cachexia, but it is for the most part secondary to cancer elsewhere than in lymphatic glands.

Finally, all the conditions named as possible to be mistaken for Hodgkin's disease are limited to single groups, while the latter always extends, and the fact of such limitation is of itself sufficient to preclude the disease.

<sup>1</sup>Case reported by Richard Geigel, quoted by F. P. Henry ("Anemia," Philadelphia, 1887), from "Deutsches Archiv für klinische Med., 1885, Bd. xxxvii., p. 59.

<sup>2</sup>*Op. cit.* p. 67.

From *leukocythemia* the disease is easily distinguished by the leukocytosis characteristic of the former.

**Prognosis.**—While the prognosis is ultimately fatal, the course of the disease varies greatly, and death seldom results in less than a year. F. P. Henry places the average duration of life at two years, but admits it is greatly modified by such circumstances as age and previous health of the patient.

**Treatment.**—Treatment, too, may avert the fatal termination for a long time. Extraordinary results in this respect have followed the administration of arsenic, and even recoveries have been reported. Large doses, arrived at by gradual increment, should be attained and kept up until some physiological effects are observed. Such doses are from 15 to 20 minims (1 to 1.3 c.c.) of Fowler's solution. Particularly happy results are claimed for the injection of arsenic into the lymphoid masses. Especially is this recommended when arsenic is not well borne by the stomach. From 8 to 30 minims (0.5 to 2 c.c.) of Fowler's solution have been injected daily in divided doses. The kakodyllate of soda is now used hypodermically, the dose being  $1\frac{1}{2}$  a grain. Atoxel still more recent preparation of arsenic administered hypodermically in doses  $\frac{1}{3}$  to  $1\frac{1}{2}$  grain (0.022 to 0.033 gm.) on alternate days. Inunctions of iodine and iodide of potassium are also recommended. Supporting treatment of all kinds, including quinine, cod-liver oil, and the best of food, is necessary. Bone-marrow is indicated here as in other forms of anemia, if it possesses the qualities claimed for it.

Operative interference is sometimes necessary to avert danger to life, threatened by the encroachment of enlarged glands on vital organs and functions, such as respiration. It has even been claimed that the removal of a group of primarily enlarged glands has cut short the spread of the disease, but such an apparent result is rather an evidence of error in diagnosis. In view of the fact that at an early stage a diagnosis is impossible, the removal of a local group of glands should be recommended.

#### STATUS LYMPHATICUS.

#### SYNONYM.—*Lymphatism.*

**Definition.**—A hyperplastic state of the lymphoid tissues throughout the body, including the lymphatic glands, the spleen, the thymus, and the lymphoid marrow of bones, occurring chiefly in children and young persons.

This condition is rare in this country, and has never come under my observation. It has been described by Poltau and other Vienna physicians, and by James Ewing, of New York.<sup>1</sup>

**Morbid Anatomy.**—The lymphatic glands most frequently affected are the pharyngeal, thoracic, and abdominal; those of the cervical, axillary, and inguinal regions less frequently and in less degree, while the lymphatic elements of the tonsils and the upper pharynx, and the solitary and agminated follicles of the small and large intestines, are often much involved.

<sup>1</sup>"New York Medical Journal," July 10, 1897.

The spleen is moderately enlarged, while the Malpighian bodies stand out distinctly. The thymus gland is enlarged and soft, and on section may exude a milky fluid. The bone-marrow may be hyperplastic, and the yellow marrow replaced by red marrow. Along with these anatomical changes have sometimes been found rickets, and, again, hyperplasia of the heart and aorta.

**Symptoms.**—The symptoms in addition to the anatomical changes noted are a lowered power of resistance, sometimes evidenced by sudden death or death from insufficient cause. The subjects are said to be poorly developed and infantile in appearance. As might be expected, the recognition of the actual condition is not always easy, if it dare be assigned a separate place in the nosology.

So far as I may judge from my limited knowledge, a separation of it from Hodgkin's disease seems scarcely justified.

## V. SPLENIC ANEMIA, OR SPLENIC PSEUDOLEUKEMIA.

**SYNONYMS.**—*L'épithéliome primitif de la rate; Splénomégalie primitive.*

**Definition.**—A chronic condition in which there is progressive enlargement of the spleen without marked swelling of the lymphatic glands, associated with more or less pronounced anemia. The term Banti's disease is applied to its termination in cirrhosis of the liver with ascites.

**History.**—Soon after Hodgkin's original paper, attention began to be called to enlargements of the spleen unassociated with leukemic blood. Among the early writers on this subject were Cohnheim and Strümpell. In 1866 Gretzel reported from Griesinger's Clinic a case of spleno-megaly, in which there was little or no swelling of the lymph glands. Gretzel believed this to be a case of true pseudoleukemia, involving the spleen rather than the lymphatic glands, and called the condition *anæmia splenica*, in contradistinction to *anæmia lymphatica* of Trousseau. The name splenic anemia was first applied by Griesinger in 1866. In 1867 Müller described several cases. In 1871 H. C. Wood<sup>1</sup> called attention to it as a separate variety of pseudoleukemia.

In 1882 Banti<sup>2</sup> described a spleno-megaly with hepatic cirrhosis and ascites. The former he regarded as primary, the latter as secondary and due to the former, claiming that the condition of the liver is a consequence of the splenic disease and not a cause. Banti also recognized the preascitic stage of the disease which he considered to be the same as splenic anemia of other authors.

In 1893 Westphal reported a series of cases of pseudoleukemia, five of which he regarded as of the splenic type, in which the disease started in the spleen rather than the lymphatic glands. More recently many cases have been reported, notably by Jarvin,<sup>3</sup> Osler,<sup>4</sup> Lichty,<sup>5</sup> Stengel,<sup>6</sup> S. Solis-Cohen,<sup>7</sup> J. and A. O'Malley,<sup>8</sup> and others. In 1900 Osler added the weight of his authority to those who separated the group entirely from Hodgkin's disease and called it splenic anemia. He also prefers to consider Banti's disease the second stage of splenic anemia.

On the other hand, Herman Senator<sup>9</sup> says that splenic anemia as a special disease cannot be distinctly differentiated from similar affections of the hemopoietic viscera, which are called pseudoleukemic. Naturally this view is held to some extent by others in Germany but has no following here.

Wentworth<sup>10</sup> considered the relation of splenic anemia to the *pseudoleukemia infantum* of von Jaksch and the *anæmia splenica infectiva* of the Italians.

<sup>4</sup>Osler, "Amer. Jour. Med. Sci.," 1900-1902.

<sup>5</sup>Lichty, "Jour. Am. Med. Assoc.," Feb. 20, 1904.

<sup>6</sup>Stengel, "Trans. Assoc. Am. Phys.," 1904.

<sup>7</sup>Cohen, "Am. Jour. Med. Sci.," Aug., 1904.

<sup>8</sup>O'Malley, "Am. Jour. Med. Sci.," June, 1905.

<sup>9</sup>"British Med. Jour.," 1903, vol. xii, p. 573.

<sup>10</sup>Wentworth, "Boston Med. and Surg. Jour.," 1901.

**Etiology.**—This is undetermined, except that there is reason to believe that the condition sometimes succeeds the infectious diseases. It is to be separated from the enlarged spleen sometimes associated with a moderate anemia, so often the result of chronic malaria. It occurs alike in old and young, but is more common in adults, and in males rather than females four to one.

**Morbid Anatomy.**—The organ is greatly enlarged, approaching that of the leukemic spleen rather than the spleen of Hodgkin's disease. It is three or four times its normal size, but retains its normal shape. It is indurated, and its incisures are deep. Its capsule is thickened and opaque in spots and sometimes adherent to adjacent tissues as is often true of any large spleen.

There is nothing distinctive in the histology of splenic anemia or Banti's disease. The process in the spleen is commonly regarded as chronic inflammatory, due to some unknown cause. There is a hyperplasia of all the splenic elements combined with a diffuse increase in the connective tissues and overgrowth of the reticulum, destroying and replacing the Malpighian body, a product of which may be tubercles as large as a pea containing central giant cells. There may be endothelioid proliferation and multinuclear epithelioid cells scattered through sections, and especially about the Malpighian bodies, the centers of which may also be the seat of hyaline degeneration. Eosinophiles may be present; also plasma cells. In the stage known as Banti's Disease there is super-added interlobular cirrhosis of the liver with pigmentation, and sometimes chronic diffuse nephritis.

There are no lymphomatous masses in the spleen as in Hodgkin's disease or enlarged lymphatic glands.

The bone-marrow is cellular, made up chiefly of large mononuclear leukocytes and myelocytes some of which contain eosinophilic granules; also many normoblasts and a few megaloblasts.

**Symptoms.**—The symptoms are analogous to those of pernicious anemia, and include *pallor*, *weakness*, *dyspnea*, *palpitation*, associated with the signs of *enlarged spleen*, evidence of which is sometimes shown by its weight and the pressure it exerts before other symptoms show themselves. There is also pain in the region of the spleen which increases on pressure and may radiate toward the back and loins. Rarely it may be due to perisplenitis, which may even invade the adjacent pleura. Finally, there results the cachectic state characterized by *emaciation*, *a deeper yellow color and pigmentation of the skin and mucous membranes*, a tendency to *hemorrhage* and *pyrexia*, with a possible temperature of 102° F., *edema*, *serous effusions*, *nausea*, and *diarrhea*, *extreme muscular prostration*, and *mental hebetude*. There is also said to be at times, as in lymphatic pseudoleukemia, an intermittent or *per saltum* course in the symptoms to the extent of apparent complete restoration to health in the intervals.

The *blood* exhibits the changes one would expect in cases in which there is destruction of the tissue devoted to its reproduction. It is anemic. The red disks are notably diminished, from 5,000,000 to as low as even 1,000,000. The hemoglobin is diminished, relatively less than the corpus-

cles. There are found also the other changes of the erythrocytes characteristic of pernicious anemia. There are poikilocytosis, megalocytosis, and microcytosis. Nucleated red blood-cells are numerous. The leukocytes are sometimes slightly more numerous; at other times they are in normal proportion and are said to be generally mononuclear.

Hemorrhage manifests itself especially as hematemesis, epistaxis, bleeding from the gums and even in the fundus of the eye. Hematuria and hemoptysis are infrequent; hematemesis is often excessive. Late in the disease there is ascites due to cirrhosis of the liver (Banti's disease).

An *increase in the urca* of the urine has been noted by Strümpell, and is regarded as evidence of increased proteid metabolism.

All clinical facts go to show that the spleen is responsible in some way for a destruction of erythrocytes and of their capacity for carrying oxygen.

The duration of the disease is from five to six months to three years.

**Diagnosis.**—The diagnosis of splenic anemia depends upon the presence of splenic enlargement associated with the phenomena of anemia previously described, and the absence of glandular enlargement, so conspicuous in Hodgkin's disease. Anemic symptoms attend the chronic malaria so often associated with enlarged spleen, but the history of malaria in such cases is invariably present, while the degree of anemia in malaria is not so high.

**Prognosis.**—The disease always prolonged, was formerly alternately fatal, but the prognosis has been modified by splenectomy.

**Treatment.**—The medical treatment is that for the other anemias, by iron and arsenic and nutritious food. Bone-marrow may be tried.

It is in this disease that splenectomy has been so satisfactory. In Banti's collection it appears to have been successful in three out of four cases, and later statistics seem to confirm this statement. Banti recommended splenectomy in all cases except profound cachexia and in pseudo-leukemic hypertrophy of lymphatic glands. He considers ascites indicates cachexia. Joseph O'Malley collected the cases up to the date of his paper, June, 1905. They numbered 32 with 24 recoveries or 75 per cent. G. E. Armstrong, in the "Lancet" of Sept. 15, 1906, reported that of 32 cases of splenectomy in Banti's disease 23 recovered and nine died, a mortality of 28 per cent., a little higher than that of O'Malley. Talma's operation has also been performed in these cases, but the cases have been too few to justify any conclusion.

## SECTION VI.

### DISEASES OF THE DUCTLESS GLANDS.

#### DISEASES OF THE THYROID GLAND.

##### GOITER.

##### SIMPLE GOITER OR STRUMA.

SYNONYMS.—*Bronchocle; Thyrocle; Thick Neck; Derbyshire Neck.*

**Definition.**—The name is derived from Latin, *guttur*, throat. Under this name are included all enlargements of the thyroid gland other than those due to inflammation, malignant disease, exophthalmic goiter, or parasites.

**Distribution.**—Simple goiter may occur endemically or sporadically, but in this country it is only sporadic. It is, however, quite prevalent about the eastern end of Lake Ontario and in the State of Michigan. It is still endemic in certain parts of Switzerland (cantons of Freiburg and Berne), in Italy (in the Southern Alps and in Savoy), in England, the Himalayas, in Asia and in Siberia. In the cantons named as many as 80 and 90 per cent. of recruits are found goitrous. It has even occurred in *epidemic* form in Finland.

**Etiology.**—The exciting cause of goiter still remains unknown, although a belief has long prevailed as to the endemic form that some constituent of drinking-water is responsible for it. That locality is in some way responsible is shown by the fact that removal from a territory subject to it arrests its development, while, if a healthy family moves into a goitrous district, the disease develops in some one or more members. A change in the water-supply of a district where goiter has been prevalent has led to its disappearance, while the water in certain wells on the continent of Europe is known to produce it. In fact, certain water is said to be drunk by men who desire to develop in themselves a goiter in order that they may be exempt from military service. What the responsible constituent of the water is, is, however, unknown.

In is much more common in women than in men, according to different authorities seven to 41 times as frequent. It has been suggested that this is because women drink more water. The disease generally develops after puberty, sometimes after 50. Congenital cases are known. It is sometimes hereditary, but heredity must be separated from the operation of one cause on different members of the same family.

**Morbid Anatomy.**—All simple goiters start in a true hypertrophy of the gland follicles, but ultimately assume special peculiarities, on which are based anatomical varieties. According to anatomical peculiarities assumed after the goiter sets in, there occur: (1) *Struma mollis*, or parenchymatous or hypertrophic goiter, in which there is a true hypertrophic enlargement; (2) *struma aneurysmalica*, in which the vessels are enlarged

and dilated; (3) *struma fibrosa*, in which there is an excessive development of fibroid tissue; (4) *struma colloides*, in which the follicles are enlarged and filled with colloid matter; (5) *struma cystica*, when the follicles have enlarged to cysts with liquid contents; (6) *struma ossca*, characterized by calcareous infiltration; (7) *struma amyloidea*, in which there is a wax-like product caused by amyloid change. There are various combinations or intermediate types.

**Symptoms.**—It may be said of the majority of goiters that they cause no inconvenience, and are mainly objectionable through the resulting deformity. The size attained varies: the enlargement may but slightly exceed that of the normal gland, or the organ may be very large and pendulous. It may be one-sided or bilateral, or only affect the isthmus. It is characteristic of all goiters and enlargements of the thyroid of any kind that they rise up when the patient swallows, and tumors of doubtful locality may thus be located. The goiter is sometimes low down, behind the sternum, and can only be felt during deglutition.

A goiter may press on the trachea, causing dyspnea, or upon the esophagus, causing difficulty in swallowing. When behind the sternum, it may press upon the veins in the neck, causing swelling of the face and head, and sometimes headache and drowsiness. There may be pressure on nerves, especially the pneumogastric, causing spasm of the glottis, paralysis of the abductor, and even complete paralysis of one or both vocal cords.

**Treatment.**—The medical treatment of goiter consists principally in the topical application of tincture of iodine. It is undoubtedly efficient at times. The simple iodine ointment or ointment of the red iodide of mercury may be daily rubbed into the goiter. It is recommended that after applications of the latter the neck should be exposed to the rays of the sun. This treatment has been especially efficient in India. Injections of iodine into the cyst are also used—20 to 30 minims (1.3 to 2 c.c.) of a solution of one part in twelve parts of alcohol twice a week, a new point being selected each time, care being taken not to wound any vessels or nerves.

Internal treatment is also recommended. Naturally, the iodide of potassium is conspicuous among remedies, in the usual doses—5 to 20 grains (0.3 to 1.3 gm.) three times a day. Thyroid extract is also being used with disputed success. Bruns treated 12 cases with raw thyroid glands in doses of 75 to 150 grains (5 to 10) gm. twice a week at first and once a week afterward. Nine were benefited. Kocher, however, thinks that the results with thyroid extract are no better than with iodine, and this view is now generally held.

If the goiter is produced by local causes, a change of residence is, of course, desirable.

When large and causing dangerous symptoms, goiter falls properly into the hands of the surgeon, who treats it as exigencies demand, sometimes extirpating it, though the operation is rather formidable at times and there is some risk of its being followed by myxedema. Cysts may be incised and drained or injected with iodine or perchloride of iron solution. Sir Morell Mackenzie injected the latter after tapping, using 2 drams (7.4 c.c.) of a 25 per cent. solution.

## EXOPHTHALMIC GOITER.

SYNONYMS.—*Struma exophthalmica*; *Graves' Disease*; *Basedow's Disease*; *Parry's Disease*; *Cardiothyroid Exophthalmos*; *Tachycardia strumosa*.

**Definition.**—A disease characterized especially by enlargement of the thyroid gland, protruding eyeballs, and frequent pulse, probably due to some perversion or hyperactivity of function of the thyroid gland.

**Historical.**—In the early part of the nineteenth century cases in which exophthalmos was a symptom were published by different authors. Some of these were probably examples of exophthalmic goiter. In 1825 C. Parry published several instances of a disease not previously described which were evidently cases of exophthalmic goiter. In 1828 Adelman published a case declared on Virchow's authority to be one of exophthalmic goiter, and therefore the first described in Europe. In 1833 Trousseau reported the history of a woman affected with goiter, exophthalmos, and cardiac palpitation at the same time, of which he said afterward that he was far from supposing that this symptomatic triad constituted a special morbid entity. In 1835 Graves published the clinical lecture whence arose his association with the name of the disease, which will perhaps continue through all time. He also described it in his "System of Clinical Medicine," published in 1843. He was the first to emphasize the absence of *organic* cardiac disease. In 1840 von Basedow published the results of his study of four cases of exophthalmic goiter, and with it the most exact description of the disease which had yet been given. He gave to the disease the name *exophthalmic cachexia*. Although his name has also become associated with it, and the Germans insist on the priority of his studies, he seems to have been clearly anticipated by Graves. Others who described the disease were: Romberg in 1851; Shoch in 1854; and in 1855 Koeben, who first ascribed it to derangement of the sympathetic nervous system. In 1855, too, Stokes included the disease in his book on "Diseases of the Heart," and drew special attention also to the nervous phenomena. Charcot thoroughly described it in 1856 and 1857, and in 1857 von Graefe described the symptoms known as Graefe's. In 1859 Fischer referred the symptoms to the remote effects of anemia. In 1860 Trousseau asserted the nervous origin of the disease, and that it should be classed as a neurosis. In the same year Aran ascribed the exophthalmos to a contraction of the muscular fibers of Müller supplied by the sympathetic. In 1862 a notable discussion in the Academy of Medicine of Paris took place, when Trousseau maintained that in all cases of exophthalmic goiter there was either an antecedent or a coincident derangement of the heart, and reasserted its nervous origin. Piörny denied the unity of the disease, and claimed that the prominence of the eye-balls was the result of retarded intracranial circulation due to pressure of the enlarged thyroid upon the external and internal jugular veins.

The neurotic nature of the disease has much in its favor, and most recently the medulla oblongata has been selected as the site for the lesion. This view has the support of some experimental evidence, and in a few autopsies changes have been found in the medulla. The view that it is a sympathetic neurosis has always commended itself, appearing as it does to explain the symptoms more satisfactorily than any other—the frequent pulse, the exophthalmos, the thyroid pulsation, the sweating, and the general nervousness being all thus accounted for.

Most recently the startling facts developed in connection with myxedema and the results of its treatment have drawn attention to a possible antithetic relationship between the two conditions. Thus we have, on the one hand, associated with exophthalmic goiter, excitability of the nervous system, manifested in restlessness of mind and body, a rapid action of the heart, and a moist, flushed skin; with myxedema the opposite conditions of dullness of intellect, torpor of body, slowness of pulse, dryness of skin. From this standpoint Moebius and Greenfield have taken the position that exophthalmic goiter is such an antithetic disease. Greenfield further adduces the fact that the changes in the gland are those of an organ in active evolution—i. e., proliferation with production of new tubular spaces and absorption of the colloid matrix, to be replaced by a more mucous fluid. Further are the facts that thyroid extract in excess produces tachycardia, tremor, headache, sweating, and prostration, symptoms of Graves' disease; that when administered during the disease, it aggravates the symptoms—has, indeed, in an overdose caused it, as in a case of Beclère's; and that the most successful treatment has been such as reduces the bulk of the gland.

**Etiology.**—Exophthalmic goiter is more common in women than in men—according to Trousseau, as 50 to eight. Others make it twice as frequent, others ten times. It is also more common in the young adult and

in the middle-aged. The average age may be put down at from 30 to 31 years; Bryon Bramwell says 15 to 30 for women and 30 to 45 for men. The oldest patient I have ever seen was 44. It has been observed as early as two and a half years, and as late as 68. Heredity is a rare factor, but its influence cannot be denied. It sometimes happens that several members of a family are affected. Sometimes myxedema affects one member of a family, and exophthalmic goiter another. It occurs with especial frequency in neurotic families. Sudden mental shock, worry and grief, and physical fatigue are assigned as exciting causes. So are many acute diseases, of which rheumatism is especially cited, also typhoid fever. Some of these are more likely to be coincidences. Its association with diabetes mellitus though infrequent, is a recognized one. Prof. W. H. Thomson ascribes Graves' disease to gastro-intestinal ptomain poisoning from excessive meat ingestion. Some perversion of function of the thyroid gland lies at the foundation of exophthalmic goiter.

**Symptoms.**—Of the cardinal symptoms mentioned in the definition, the cardiac and vascular usually appear first. The *palpitation* is extreme, delirious, as it were, the pulse-rate being commonly in the neighborhood of 120 to 140, and is said sometimes to reach 200. The slightest excitement augments the pulse-rate instantly. The *cardiac impulse* is *strong*, but the volume of the *pulse small*. The *heart-sounds* are loud, audible to the patient and even at a distance from the body, in one case described by Graves himself as far as four feet. A *systolic murmur* is often heard at the base, usually soft, but sometimes loud; more rarely at the apex, when it may be due to relative insufficiency of the mitral or tricuspid valve.

*Exophthalmos* is commonly described as the second of the cardinal symptoms to appear, but it is not much more infrequent than palpitation. The degree of this protrusion varies very decidedly. It may be so slight as to be scarcely noticeable, while again the peculiar staring effect arising from it is conspicuous, and attracts attention instantly. Exophthalmos may be present on one side only, although some do not admit such cases in the category of true exophthalmic goiter.<sup>1</sup> The eyes show a large amount of white, and the eye-lids when closed often cannot cover the eyes. It is in these extreme cases that *von Graefe's symptom* presents itself—a condition in which, when the eye is cast down or raised, the lid fails to follow it as it does in health. This symptom, of which so much has been said, is not a very frequent one. *Stellwag's sign*, which is less known, seems more frequently met. In it, the palpebral fissure is increased in width, owing to the persistent retraction of the upper lid. It may occur with or without von Graefe's sign. Retraction of the lower lid is occasionally seen. Moebius considers Graefe's symptoms the result of *Stellwag's*. The patient *winks* less frequently than in health. *Pulsation of the retinal arteries* can be seen with the ophthalmoscope, but other changes in the retinæ are rare. The same is true of the pupils. A *lack in ability to converge* the two eyes was pointed out by Moebius. Exophthalmos is absent in 20 per cent. of cases.

<sup>1</sup> See paper on "Unilateral Exophthalmos in Exophthalmic Goiter" by Posey and Swindells, "Ophthalmic Record," May, 1904.

The *thyroid enlargement* commonly presents itself at about the same time as exophthalmos. A patient of mine said, almost as early as she noticed swelling she observed her eyes began to protrude, showing that the events are not far apart, and that the three distinctive symptoms appear almost simultaneously. The goiter itself is in no way peculiar. It is usually of moderate size, almost never reaching the dimensions sometimes attained by a simple goiter. The tumor is largely contributed to by its vascularity, though there is also an overgrowth of the proper glandular tissue of the thyroid. *Pulse* and *thrill* are both palpable, while a loud systolic *murmur* may be heard on auscultation. The enlargement may be on one side only. In other cases there may be no enlargement. This may also be apparent only, but we are informed by the Mayo brothers that they have operated on exophthalmic goiters hardly palpable which proved greatly enlarged on exposure. When such a condition is associated with absent exophthalmos, the disease may be completely masked.

Another symptom, already alluded to, included by some as cardinal, is what is commonly known as "*nervousness*." It includes irritability, restlessness, a disposition to start at the slightest sound, and wakefulness at night. A part of this, or due to the same cause, at least, is "*tremor*," a highly important symptom, of such frequency as to be included by George R. Murray in his definition.<sup>1</sup> It does not, however, appear, as a rule, until the other symptoms have been present for some time. It may be best studied by holding out the hand with the palm downward; even better by laying the examiner's palm lightly upon the patient's fingers when the hand of the latter is held out. The tremor affects the flexor and extensor muscles of the wrist, and not the intrinsic muscle of the hand, so that the fingers do not vibrate independently, but the whole hand moves. It is rapid, regular, and uniform while it lasts. It occurs *eight or nine times in a second*. Its extent is small, but not always the same. It may be seen, too, in the foot, and in some instances the whole body appears to tremble. It is generally equal on the two sides of the body, but has been unilateral when goiter and exophthalmos have been on one side. It is variously modified by position—lying, sitting, or standing. It does not, as a rule, interfere with the movements of the hand, but when excessive may hinder sewing or writing. The tremor of general paralysis and alcoholism is less regular in extent, while the individual fingers tremble, the rate being practically the same. In the tremor of old age and disseminated sclerosis the rate is only one-half as rapid; and in paralysis agitans it is less regular. It resembles more the tremor of fatigue or that seen in recovery from long illness. Another symptom included in the same category is a *sudden giving away of the legs*, so that the patient falls to the ground without previous feeling of faintness or giddiness, and Charcot mentions also a weakness of the legs. *Painful cramps* sometimes occur. *Localized muscular atrophy* and that peculiar nervous symptom known as *astasia abasia*, in which there are inability to stand and inability to walk, are occasionally met.

Excessive *sweating* is a frequent symptom. It may be intermittent or irregular, or there may be a simple feeling of flushing without sweating.

<sup>1</sup> "Twentieth Century Practice of Medicine," vol. iv., 1895.

*Diminished electrical resistance* was pointed out by Vigouroux. This is a natural result of the constant moisture of the skin. *Polyuria* often occurs, caused, perhaps, as is the sweating. A dark coloration of the skin sometimes takes place, more decided in those situations in which the pigment is naturally more abundant, such as the face and arms. Yet the flexures of the joints, the axillæ, the genitals, and the inside of the thighs are also affected. The skin may be uniformly bronzed, or it may be darker in patches. Parts of the body which are subject to constant pressure are also disposed to take on pigmentation more deeply. *Edematous swellings* of the skin in various parts of the body may occur, and are to be carefully separated from edema the result of associated conditions, such as anemia, organic heart disease, etc. It manifests itself as swelling in the feet and ankles, and has been ascribed to vasomotor paralysis. The *nails* sometimes become thin, and occasionally have a corrugated appearance.

*Gastro-intestinal* symptoms are frequent, manifesting themselves by attacks of *diarrhea*, apparently of nervous origin, coming on suddenly without pain, with copious loose motions, of which there are two or three or more in a day. Uncontrollable *vomiting* may be associated with this. Acute forms are sometimes thus ushered in. The *tongue*, however, *remains clean*, and there is, *as a rule no rise of temperature*. Sometimes there may be very slight fever. The skin discoloration and gastro-intestinal symptoms suggest those of Addison's disease, and it is not impossible it may have been associated. *Rapid breathing* is a frequent accompaniment, equaling 30 to 40 respirations a minute. It may be associated with *cyanosis* of the face and swelling of the vessels of the neck. *Intermittent albuminuria* is frequent, as pointed out by Begbie. *Derangements of menstruation* are less frequent than might be expected, this function being normally maintained in the majority of instances. *Pregnancy is infrequent*.

The *mental condition* has been alluded to. It may be added that fits of depression alternate with buoyancy, while the moral nature may also be changed to a degree amounting to melancholia and mania. Active cerebral symptoms are sometimes present. This mania is of bad augury. Dullness or stupor seems to be entirely absent.

Occasionally Graves' disease may be associated with myxedema, when instead of the skin being moist it is dry and the nails are cracked.

Among complications, *hysteria* and *chorea*, and even *epilepsy* are included.<sup>1</sup>

**Diagnosis.**—This needs no detailed consideration. The combination of the three cardinal symptoms named can receive no other interpretation. There may be some doubt at the beginning, which time will shortly remove.

**Prognosis.**—Exophthalmic goiter is rarely fatal in itself, the patient usually dying of some other disease. At times the condition remains permanent, with little change, but in the course of time the majority of cases improve greatly, and some get well. I have been watching for years a young woman who, 19 years ago, had striking exophthalmic goiter, with its usual train of symptoms, who is now well, except that her eyes are

<sup>1</sup>Many further facts in relation to this disease may be found in a paper by W. Gilman Thompson in the "American Journal of the Medical Sciences," Dec., 1906, entitled "A Clinical Study of 80 Cases of Exophthalmic goiter."

slightly more prominent than is strictly natural. A physician of my acquaintance is in the same condition, attending actively to practice.

In some rare instances a rapidly fatal course ensues, death taking place in a few days after the onset. The majority of cases run a chronic course, the symptoms persisting more or less for years. When death occurs, it is from failure of the heart. It is generally preceded by an aggravation of all the symptoms. It may be sudden, as by syncope. Acute cases are reported, following one of the cited causes, in which the symptoms lasted a few days, and then disappeared completely.

**Treatment.**—Rest and protection from excitement are essential conditions to successful treatment. After this, the treatment has been mainly directed to the symptoms. The remedies heretofore used were mainly the bromids and digitalis: the bromids as nervous sedatives, and for their reputed action in producing anemia of the nerve centers, digitalis for its effect on the heart and pulse.

Among numerous other remedies is ergot, for its power of contracting the caliber of blood-vessels. By German writers, galvanism of the sympathetic is claimed to be of service. Theoretically, it should be. A constant current of from five to eight cells is used; the negative pole is placed on the fifth cervical vertebra, the positive pole along the sternum. Special efficiency has been claimed for the tincture of nux vomica by J. Newton Hunsberger, of Skippack, Pa. Hunsberger gave it to a well-marked case, beginning with doses of 25 drops, increased to 50 (0.77 to 1.54 c.c.). In three months after the treatment commenced the patient was able to do all her work, and has continued well ever since. Thyroid extract has not proved useful so far as tried—in fact, has appeared to be harmful. James C. Wilson, has used extract of suprarenal capsule with apparent advantage—5 grains (0.33 gm.) in tablet form at a dose.

Consistent with his view as to its etiology, Prof. W. H. Thomson insists upon the absolute necessity of a milk diet, which he says should be kept up for two years. He suggests the fermented milks where the ordinary milk is not well borne.

Opium in small doses has been recommended. It is certainly a rational remedy, quieting the irritability which is so marked a feature. Codein should be preferred, as a rule, because it is less likely to produce the harmful effects which attend the use of opium, especially constipation and the opium habit. Iodids are of doubtful value, but iodine is especially recommended by Rogers and Beebe (see p. 737).

The results of *operative treatment* have been more satisfactory, especially at the hands of such surgeons as the Kochers, of Zurich, and the Mayos, of Rochester, Minn., U. S. A. Oppenheimer collected 68 cases, of which 18 recovered completely, in 26 there was more or less improvement, in nine there was no change, five died almost immediately, and four within 24 hours.

Still more satisfactory were the results of the brothers Mayo. They operated on 110 cases of exophthalmic goiter, up to January, 1907, with nine deaths in all, and but two in the last 64 cases. They further say that of those who survive the operation, 50 per cent. make an early recovery, 25 per cent. improve of the main symptoms during several months,

and 25 per cent., while greatly improved, have occasional temporary relapses of the tachycardia and tremor. The exophthalmos is often one of the last symptoms to disappear."<sup>1</sup>

The *antiserum treatment* for exophthalmic goiter proposed by Rogers and Beebe,<sup>2</sup> though it has passed the experimental stage, must be regarded as still on trial. It is based on the assumption that the disease is due to an excess of thyroid activity and consequently an excess of thyroid secretion. For this they offer a specific antiserum which is made by injecting rabbits or sheep with the nucleo-proteid and thyro-globulin obtained from the human thyroid gland. The pathological thyroids obtained from patients suffering from Graves' disease seem to make a somewhat better serum than can be obtained by employing the normal human thyroid gland secured at autopsy; nevertheless the normal gland is sufficient for producing a very useful antiserum.

The statistics of the originators of this method of treatment cover some 300 cases and compare favorably with the more popular though more dangerous surgical procedure of excision of one lobe or of one lobe and the isthmus of the offending organ. According to latest reports, these statistics are as follows: 30 per cent. complete cures; 50 per cent. improved; and 20 per cent. of failures to affect the course of the disease and in this 20 per cent. of failures are included ten per cent. of deaths not because of, but in spite of every method of treatment. The authors confidently expect that with increasing experience and greater knowledge of the disease a much better statistical result will within the next few years be possible.

Rogers explains that there are different indications for treatment in different stages or forms of so-called exophthalmic goiter or Graves' disease, and he therefore designates the symptoms recognized as dependent upon overactivity of the thyroid gland as thyroidism. From anatomical studies and clinical experience it is known that the pathological changes in the thyroid of exophthalmic goiter may gradually progress into a state which is anatomically and clinically myxedema. Hence between these two extremes there are numerous cases which give some of the symptoms of both diseases, and sometimes one group of symptoms and sometimes another may predominate. In the Mutter lecture of 1907 Rogers gives illustrative cases of this type and describes the appropriate treatment.

From this it appears that some individuals require antithyroid treatment, either medical or surgical, in the sense of measures intended to check the excess of thyroid secretion. Others giving some of the symptoms of thyroidism or overactivity of the thyroid gland, but more of *deficient* function require prothyroid treatment, or treatment designed to help out the supposedly impoverished quality but excessive quantity of thyroid secretion.

It has not hitherto been generally accepted or believed that the thyroid secretion can vary both in quantity and in quality, but a double abnormality of this kind seems the only explanation possible in Rogers' opinion. In the early typical cases of exophthalmic goiter he believes there is an excess in the quantity of thyroid secretion which is only slightly

<sup>1</sup>C. H. Mayo, "Journal of the American Med. Assoc.," Jan. 26, 1907, vol. xlviii, p. 273.

<sup>2</sup>Mutter lecture for 1907 before the College of Physicians, Philadelphia.

impaired in quality, and for these he recommends the antiserum alone or in combination with ligation of one or more of the thyroid vessels, or if preferred excision of the part of the gland. For the cases which have run a longer course or which present atypical symptoms, such as a dry instead of a moist skin, or one with a yellowish-brown color, or which show any signs of myxedema like the well-known supraclavicular fatty pads or edematous ankles or puffy eye-lids or face, then prothyroid rather than antithyroid treatment is needed. By prothyroid is meant specific medication designed to help out or supplement the thyroid secretion or activity. For this purpose the ordinary commercial thyroid preparations, according to Rogers and Beebe, are, as a rule, useless or harmful.

Rogers and Beebe have found that sheep thyroids ground to a pulp and suspended in normal salt solution can be separated into a nucleoprotein material and thyroglobulin. The nucleoprotein portion, when dried and given by mouth in doses of  $1/50$  to  $1/100$  of a grain (0.00132 to 0.00066 gm.) three or four times daily, has little or no tendency to accelerate the pulse and yet has an extraordinary power of promoting nutrition and improving the general well-being and, in suitable cases, of actually reducing the tachycardia. Hence the nucleoprotein material derived from the thyroid is designated as "detoxicated" thyroid. It is indicated generally in combination with the antiserum, in the cases of thyroidism of some considerable duration but without manifest approach to myxedema.

It is given by itself or in combination with other adjuvants like iodine or dilute hydrochloric acid (2/10 per cent. in dosage of 4 to 6 ounces with each meal), in the atypical cases especially if there is any evidence of myxedematous taint.

Some cases, however, in this group of late thyroidism or some presenting atypical symptoms will not do well unless the thyroid proteins are given subcutaneously. For this purpose the authors recommend a 1 to 1000 solution of the normal human thyroid nucleoprotein or a 3 to 1000 solution of the normal human thyroglobulin. The indications for this rather unusual medication are as yet more or less undefined and a matter for experimental determination. Nevertheless, the cases cited indicate its necessity.

The dose of the antiserum is about 10 minims given not oftener than once daily in the back of the upper arm, the amount of reaction regulating the repetition. If there is none locally or generally, it should be given every day. If there is local swelling, wait until it has entirely subsided. If there is no improvement at the end of 4 to 6 weeks or if there is manifest injury earlier, do not repeat. The best resource is then hydrochloric acid and the detoxicated thyroid tablets (2 per cent.) one three times daily. If the tablets intensify the symptoms, try iodine.

Rogers believes from his experience that radical operation by removal of more or less of the gland in exophthalmic goiter can only be expected to cure the disease in its early and typical stages.

In the conditions intermediate between acute typical exophthalmic goiter on the one hand, and myxedema or extreme degeneration of the thyroid on the other, improvement may thus be obtained, but it will be only temporary.

In the later stages of the disease and in the atypical cases Rogers regards radical operation as always dangerous and generally harmful. The great difficulty at present is in distinguishing with any degree of certainty the period and character of the disease. For this purpose he claims the antiserum is invaluable. For cases which do not respond well to the antiserum he has found almost invariably do poorly after removal of  $1/2$  or more of the gland.

### MYXEDEMA.<sup>1</sup>

SYNONYMS.—*Cachexie pachydermique* (Charcot); *Cachexia thyroidea vel strumipriva vel thyreopriva* (Kocher); *Athyrea*; *A Cretinoid State Super-vening in Adult Life in Women* (Gull).

**Definition.**—A myxomatous infiltration of the subcutaneous connective tissue of the body, characterized also by dryness of the skin, subnormal temperature, mental failure, and atrophy of the thyroid gland.

**Historical.**—Nearly one hundred years ago King, of Guy's Hospital, London showed experimentally that the colloidal matter of the acini of the thyroid gland passed into the lymphatics and thus suggested the idea of what is called in modern times an internal secretion. Schiff showed in 1850, by experiment on carnivora, that the gland is important to life, and confirmed this in 1884 by showing that the removal of the organ alone in these animals is followed by striking symptoms preceding death. In 1884-85-86 Victor Horsley, experimenting on monkeys and later herbivorous animals, showed that myxedema could be produced in the monkey by removing the thyroid gland. The disease itself, as occurring in man, was first described by Sir William Gull in England in 1873 as a contribution to the anatomy of the cretinoid condition. Further described by William M. Ord in 1877, and named by him myxedema. It was also studied by Charcot, who called it *cachexie pachydermique*. In 1882 Jacques L. Reverdin called the attention of the Medical Society of Geneva to the occurrence of the symptoms of myxedema after total extirpation of the thyroid in the human subject. Theodor Kocher states that in the autumn of 1882, previous to this event, he spoke to Professor Reverdin of the remarkable consequences of the operation, and that six days later Reverdin read a paper on the subject. In 1883 Kocher reported to the Twelfth Surgical Congress at Berlin similar results in patients from whom he had entirely removed the thyroid gland, calling the condition *cachexia strumipriva*, having previously known nothing of myxedema as a separate disease. He did not attribute the condition to the loss of the thyroid, but to injuries received in the structures of the neck in the operation. In a succeeding paper the brothers Reverdin recognized the condition as identical with myxedema, and called it *myxedema operatoire*. Shortly afterward Felix Semon suggested that the loss of function in the thyroid gland was probably the common factor in the production of both. Victor Horsley's results were not published until 1890, the same year in which von Eiselberg<sup>2</sup> announced that the removal of the thyroid caused tetany. Horsley ascribes the tetanic symptoms to the fact that the animals were kept at a temperature of 90°F. (32.2° C.) after the operation. N. Weiss also pointed out that tetany is apt to follow operative extirpation of goiter. In 1890 Horsley published a note on the possibility of the successful treatment of myxedema, sporadic cretinism, and cachexia strumipriva by grafting with thyroid tissue from the necks of animals, though in this he was anticipated by Kocher in 1883 and Bircher in 1889. Kocher's graft was absorbed, but Bircher's patient was enabled to return to work. Victor Horsley's results were a part of a report by a committee of the Clinical Society of London, appointed in 1883, whose conclusions were as follows:

1. Myxedema is identical with cachexia strumipriva.
2. Sporadic cretinism is myxedema occurring in childhood.
3. Endemic cretinism is also closely allied to myxedema.
4. Further, that while these conditions are dependent on loss of function due to removal or disease of the thyroid gland, the ultimate cause of this loss of function in

<sup>1</sup>The student is referred to five noteworthy papers on the subject of "Myxedema and Cretinism" in vol. viii., 1893. "Transactions of the Association of American Physicians," by Francis P. Kinnicutt, James J. Putnam, M. Allen Starr, W. Gilman Thompson, and William Osler; to the "Atlas of Clinical Medicine," by Byrom Bramwell, for admirable illustrations; and to the exhaustive article on "Myxedema" by George R. Murray, of Newcastle, England, in the "Twentieth Century Practice of Medicine," vol. iv., 1895. Also to an address by Victor Horsley on the "Physiology and Pathology of the Thyroid Gland," published in the "British Medical Journal," December 5, 1896.

<sup>2</sup>Von Eiselberg's experiments were made chiefly on cats.

ordinary myxedema is not as yet explained. George R. Murray suggested the hypodermic injection of the gland extract in 1891 and Horwitz, of Copenhagen, E. L. Fox, and H. Mackenzie its internal administration.

**Etiology.**—All forms of myxedema are the result of disease or removal of the thyroid gland, but what excites this disease is not known. It is much more common in girls. In the simple form, a minor rôle may be assigned to heredity, but in cretinism heredity plays no part, as cretins are not sexually developed. Yet it occurs in members of the same family, which only goes to show that one cause operates to produce it. Many are the children of neurotic persons, while Langdon Down considers that alcohol is responsible, especially if the alcohol habit is present at the time of procreation.

**Morbid Anatomy.**—The morbid changes in the myxedema after death are those described as characteristic in life, but autopsy has disclosed the thyroid absent in nine out of ten cases of cretinism examined, confirming the theory of its origin. Enlargement of the *hypophysis cerebri* was found in six cases of cretinism by different observers, and Horsley says that the convolutions of the brain are ill-defined, and the blood-vessels small, even in proportion to the rudimentary condition of the nervous system.

**Symptoms.**—Three groups of cases are recognizable:

1. Pure myxedema.
2. Myxedema associated with congenital or sporadic cretinism.
3. Operative myxedema or cachexia strumipriva.

1. *Pure Myxedema.*—This is much more frequent in women than in men—at least as six to one—and occurs usually between the ages of 30 and 50, but is not confined to these ages, being found in those who are younger and older. Heredity is a recognized factor, acting usually through the mother. Several members of a family may be affected. The poor suffer most. It is said to have no relation to the catamenia, but has followed frequent pregnancies, injuries, severe hemorrhage, and mental disturbance. Most essential is some change in the thyroid gland. Formerly thought to be rare in this country, cases have multiplied since attention has been called to it.

The face is the chief seat, but the extremities, the trunk, the tongue, and even the internal organs may be involved. The *face is uniformly swollen, broadened, and flattened, the nose is broad, the mouth large*, all lines are obliterated, and expression is gone. The *skin* of the neck above and below the clavicle is thrown into folds of fatty and myxomatous tissue. It is yellow, translucent or waxy, dry and scaly. The cheeks and sometimes the nose are flushed. True edema may be associated, and there are rarely albuminuria and glycosuria. The *hands lose their natural shape*, and were described by Gull as "spade-like;" the *feet* are also misshapen; the *gait* is slow and labored. The *mind is feeble*, slow in its action, memory is poor, while irritability and suspicion are added qualities, and sometimes there are delusions and hallucinations, ultimately often dementia. The organic functions are fairly well performed. *Atrophy of the optic nerve* is a rare but possible symptom, also *synovitis* from trifling causes. *Sub-normal temperature* is characteristic, though in early stages the temperature

may be normal or slightly above. In winter the patient always feels cold and hugs the stove. The course of the disease is slow, and the patient usually dies of some intercurrent affection.

2. *Myxedema Associated with Cretinism, Congenital or Acquired.*—(Cretinoid idiocy: Idiotie avec cachexie pachydermique.) Cretinism is a form of idiocy associated with absence of the thyroid or with a functionless thyroid. It is myxedema in childhood. There is almost complete arrest of mental and bodily development. The cretin is a dwarf. In the congenital form, there is congenital absence of the thyroid, and the child is further characterized by its thick neck, short arms and legs, and prominent belly. The face is large, the lips are thick, and the tongue is large and often protruding. All the bones of the skeleton are short and broad, the epiphyses swollen, but not ossified. The skull is short and broad, and the basosphenoid junction early ossified. The cretin resembles the rickety child, and may be confounded with it.

Acquired cretinism may start before birth and be barely appreciable at birth. More frequently the infant appears normal at birth, and the changes make their appearance between the second and fifth years. The arrest of development continues, or, rather, there is very slow development, so that at adult age the man or woman does not exceed in stature a child of from five to seven years. The myxedemic symptoms are similar to those described in pure myxedema.

From the fact, however, that the disease may start to develop later than infancy, there results a series of types intermediate between those represented by congenital and adult cretinism. This arrest of mental and physical development is, of course, greater the earlier the disease begins to develop; whence two cretins of the same age will differ materially if one has commenced to develop at or before birth, and the other not until seven or eight years of age.

True congenital cretinism—that is, cretinism which is evident at birth—is very rare. Some cases of supposed intra-uterine rickets may have been cretinism. In most cases, the child does not long survive its birth. In another form described by Horsley the disease is supposed to begin shortly before birth, but develops slowly, so that at birth it has not attained the degree incompatible with life, and the child can live. In this there is usually a goiter at birth.

Cretinism may be endemic, as in some parts of the continent of Europe; or sporadic, as in England, and America as well. The sporadic cases are, as a rule, without goiter, the thyroid glands being either undeveloped or atrophied, while one-third also of the endemic cretins are without goiter. In either event, the gland is functionally dead, even though it may appear natural in size, the original true gland tissue having been replaced by an indifferent element. Endemic cretinism occurs in localities where goitre is also endemic—in the shut-up valleys of mountainous districts of Europe and Asia, to which it is confined. At one time—in 1847—a number of cases—some 24 out of a population of 350—prevailed in Cheselborough, Somerset, England, but the disease has died out. The endemic form is commonly ascribed to the use of certain drinking waters, but no responsible constituents have been isolated. The child, being normal at birth, remains

so until the change begins in the thyroid, when it becomes less lively, development is arrested, and the conditions described on page 740 slowly develop. The cretin may reach the age of 30 or 40 years, but ceases to change after the 20th year, whether the case be sporadic or endemic.

3. *Operative Myxedema or Cachexia Strumipriva*.—By this is meant a condition of myxedema the result of removal of the thyroid (see History, p. 738.). It is more likely to follow total than partial removal of the thyroid, but does not follow every case, having been observed in 69 out of 408 cases. Cases of operative myxedema are very rare in this country.

**Diagnosis.**—This is easy. The *edema of Bright's disease or heart disease* may be confounded, especially as albuminuria and casts are sometimes present in myxedema; but the peculiar flat face, the absence of pitting on pressure, and of the signs of heart disease are distinctive features of myxedema.

**Prognosis.**—This was regarded as unfavorable until the hypodermic use of thyroid extract was suggested by George R. Murray, of Newcastle, England, in 1891, based upon the satisfactory effect obtained by Bettencourt and Serrano, in 1890, in ingrafting sheep's thyroid in human subjects having myxedema, the idea being in this manner to substitute the juice or secretion of the gland. Every expectation was realized. In 1892, Howitz, of Copenhagen, and soon after, E. L. Fox and H. Mackenzie, in England, substituted for the hypodermic use the administration of the gland itself or some preparation of it by the mouth. At the present day, the effects of the administration of thyroid preparations in myxedema are among the marvelous results of medicine.

**Treatment.**—The treatment at the present day is, therefore, solely by the sheep's thyroid. The gland is best administered in the shape of glycerin extract or tablet. From 15 to 30 minims (1 to 2 gm.) of the former and 5 grains (.33 gm.) of the latter are to be given daily, its effect being carefully watched. If no effect follows, the dose should be doubled, and further increased if necessary. As improvement takes place, smaller doses should be given at longer intervals, until finally from 10 to 15 minims (0.66 to 1 gm.) or 10 to 15 grains (.66 to 1 gm.) of the solid extract are given once a week or less often. During the first week the patient should be watched, with a view to guarding against heart failure, prohibiting all physical exertion on his part, this being an apparent effect of the medicine in excessive doses.

The myxedema being removed, it is necessary, of course, to continue the treatment in this second stage by such doses as will maintain the cure, for it is to be understood that, as the thyroid is still functionless, the omission of the treatment is followed, sooner or later, by its return. The quantity required varies in different cases, but it is found to range between 5 and 15 minims (0.33 to 1 c.c.), the more precise dose being determined by trial. A single daily dose is preferred by Murray to a smaller dose more frequently repeated. A fall of temperature below normal, a slight return of swelling or of other symptoms, indicate that too small a dose is being given, while acceleration of the pulse indicates that the dose should be reduced. In a climate not subject to great variations the same dose may be given the year round. In hot weather a smaller dose suffices

than in cold, and a dose that has been found sufficient during the summer may not be enough in the winter.

The treatment of cretinism is also by the thyroid extract. Relatively larger doses of thyroid extract can be given to children than to adults. The liability to syncope during treatment is less marked than in myxedematous adults, but it is advisable not to allow any unusual exercise during the first part of the treatment. In the absence of the extract, the sheep's raw thyroid may be administered, giving one-eighth to one-quarter of a lobe twice a week.

Thyroid grafting is also employed for the treatment of cretinism, with the same results and same shortcomings, and is carried out in the same way. It is especially with a view to more permanent results that the successful application of this method is desirable, and symptoms have been kept in abeyance for some time by it. Sooner or later, however, they return, and the operation must be repeated or the extract administered. If grafting, which is usually done into the peritoneal cavity, is practiced, it should be preceded by a course of thyroid extract, and the symptoms of myxedema removed as far as possible before the operation is done, usually for two or three months. The details of operative treatment are left to the surgeon.

The results of treatment in cretinism are as marvelous as in myxedema. They include not only the removal of the hideous deformity and the restoration of intellect, but also an increase in height, which, though not amounting to a restoration of the normal height, is still appreciable. The earlier treatment is commenced, the more prompt and marked is its effect.

Of the treatment previous to the introduction of that by thyroid extract, that by *jaborandi* and *pilocarpin* should be mentioned, because the partial benefit derived from them is explainable by supposing that they produced increased activity in small portions of residual glandular tissue. Should thyroid extract be unattainable, these drugs may still be used.

## TETANY.

SYNONYMS.—*Tetanilla*; *Intermittent Tetanus*; *Hypoparathyreosis*; *Status Parathyreoprivus*; *Contracture des nourrices*.

**Definition.**—A condition of deranged metabolism exhibiting continuous or intermittent tonic spasm of the extremities, usually symmetrical, but occasionally confined to one limb, rarely even becoming general. It is ascribed to disease of a ductless gland (the parathyroid) or its insufficiency.

**Historical.**—A knowledge of the symptom complex of tetany was gradually acquired. The first to describe it in a recognizable form was Steinheim, in Germany, who in 1830 called it *hitziger Gelenkrheumatismus*, from its apparent relation to acute multiple articular rheumatism. A year later it was described by Dance, in France, who especially noted the intermittent character of the attacks of spasm. In 1844 it was described by Imbert and Goubeyre, and again in 1846 by Drepach. In 1852 Corvisart, after a careful study of the disease, published his treatise in which he suggested the name *tetany*, by which it has been since known. In 1860 Trousseau

discovered the effect of pressure on the large vessels and nerves of the arm in producing the contraction in the hand muscles, and suggested the name *contractures des nourrices*, because of its frequent occurrence in nursing women. In 1877 Chvostek described the markedly increased motor excitability of nerves known as Erb's symptoms. In 1890 Chvostek and N. Weiss discovered the phenomenon of facial and lip muscle contraction elicited by tapping the facial nerve. In 1887 Hoffman showed that in tetany even sensory nerves are overexcitable and L. von Frankl-Hochwart showed that only galvanic excitability is increased and faradic not. Later the same observer published a second monograph on the disease in Nothnagel's System of Medicine.

The relation of the thyroid gland to tetany appeared in the results of removal of the thyroid in Billroth's Vienna Clinic many years ago (1860-70) when tetany was found to occur in 13 out of 37 operations for removal. This event became so frequent that it resulted in a partial discontinuance of the operation, both for simple cases of goiter and for Graves' disease. The discovery that it was the loss of the little parathyroids was made by Gley,<sup>1</sup> confirmed by Vassale and Generali<sup>2</sup> who cleared up many difficulties which Gley had found. Indeed W. G. MacCallum, whose studies are the most recent and have greatly enlarged our knowledge, regards their paper as the first convincing one.

**Etiology.**—Tetany occurs in children and in adults, and when present in the latter, it has usually made its appearance in comparatively early life. It has been supposed to be rare in North America, but J. P. C. Griffith, in a noteworthy paper read before the Association of American Physicians in 1894, collected 72 cases occurring in this country. Of these, five happened in his own experience. It is rather more frequent in girls than boys. The disease is more common in Vienna and Heidelberg than anywhere else, especially in the late winter and early spring. L. von Frankl-Hochwart has shown that it occurs quite frequently among the shoemakers and tailors of Vienna.

Among possible causes may be mentioned digestive derangement, including dentition, dilatation of the stomach, hyperchlorhydria, and diarrhea; rheumatism, whence this form is sometimes called rheumatic tetany; osteomalacia; rickets; open wounds; laceration. Pregnancy, acute fevers, and diphtheria are also alleged causes.

The effect of removal of the thyroid and especially of the parathyroid glandules in producing tetany received consideration in the historical sketch. What relations the associated conditions just mentioned have with parathyroid disease is unknown. It has been suggested that gastric tetany and that of the infectious fevers is connected with disturbance of calcium metabolism, which is even more likely to be true of osteomalacia and rickets. Its presence in nursing women, as pointed out by Trousseau, may have to do with the drain of calcium in the formation of milk which is rich in calcium, and in pregnancy with the formation of the bones of the child. The analyses of MacCallum tend to confirm this explanation.

**Symptoms.**—The characteristic *spasm* is usually limited to the hands and feet, arms, and legs. In the hands the thumbs are flexed into the palms, the fingers firmly bent at the metacarpophalangeal articulation, but straight elsewhere. The fingers are adducted, the ring and middle fingers sometimes overlapping. The wrists are flexed, the elbows bent, and the arms folded over the chest. The hand is described as the obstetrical hand, from the position caused by the cramp. In the lower

<sup>3</sup>"Archives Italiennes de Biologie" (Turin), 1896, vol. xxv, pp. 459 to 464; 1896-97, vol. xxvii, p. 61-65. Translation of the same paper in the "Amenist and Neurologist," 1897, vol. xviii, p. 57-61.

limbs the knees and hips are stiff and extended, the feet extended, and the toes adducted. Sometimes there is dorsal flexion of the foot and flexion at the knee. Contractions may last from a few hours to several days. The term *continuous* may be applied to those cases in which the contractions have lasted uninterruptedly for over two days, and *intermittent* when they do not last longer than two days without permanent or temporary disappearance. Following this standard, Griffith found 38 cases intermittent and 25 continuous. The spasm is always associated with *tenderness* or *pain*, the latter being often extreme. At other times these symptoms are present only in the beginning of the attack or when the members are handled. Rarely the muscles of the back, neck, and face are involved; and there may be *trismus*, the angles of the mouth being drawn out.

Associated symptoms are *stridulous respiration*, regarded by some as an essential part of the disease or as a manifestation of the disease in the larynx.

Further interesting phenomena, especially studied and called cardinal symptoms, are *contraction caused by tapping the muscles*, as, for example, the pectoralis or the facial muscles, known as Chvostek's symptom. Another is Trousseau's symptom—the production of *spasm by pressure upon a large artery or nerve*, especially in the arm; and still another is Erb's symptom—*increased electrical excitability*. *Inability to urinate* may be present, and anesthesia has been recorded among symptoms. There may be *slight elevation of temperature* and *frequent pulse*.

**Diagnosis.**—The rarity of this disease sometimes causes it to be overlooked, while differences of view as to what constitute its essential symptoms also cause a different diagnosis. Thus, some would exclude the *carpopedal spasm* of children; while Gowers, Dana, and Griffith include these cases under tetany. Many cases of *mild spasm succeeding gastrointestinal irritation* and the like would be regarded by some as tetany and by others not. It possesses nothing in common with *tetanus*, whose name it so closely resembles, but whose symptoms are totally different.

**Prognosis.**—This is usually favorable, recovery taking place in from a few days to months. The fatal cases are those associated with dilated stomach, gastric carcinoma, and thyroidectomy. The disease has a marked tendency to return, and is most common in late winter and early spring.

**Treatment.**—The *cause* of the condition should be sought and, if possible, eliminated. After this, *remedies calculated to diminish nervous excitability* should be administered; also wholesome hygienic measures availed of, including *massage*, *passive motion*, and *electricity*. *Warm baths* are especially recommended. The cases attended with severe pain may require the hypodermic use of morphin, and delayed response to the latter may even demand chloroform inhalation.

The rational treatment of tetany includes any measure which will restore the function of the parathyroids. Parathyroid may be administered by the mouth, but the effect is found to continue only so long as the administration is continued. The hypodermic injection of a serum from the same source promises more permanent results, but most promising of

all is the transplantation of the parathyroid itself into the spleen, as suggested by Pays and repeated by Halsted, using as large a portion of the thyroid as will presumably contain parathyroid structure.

## NEOPLASMS OF THE THYROID.

The thyroid is subject to a variety of morbid growths, among which may be mentioned:

1. *Adenoma*, which occurs as an encapsulated growth, varying considerably in size. There may be nodules in both lobes. Metastases of growths resembling thyroid tissue are reported to have been found in the lungs and bones of the body.
2. *Primary medullary cancer*, as a rare growth with a tendency to invade the trachea and esophagus, developed from the epithelial cells of the follicles. *Secondary cancer* has also been reported.
3. *Tuberculosis*, always supposed to be a possible but rare disease, has been found by Chiari in seven out of 100 postmortems on persons who had had tuberculosis. Bruns refers to six cases of tuberculous goiter.
4. *Syphilis*, including gummy growths. 5. *Hydatid disease*. 6. *Actinomycosis*.

*Abscess* of the thyroid is an occasional event.

The *treatment* of these abnormalities is surgical, except in the case of tuberculosis and syphilis, which demand the usual antituberculous and antisyphilitic remedies.

## DISEASES OF THE SUPRARENAL CAPSULES.

### ADDISON'S DISEASE.

**Definition.**—A term applied to any disease of the suprarenal capsule attended with pigmentation of the skin.

**History.**—Addison's disease was first described by Addison, of Guy's Hospital, in 1855, in a paper entitled, "The Constitutional and Local Effects of Disease of the Suprarenal Capsules." A surprisingly small number of facts has been added since Addison's original paper was published. Greenhow's paper is a noteworthy one written in 1866; also that of R. D. Rolleston, the Gulstonian lectures for 1895 on the "Anatomy, Histology and Morbid Anatomy of the *Suprarenal Bodies*."

**Morbid Anatomy.**—This includes (1) tuberculosis with fibrocaseous and calcareous degeneration; (2) cystic degeneration; (3) fatty degeneration; (4) simple atrophy; (5) chronic interstitial inflammation which may lead to atrophy; (6) malignant disease, including carcinoma and sarcoma; (7) hemorrhagic extravasations; (8) embolism. Whatever causes these morbid conditions constitutes the causes of Addison's disease. Blows on the abdomen or back may be such causes. It is more frequent in men, 119 men to 64 women.

**Symptoms.**—Some of these morbid states appear to be totally without symptoms, the conditions having first come to light at autopsy. Other symptoms may be produced by any of them, and there is none distinctive for any one state. They include:

*Pigmentation* or *bronzing* of the skin. This was first described by Addison as associated with disease of the suprarenal capsules, an association which, since the publication of his paper in 1855, has been called Addison's disease. The clinical concept thus named especially affects the lower classes, Dr. Greenhow having found nine-tenths of cases among laboring people. It is also a disease of adults, being rare under 35 years. The lesion most frequently thus associated is the fibrocaseous tuberculous one. But, as stated, the pigmentation may accompany any one of the above-named lesions, if prolonged, or may be absent. As to the *coloration* itself, which is usually the first symptom to attract attention, it varies from a light yellow to a deep brown, and even almost black. It is deeper on the more exposed parts of the body, where the normal pigmentation is greater, and therefore is commonly first seen on the face and hands. In rare instances only is it general. It is associated at times with unpigmented patches—leukoderma. It is noticeable also at times on the mucous membrane of the mouth, conjunctiva, and vagina, and very rarely even upon serous membranes in patches.

Great pains have been taken to explain this peculiar "bronzing," ascribed by Addison himself to the loss of function of the adrenals. Two chief theories have been suggested:

1. By experimental evidence it has been sought to show with some reason that these glands furnish some sort of internal secretion essential to normal metabolism. To explain those cases in which the adrenals are diseased and yet there is no pigmentation, it is suggested that accessory adrenals may be present, though none has been demonstrated, so far as I know; while the presence of pigmentation in association with healthy adrenals is ascribed to disease of the adjacent semilunar ganglia interfering in some way with the function of the glands. Such a theory, that a secretion furnished in health by the suprarenal capsule is necessary to normal metabolism, is analogous to that which ascribes myxedema to the loss of function of the thyroid gland, and has acquired some additional support from the knowledge recently added upon this subject.

2. According to the second theory, the pigmentation is due to disease of the abdominal sympathetic system itself, commonly associated with disease of the adrenals, but also at times caused by other chronic disorders which invade the solar plexus and ganglia. In one of my own cases in which all the symptoms, including pigmentation, were conspicuous, and which came to autopsy, there was found, in addition to advanced tuberculosis of the suprarenal capsules, also an enlarged semilunar ganglion. The latter view would make it a disease of the nervous system, and the pigmentation a trophic phenomenon.

As stated, there are no other symptoms which are distinctive of any one of the lesions of the suprarenal capsule described, but among those which are more or less constantly associated are *anemia*, *extreme debility* and *general languor*, *irritability of the stomach*, and quite often *diarrhea*. The irritability of the stomach is manifested by *anorexia*, *nausea*, and *vomiting*, and may be a very early symptom. The heart's action is feeble, the pulse correspondingly small and rapid, and there is also often a tendency to fainting. There is *dyspnea*. At other times there is *headache*.

*Mental hebetude* goes *pari passu* with bodily weakness, while the other symptoms commonly associated with the latter condition are also present—namely, dizziness and ringing in the ears. Ultimately, the *asthenia* becomes so profound that the patient cannot rise, but keeps his bed, growing weaker and weaker, until he dies of sheer exhaustion. Sometimes there are *convulsions*, possibly due to brain anemia.

The *urine* is usually normal, although occasionally there is polyuria, and sometimes the urinary pigments have been found increased.

**Diagnosis.**—It is probable that pigmentation alone, at least unless it be very decided and general, is never sufficient to justify a diagnosis of suprarenal disease, since other abdominal affections are known to produce a similar condition. Among these are tuberculosis of the peritoneum, cancer and lymphoma; pregnancy, uterine and even hepatic disease. The popular notion that every discoloration of the skin is due to some *derangement of the liver* (liver-spot) has scanty foundation. In the hardening of the liver sometimes associated with *diabetes*, pigmentation has been noticed. All these facts go to show that the nervous system must have some powerful influence, supporting the second theory. The same testimony is afforded by the pigmentation which attends *exophthalmic goiter*. *Protracted filthiness* and vagabondism also produce discoloration of the body which is not distinguishable *per se* from that of Addison's disease. Deep general pigmentation has been found associated with *melanotic cancer*. Finally, pigmentation is sometimes the result of the prolonged administration of *arsenic*. It is well, therefore, to seek carefully for signs and symptoms other than pigmentation before a diagnosis is made. In the case of my own referred to, there were pulmonary tuberculosis and tuberculous disease of the spine, with pigmentation and asthenia, on which was based the diagnosis of Addison's disease, confirmed by autopsy.

**Prognosis.**—In a well-determined case of Addison's disease, as might be inferred from the nature of the causes, recovery is impossible, though the course of the disease is commonly prolonged and improvement may take place. In a few cases only is the course rapid. From 18 months to several years usually cover the duration.

**Treatment.**—This is principally symptomatic. We aim to restore the condition of the blood, and, of course, above all, iron is indicated. It may be associated with that other tonic so constantly used with iron especially—arsenic. An excellent preparation of arsenic is the solution of the chlorid, which is as good as Fowler's solution and mixes well with the chlorid of iron. The doses are the same as those of Fowler's solution—from 3 to 5 minims (0.18 to 3 c.c.); or the iron and arsenic may be given in pill form as the carbonate of iron and arsenious acid, and to this strychnin may be conveniently added. If very asthenic, the patient should be kept in bed and fed with nutritious, easily-assimilable food, of which peptonized milk and broths, beef-juice, cod-liver oil, and glycerin are the type. The diarrhea should be treated as other diarrheas, with bismuth and other remedies. For the nausea the usual gastric sedatives, including ice, carbonic acid water, champagne, milk and lime-water in small doses, koumiss, whey, and the like are suitable, massage may be helpful.

With the knowledge which has grown out of the treatment of myx-

edema with thyroid extract, no treatment of the combination of symptoms known as Addison's disease would be complete without the administration of some similar preparation of the adrenal gland. There have been prepared an extract in the shape of the tincture, a powder and a glycerin extract; and the glands are eaten fresh or dried. The equivalent of two a day is recommended. Of the powder, 3 to 5 grains (0.2 to 0.3 gm.) are given three or four times a day. At the present day, solution of adrenalin 1-1000 would be employed in doses of from 5 to 15 minims or more. In an analysis by E. W. Adams of 97 cases, treated by suprarenal extract, there was seeming permanent relief in 16. In two cases treated at the Johns Hopkins Hospital, one died of an acute infection after all severe symptoms had disappeared, and at the autopsy the suprarenal bodies were found sclerotic. The remedy is still *sub judice*, and as the disease is rare some time must elapse before its value can be determined.

### DISEASES OF THE SPLEEN.

Most of the morbid states of the spleen which possess clinical interest are considered in connection with diseases of the blood and with malaria.

**SPLENITIS.**—Splenitis occurs rarely as the result of extension of inflammation from a neighboring organ, such as the stomach, perinephric tissue, the diaphragm and lungs, or as the consequence of injury.

The symptoms are *tenderness* and *enlargement* in connection with the inflammatory conditions of adjacent organs referred to, and it is upon the association of such symptoms with those in the spleen itself that the diagnosis depends.

**PERISPLENITIS.**—This may occur as the result of the same causes as produce splenitis, and may be recognized by the presence of palpable friction fremitus. It may be suppurative in association with abscess of the spleen giving rise to one form of subphrenic abscess.

**ABSCESS OF THE SPLEEN.**—Abscess of the spleen occurs along with pyemic processes elsewhere, in the presence of the usual causes of pyemia. It is characterized by tenderness and enlargement. A remarkable case associated with suppurative splenitis occurred in my wards at the Pennsylvania Hospital, after metritis following criminal abortion. It was also associated with luxuriant mitral valvulitis. Such abscess may break into the stomach, bowel, or lungs, as well as into the peritoneal cavity.

**RUPTURE OF THE SPLEEN.**—This arises from severe injury, also from extreme and sudden acute hyperemia, due to malignant malaria, and from rapidly growing splenic tumors. The symptoms are sudden pain in the region of the spleen, collapse, pallor, and death, associated with the causes named.

**THE AMYLOID SPLEEN.**—This appears as a hard, smooth, and enlarged organ, associated with amyloid disease of other organs, such as the liver and kidneys, especially when there has been long-continued suppuration, as in hip disease, osteomyelitis, tuberculous consumption, or syphilis.

**ATROPHY OF THE SPLEEN.**—On the other hand, the spleen may be reduced in size by fibroid overgrowth and contraction due to syphilis.

**HEMORRHAGIC INFARCT OF THE SPLEEN.**—Infectious hemorrhagic infarct results in abscess of the spleen. The noninfectious is the result of embolism by a noninfectious embolus such as arises from the cardiac valves in acute or chronic endocarditis, from clots in the cavities of the left ventricle, or from clots in aneurysm in the large arteries. After the kidney, the spleen is the most frequent seat of such lodgement.

**Symptoms.**—The infarction is sometimes ushered in by chills, vomiting, and painful enlargements, the true nature of which can only be inferred when the causes named are present or the symptoms of embolism elsewhere occur simultaneously.

**NEOPLASMS OF THE SPLEEN.**—These are represented most frequently by gummy tumors, which are almost never recognized before death. *Carcinoma*, *sarcoma*, and *tuberculosis* occur, but are not recognizable by special characters. A nodular and uneven spleen may be regarded as due to cancer when associated with cancer elsewhere, sarcomatous when there is general sarcoma, tuberculous if there is tuberculosis elsewhere, and syphilitic if associated with the history of syphilis, especially the congenital form.

**ECHINOCOCCUS OF THE SPLEEN.**—The spleen may present a fluctuating tumor the nature of which can only be determined by the certain knowledge that a tumor of the same kind exists elsewhere, or by the recognition of hooklets in the aspirated fluid. Should the fluctuating tumor be associated with chills and fever, it is more likely to be abscess, which, it is to be remembered, may also begin as echinococcus disease which later takes on suppuration.

**WANDERING SPLEEN.**—This is a term applied to a condition of the spleen analogous to the movable kidney and liver. It is the direct result of an elongation of the gastrosplenic ligament and splenic artery and vein. Under these circumstances the usual splenic dullness in the midaxillary line, between the ninth and eleventh ribs has disappeared, and the spleen can usually be felt elsewhere in the abdominal cavity, usually, however, on the side below its normal site, whence it may be pushed into the natural situation, to leave it immediately as the upright position is assumed. Rarely, it is found in more distant situations, even in the pelvis. At times it may form attachments by inflammatory adhesion in the new situations, making its restoration difficult or impossible.

**Symptoms.**—The symptoms are not unchanging. The most constant is a *dragging sensation*, while there may also be the *effects of pressure*, which vary with the situation. There may be pressure on the ureter or bladder, causing difficulty in micturition; upon the bowel, causing partial obstruction or pain from compression of sensitive parts. The same train of nervous symptoms which attends floating kidney may also be present.

**Diagnosis.**—Some difficulty of diagnosis may result in consequence of such vagueness of symptoms. There may be a question between the existence of wandering spleen and *fecal tumor*. With the former, the

normal splenic dullness is wanting, though the well-known fact that the dullness is sometimes very small in health may give rise to error. A freely movable *cancer of the pylorus*, a tumor so movable that it may be felt in the left hypochondrium, may occasion similar difficulty, which must be settled in the same way. And so with other abdominal tumors of movable nature—the normal splenic dullness remains. The question as to whether a *movable* organ is the spleen or *kidney* is not likely to be a knotty one, even if the movable kidney be the left, if the same guide be availed of. The difference in outline of the two organs may be recognized in persons with thin abdominal walls, and, in rare instances, by the splenic notch. The possible coexistence of a movable spleen and a movable kidney is to be remembered.

**Treatment.**—The treatment must consist of mechanical measures to keep the spleen in place—measures which must be determined by the requirements of each case. They are variously successful.

## SECTION VII.

### DISEASES OF THE URINARY ORGANS.

#### GENERAL SYMPTOMATOLOGY.

Three important symptoms more or less characteristic of diseases of the urinary organs, and especially of disease of the kidneys, may, for the sake of brevity, be considered at the outset of our studies of these affections. They include *albuminuria*, *renal dropsy*, *uremia* and *tube casts*.

#### ALBUMINURIA.

**Definition.**—By albuminuria is meant a condition of the urine in which it contains some one of the forms of albumin of which at present we need consider only serum albumin and globulin. The sources of the albumins in urine are various, and may be conveniently divided into *extrarenal* and *renal*.

#### EXTRARENAL ALBUMINURIA.

The pelvis of the kidney, the ureters, the bladder, the urethra, and in the female the vagina and uterus in addition, are the most important sources of extrarenal albuminuria. In all of them it is almost invariably the serum of *pus* formed during catarrhal inflammation which furnishes the albumin. The presence of pus-corpuscles, therefore, in sufficient number in the urine commonly explains the source of such albumin, which is, moreover, usually small in quantity—never more than about one-tenth the volume of urine tested, even with the most copious sediment of pus. It must not be overlooked, however, that the two sources, kidney disease itself and the mucous surfaces referred to, may coexist, in which event careful microscopic examination will sooner or later discover tube-casts, while the quantity of albumin will be larger than can be accounted for by the presence of pus alone.

Menstrual or lochial blood need only be referred to as sources of albumin in the urine hardly likely to be overlooked by any physician; while hemorrhage from any one of the mucous surfaces referred to, as well as from the kidney itself, would be a source of albuminuria. It is usually comparatively easy to determine whether a hemorrhage has its source in the kidney or in the mucous membranes previously mentioned. In the former coagula are rarely present, for the blood, entering the ureter slowly, becomes intimately mixed with the urine. It imparts to it, too, when acid in reaction, a *smoky hue* which is very characteristic. The coloring-matter of the corpuscles is commonly dissolved out by the urine which is thus tinged, and on standing, the stroma of the corpuscles sinks

to the bottom as a brownish sediment. The microscope reveals these corpuscles shrunken, almost colorless, and often crenated. I have said that the smoky hue is present only in acid urine. When the latter becomes alkaline, either by spontaneous or artificial change in reaction, it assumes a brighter red hue, the degree of which depends upon the quantity of blood. The same cause, acidity, produces the smoky hue of blood which is vomited, and therefore mixed with gastric juice. When blood comes from the pelvis of the kidney or the ureter in any quantity, coagula which are molds of the ureter are sometimes found, the descent of which is often attended with severe pain.

Another source of albuminous urine, though not likely to cause error, should be mentioned—viz., the so-called chylous urine, or chyluria, in which in consequence of some as yet imperfectly understood communication between the lymphatic system and the urinary tracts, chyle enters the urine and imparts its physical and chemical characters thereto. These are the presence of albumin, and a milk-white appearance due to the presence of fat in a molecular state.

The kidney itself may be the seat of suppuration, and contribute through the pus thus added to an albuminuria.

#### RENAL ALBUMINURIA.

**The Immediate Cause of Renal Albuminuria.**—Albumin is usually considered as transuded into the glomeruli, but it may also pass through the intertubular blood-vessels and lymph-vessels into the urinary tubules so that either a glomerulitis, irritation of the parenchyma of the kidney, derangement of the circulation, or change in the blood may be presupposed whenever albuminuria exists. Delayed circulation of the blood through the glomeruli is doubtless of itself sufficient to cause albumin, to pass through the walls of the capillary blood-vessels into the urine, though it is more than probable that an altered state of the renal epithelium also contributes to a facility of transit. The necessary obstruction is produced by any cause which sufficiently resists the movement of the blood through the kidneys, whether it resides in the organ itself or in the venous system beyond it, whence the albuminuria which so often attends extreme valvular disease of the heart. The comparative smallness of such albuminuria as contrasted with that in parenchymatous nephritis, in which the renal cells are an early seat of change, is strong evidence in favor of some active participation of epithelial change in causing albuminuria. In chronic albuminuria another important influence operating to facilitate the transudation of albumin is a hydremic state of the blood, which is in turn a consequence of albuminuria. The use of oversalted foods is held to increase albuminuria when the kidneys are diseased, such food causing chlorid retention (see p. 755).

Renal albuminuria also occurs as a secondary symptom in diseases other than renal. First may be mentioned the albuminuria of fever, such as that of typhoid fever, small-pox, etc. The albuminuria of diphtheria and scarlatina, due to an intercurrent parenchymatous nephritis, is, of course, not intended. The febrile albuminuria alluded to is not usually large, and disappears with the decline of the disease. It is in great measure

the result of irritation of the kidney by the infectious agent; possibly also, in part, the result of diminished cardiac force with which the blood is driven through the kidneys and of the resulting turgor.

Other conditions in which albuminuria thus occurs are anemia, leukæmia, diarrhea, cholera, lead colic, also certain conditions of the brain and spinal cord, including hemorrhages into the brain, meningitis, epilepsy, tetanus, and others. In all of these there is probably diminished arterial pressure directly or indirectly through the nervous system.

The significance of renal albuminuria has altered greatly as our knowledge of this subject has increased. While large albuminurias of renal origin can scarcely be due to anything else but renal disease, and the degree of albuminuria is within limits a measure of the seriousness of the disease, yet the important fact remains that there may be true albuminuria, usually moderate, in which there is no disease of the kidney whatever; there may also rarely be Bright's disease in which there is no albuminuria. The significance of albuminuria is always increased by its association with tube-casts, yet there may be both albumin and casts in urine where there is no Bright's disease, while again, there may be Bright's disease without albumin or casts. I myself incline to the belief that such cases are infrequent, and yet this possibility must be acknowledged. In illustration of what has been said I may refer to:

*Physiological or Functional Albuminuria.*—The possibility of a physiological or functional albuminuria at the present day is generally conceded. By it is meant an albuminuria unassociated with other symptoms. There are no tube-casts or feeling of ill-health. Such albuminurias are often discovered accidentally, especially by examiners for life-insurance. Much care should be exercised in concluding upon the nature of an albuminuria suspected to be functional. In the first place, it should be small, not exceeding one-tenth the bulk of urine tested, and though it is not necessary that it should be absent on rising, yet it is a strong point in favor of the functional nature if it is absent at this time and present only after some exertion has been made or on taking food. No tube-casts should be in the urine, the urea should be in sufficient quantity, there should be no retinal change, no hypertrophy of the left ventricle, no high tension to the pulse, nor even a suggestion of dropsy. Further, this condition should be watched over a considerable length of time before the conclusion is arrived at that we have to do with a harmless functional albuminuria.

*Other proteid matters* are sometimes found in the urine, such as globulin, mucin, peptone, and hemialbumose, but, except in the case of globulin, their clinical significance is not sufficiently determined to justify their further consideration in a text-book. A certain amount of *globulin* is always associated with albumin. In an ordinary serum albuminuria the ratio commonly maintained is 10 to 18 of serum albumin to one of globulin, the ratio in the blood being one of serum albumin to 1 1/2 to 3 of globulin. A like ratio holds for these constituents in pus.

This ratio in albuminuria is at times exceeded, especially in the case of the amyloid kidney, where I regard the presence of globulin in large amount as of diagnostic value.

## TESTS FOR ALBUMIN AND GLOBULIN.

TO TEST FOR ALBUMIN.—The test which is at the same time the most delicate and reliable is the heat-and-acid test. It is best applied in the following manner:

*The Heat-and-Acid Test.*—A suitable quantity of urine, filtered if not clear, is poured into a test-tube, say to a depth of five cm. (two inches), and boiled over a Bunsen flame or spirit-lamp. Then nitric acid is added, drop by drop, until from 10 to 15 drops are added to this quantity of urine. Any precipitate produced in the act of boiling which is dissolved by the acid is phosphates. After the total quantity of acid has been added the tube is placed aside for half an hour, and if at the end of this time no further precipitate appears, the specimen may, for clinical purposes, be declared free from albumin. It is very important that the acid should not be added first, as is sometimes directed, for it often happens when a considerable amount of albumin is present, acid albumin is formed which is not precipitable by heat, and thus such quantities of albumin may elude detection. The test of heat and acid applied in the manner described is really more delicate than the contact method with nitric acid, recognizing, as it does, smaller quantities of albumin.

*The Contact Method with Nitric Acid, or Heller's Test.*—On the other hand, the contact method with nitric acid is free from the error possibly occasioned by acid albumin to which the heat-and-acid test is subject. The contact method, also known as Heller's test, is best done by placing a sufficient quantity of nitric acid in the bottom of a test-tube and overlaying it gently with urine. If albumin is present, a sharp white line will promptly form above the acid. A dark, reddish-brown color-line which forms in concentrated urines at this point will not, of course, be confounded with albumin. Furthermore, in concentrated urines a layer of acid urates, dirty white, is sometimes found at the junction between the two fluids. It behaves very differently, however, from the sharp white line of albumin, since it soon begins to rise above the surface, while the albumin remains at its primary position. Further, this less definite layer is promptly dissipated on the application of a moderate heat. When the heat-and-acid method and the contact method are jointly used in the way described, it is impossible for such an amount of albumin as is of clinical significance to elude detection. It is true that picric acid solution, Tanret's iodo-mercuric solution, and one or two others are slightly more delicate than the heat and acid, but they are subject to a now generally acknowledged source of error, the precipitation of mucin and of the vegetable alkaloids of which quinin is the type, which always appear in the urine when administered in full doses.

*The Picric Acid Test.*—As confirmatory test, however, the picric acid solution is very useful, and if its application is negative, we may feel assured that there is no albumin present, while a delicate response is doubtful, for the reason named. The picric acid test is also best applied in the contact method, the urine being placed in the tube first and overlaid with the saturated picric solution, because the picric acid is commonly lighter than the urine to be tested. When they are of the same specific gravity,

it is not easy to maintain a separation at the line of contact, but a careful examination of the fused portions will recognize a diminished transparency due to either mucin or albumin. A saturated solution of picric acid should always be kept on hand for the control purposes named.

**TO TEST FOR GLOBULIN.**—Globulin may be separated by Poehl's method as follows:

Render the urine slightly alkaline by ammonium hydrate, and after several hours filter, to separate the phosphates. Then add saturated neutral solution of ammonium sulphate in the proportion of one volume to one volume of the filtrate. If a precipitate forms, it is globulin.

### RENAL DROPSY.

Renal dropsy does not differ essentially from cardiac dropsy, though it is less directly traceable to venous obstruction and consequent transudation. It very frequently appears first in the face and upper extremities, and this fact alone goes to show that something else than obstruction to the circulation enters into its causation. In addition, it is well known that there may be advanced renal disease without dropsy when one would naturally expect obstruction. Venous obstruction must, however, be considered as one of the contributing factors, especially when in the lower extremities. Aside from this we must have recourse to theory to explain it. A hydremic state of the blood very probably favors the transudation in certain cases, this being occasioned by the deficient water secretion so often present. At first thought this would seem an explanation scarcely sufficient to explain the edema which appears so early in many cases of acute Bright's disease, but this objection is more apparent than real, for one need pause but for a moment to realize how quickly blood may become hydremic with an almost total anuria, while the habitual quantity of water continues to be ingested daily. Moreover, diminished urinary secretion often exists for some time before attention is called to it. I believe that sufficient stress has not been heretofore laid on this factor.

As the disease advances, the conditions favoring the hydremic state continue and grow so that in advanced stages this element doubtless contributes largely. It is more than likely also that in such stages alterations of some kind in the vascular and lymphatic walls contribute to facilitate the transudation, while the diminished elasticity of surrounding tissues may also constitute a factor. Where edema does not occur, its absence can only be explained by the presence of continued secretion of water by the kidneys or by supplemental secretion by some other organ, as the skin and bowels.

**Chlorid Retention.**—Strauss, in Germany, and Widal and Javal, in France, in 1902 and 1903 called attention to the fact that there is an abnormal quantity of sodium chlorid in the tissues of persons affected with renal dropsy, reporting cases in which it was possible to cause edema to appear and disappear almost at will by varying the amount of chlorid in the diet. The rationale of these events is supposed to be as follows: In nephritis

the ability of the kidney to excrete chlorid is decreased, whence their accumulation in the tissues and the consequent accumulation of water in the same tissues in order to keep the chlorids in solution. Although there appear to be exceptions and the parallelism is not always demonstrable, the correctness of the statement is generally admitted. An opposite theory, that the primary trouble in nephritic edema is the retention of water to which the retention of salt is secondary, is not sustained by the weight of evidence. Chlorid retention has been observed in some cases of cardiac dropsy and with some cases of edemas occurring in patients with inflammatory disorders, but there is no evidence to show that there is any causal relation between the two conditions or that the chlorid retention is more than can be explained by the retention of fluid in the edematous parts. The effect of chlorid retention is also to increase albuminuria.

The degree of dropsy varies greatly in different cases and different forms of Bright's disease, being in some cases trifling and in others enormous, including, ultimately, invasion of serous cavities like those of the pleura, peritoneum, and even pericardium.

### UREMIA.

The third symptom common to renal disease and, indeed, peculiar to it, is uremia. It may be defined in general terms as a condition due to retention within the blood of excrementitious substances which it is the function of the kidney to excrete. When we come to separate these substances, we are, however, completely at a loss, for no clinical or experimental studies have as yet given us the required information. Preeminently the experimental introduction of urea into the blood has repeatedly failed to excite symptoms of uremia, though the animals on which these experiments were made were presumably sound. Ligation of the renal veins has been equally futile in producing them. C. A. Herter has shown that the toxicity of the blood-serum is increased in uremic states, while extirpation of the kidney or a part of it increases the accumulation in the blood of urea and nitrogenous substances of the creatin class. It is probable also that the alloxuric bases, xanthin, hypoxanthin, which are virulently toxic, contribute to the sum of toxins responsible for uremia. Retained ammonia was held responsible by Frerichs and others. Most recently Croftan has sought to show that uremia is dependent on insufficiency of the liver.

In consequence of such failure, clinicians—and preeminently Rees and Traube—sought to explain certain of the more active nervous symptoms, such as the coma and convulsions, by supposing a localized edema of the brain or its membranes.

**Symptoms.**—It is not unlikely that *gastrointestinal symptoms* including the loss of appetite, nausea, vomiting, and headache which sometimes usher in an attack of nephritis may be the result of retained excrementitious matter. At all events, these same symptoms may be the initial ones of a uremia, coming on suddenly when the cause is unsuspected. Vomiting thus caused may persist, and the patient perish in consequence. *Headache* is often occipital, extending down the neck. To it is superadded *dizziness*.

An early symptom is *drowsiness*, which may be sudden or gradual in its onset and may be slight or decided. From the latter degree the transition is easy to the next symptom, that of *coma*, from which the patient may or may not be temporarily aroused. Alternating with the latter may be epileptoid *convulsions*, which are the most alarming and dangerous symptom of Bright's disease. This is not always the succession of these symptoms. Convulsions may succeed drowsiness, but as often precede, and they may occur without warning. Indeed, there may be no suspicion of Bright's disease whatever until a convulsion suddenly occurs. Drowsiness, in like manner, may be the first symptom of the renal disease to attract attention, others being overlooked or possibly even absent. The convulsion exhibits every grade of movement, from the slightest twitching to the most violent epileptiform spasm.

*Suppression of urine*, an almost constant symptom, is frequently the initial one which should at once excite suspicion. Accompanying it is often a breath of urinous odor, and when vomiting accompanies scanty or suppressed urine, the vomited matters sometimes have the same odor, the elements of urine being thus supplementarily eliminated.

*Impairment of vision or actual blindness—amaurosis*—suddenly occurring is another symptom of acute uremia which sometimes supervenes upon others, or it may itself usher in the complication. This blindness, it must be remembered, is altogether different from that which is the result of organic retinal changes, which are rare in acute nephritis, but common in some of the chronic forms. It may be due to retinal hemorrhage but is often unassociated with demonstrable retinal change. Uremic amaurosis often disappears as suddenly as it sets in. Uremic *deafness* is also possible, but is a rare event.

*Itching of the skin* is another symptom sometimes present in uremia. It is probably due to the irritant action of urea upon the nerves of the skin as it is being supplementarily eliminated by that organ. That such increased elimination takes place is attested by that rare but still unquestioned occurrence, in which the entire integument is covered with a frost-like coating, which has been found upon analysis to be made up of crystals of pure urea.

Another symptom of uremia which belongs rather to the uremia of chronic renal disease is shortness of breath—*uremic asthma*, it is called. This is an asthma which differs from bronchial asthma in the absence of spasmodic contraction of the bronchi, and its uremic origin, I think, is extremely doubtful. I believe it is more frequently a cardiac asthma, due to heart failure, the result of dilatation succeeding some cases of hypertrophy. It may happen that true spasmodic asthma is produced by uremia, but it must be exceedingly rare. The attacks are likely to occur suddenly at night. To it alone should the name uremic asthma be given. Paroxysms of dyspnea are also caused by edema of the lung, which is not infrequent in acute nephritis. It is recognized by the presence of fine, moist râles. Of course, it is not impossible for nephritis to occur in an asthmatic, whose attacks would then occur as before, independent of the uremic cause, or they might be increased in frequency or rendered more unmanageable by the latter.

*Cheyne-Stokes breathing* is also a symptom of uremia and may last for a long time. It may occur quite independent of coma. It is more than likely that other disturbances of breathing, even some which closely resemble dyspnea, may be due to disturbances of the respiratory center.

The question of *temperature* in uremia has not been satisfactorily determined. My own experience points to the absence of any elevation, with at times a tendency to subnormal temperature. I am aware that studies have been published which go to show that an abnormally high temperature is characteristic, and this may exceptionally be the case. But in true, uncomplicated uremia I believe in the majority of cases the temperature will not much exceed the normal. It is true, too, that toward the very end there is commonly a rise, but this attends dissolution in so many diseases that it cannot be considered characteristic.

The *pulse* is often slow in uremia before the appearance of severe symptoms: sometimes as infrequent as from forty to fifty, but with severe symptoms it becomes frequent.

*Acute mania* and *delusional insanity* (*Folie Britique*) may also be symptoms. Such acute delirium is not very frequent and I believe other conditions are sometimes mistaken for it, as for example the delirium of *mania a potu*. Rarely melancholia and paralysis, including hemiplegia and even monoplegia are symptoms. These may occur independently of a convulsion or succeed it, in which event there may or may not be any coarse lesion found at necropsy. True uremic palsies are of undoubted occurrence. I have met hemiplegias which could not be distinguished from those of apoplectic origin until their total disappearance cleared up the matter.

The following table, although not distinctive gives a general idea of the differences between the effects of cerebral hemorrhage, alcoholic narcosis and uremia.

CEREBRAL HEMORRHAGE.	ALCOHOLIC NARCOSIS.	UREMIA.
Pupils unequal or dilated.	Pupils contracted or dilated; eyes injected.	Pupils generally dilated; albuminuric retinitis.
Stertorous puffy breathing and flapping cheek.	May be stertorous breathing.	Stertorous breathing.
No odor.	Odor of alcohol.	No odor, unless urinous.
Paralysis; hemiplegia.	No paralysis usually.	Paralysis usual, but may be atypical.
Pulse slow and strong or irreg.; arteries often sclerotic.	Pulse frequent and feeble.	Pulse at first strong, later weak and rapid; tension strong; arterio-sclerosis.
Coma sudden and deep.	Coma gradual.	Coma gradual or sudden.
Convulsions late; may be unilateral.	No convulsions.	Preceded by general convulsions, headache, etc.
Urine generally negative.	Urine generally negative although patient may have Bright's disease.	Urine albuminous.
Apoplectic habit; heart may show hypertrophy.	Red face and nose, heart often weak and dilated; myocarditis.	Edema and pallor; heart hypertrophied.

## TUBE-CASTS.

Tube-casts or "cylinders," as they are sometimes called, are molds of the uriniferous tubules. Their origin is not always the same. They may be produced by the coagulation of a fibrinous constituent of the blood which having exuded into the tubule entangles whatever it may have surrounded in its liquid state; subsequently it may contract and slip out of the tubule into the pelvis of the kidney, whence it is carried to the bladder and voided with the urine. Casts rarely exceed  $1/25$  inch (1 mm.) in length.

Two other possible modes of formation of casts must be mentioned, according to one of which the cast represents disintegrated and fused cells which may be the epithelial lining of the tubules, red corpuscles, or leukocytes; and according to another, of a secretion from these same cells as originally suggested by Rovidó. That casts are sometimes formed according to the first, at least, of these two methods is not unlikely, while there is

FIG. 71.—Epithelial Casts and Granular Fatty Renal Cells.

FIG. 72.—Pus Cast.

FIG. 73.—Blood Casts—(after Whittaker).

reason also to believe that the so-called "cylindroids" or mucus-casts originate in the second way.

That casts are sometimes found in urine free from albumin is undoubtedly true. That persons in whom such casts occur are entirely healthy cannot be as unqualifiedly asserted.

The mechanism of the formation of the different varieties of casts, on the supposition of an albuminoid exudation from the blood, is very simple. Thus, suppose a tubule to be filled with detached and loosely attached epithelium at the time the coagulable material is poured into it. These elements are entangled, and, as the casts contract, are carried out in the shape of an "epithelial" cast (Fig. 71). If the tubule should happen to have contained blood, the cast entangling it is called a "blood-cast" (Fig. 73); if white corpuscles or leukocytes, a "pus-cast" (Fig. 72). Casts containing even a few blood-corpuscles are also called blood-casts. The basic substance of blood-casts is most probably the fibrin of the blood. If the epithelium be firmly attached to the basement membrane of the

tube and remain behind when the cast passes out, or if the tube be entirely bereft of epithelium, then is the cast a "hyaline" (Fig. 74) or structureless cast. In the former instance the cast is of *smaller* diameter, and in the latter of *larger*, the diameter in the latter being that of the former plus twice

FIG. 74.—Hyaline Casts.  $\times 210$ .

FIG. 75.—Hyaline and Granular Casts. Illustrating the Formation of the Former at *a*.—(*Rindfleisch*).

the thickness of an epithelial cell. Figure 75, *a*, from Rindfleisch, explains this sufficiently. From causes like these, as well as a subsequent contraction of the cast itself, the diameter of casts may vary considerably, ranging commonly from  $1/2500$  to  $1/500$  inch (0.01 to 0.05 mm.). A cast

FIG. 76.—*a. a.* Dark Granular Casts. *b. b.* Casts Partially Hyaline, Containing Oil Drops and Granular Matter.  $\times 225$ .

FIG. 77.—Waxy Casts.  $\times 150$ .

is seldom completely hyaline, generally containing a few granules and sometimes one or two glistening oil drops, but it is still called *hyaline*. Completely hyaline casts are, however, not infrequent. A variety of hyaline cast, more solid in appearance and resembling molten wax, is a "waxy

cast" (Fig. 77). Some hyaline casts are so delicate as to be overlooked unless the light from the mirror illuminating the field of view be modified by shading with the hand or by manipulation of the mirror itself. If a cast contains granular matter, which is generally the granular debris of the degenerated epithelial lining of the tubule or blood-corpuscles, it is called a "*granular*" cast, and *highly granular* (Fig. 76, a), *moderately* or *pale granular* (Fig. 75, c), *slightly* or *delicately granular* (Fig. 75, b), according to the amount of granular matter present. When the material of granular casts is derived from broken-down blood-corpuscles, the casts appear yellow or yellowish-red. Finally, if a cast is loaded with oil drops, either free or contained in epithelial cells, it is called an "*oil cast* or *fatty cast*" (Fig. 78).

Casts of smaller diameter are sometimes found within those of larger, the material of the latter having been poured out around that of the former after it has undergone some contraction. This occurs usually with waxy

FIG. 78.—Oil-Casts and Fatty Epithelium.  $\times 200$ .

FIG. 79.—Cylindroid or Mucus Casts.  $\times 200$ .

or hyaline casts. In consequence of the mode of formation previously referred to, hyaline and waxy casts vary considerably in diameter, some being as narrow as  $1/1000$  inch (0.025 mm.) and even narrower, while others are as much as  $1/500$  inch (0.05 mm.) wide. There is no doubt that some of these are formed in the straight or collecting tubes near their openings on the papillæ. To these a limited number of epithelial cells is sometimes attached.

In addition to the epithelial casts previously described, there are found in urine under the same circumstances molds of the uriniferous tubules made up of simple *aggregations* of the *epithelial cells themselves*—simple exfoliations of the cellular contents of the tubule, which, having increased by proliferation, form a compact cellular mass. In addition to this are sometimes found epithelial casts in which the cells are seated on the outside or around the fibrinous mold.

**Mucus-casts, Cylindroids.**—Casts are occasionally found which are apparently pure *mucus-molds* of the uriniferous tubules (Fig. 79). Unless covered by accidental elements, as granular urates or phosphates of lime, they are smooth, hyaline, or gently fibrillated molds, especially

characterized by their great length, in the course of which they divide and subdivide, diminishing in diameter as the division proceeds, showing positively that they come from the kidney. Yet there is no albumin, or merely as much as could be accounted for by the presence of pus which sometimes attends them. For they are particularly apt to occur where there is irritation of the bladder, which is apparently extended through the ureters of the kidney. Under these circumstances they are frequently met. They are not infrequently voided in cases where the urine has a very high specific gravity, 1030 or higher, containing an excess of urea and urates.

These casts are not identical with the bands of mucin which are found in urine of highly acid reaction. The mucin bands are probably precipitated by the acids, are often beset with granular urates, and might on this account be mistaken for casts. At the same time the mucus-cast is probably nothing but pure mucus or mucin.

## DISEASES OF THE KIDNEY.

### DERANGEMENTS OF CIRCULATION.

#### ACTIVE CONGESTION.

**Etiology.**—Active congestion occurs as the result of poisoning by cantharides or arsenic, overdoses of turpentine, copaiba, cubebs, and carbolic acid. It is identical with the first stage of acute nephritis, however caused. The kidney in acute fever has usually been considered as actively congested, but recent experiments by Walter Mendelsohn go to show that the kidney in fever is really anemic, small, pale, and bloodless, so that the kidney is really comparable to the anemic kidney of cholera, in which, too, there are albuminuria and nutritional changes of a degenerative kind analogous to the cloudy swelling affecting the renal cells in acute fever, but more advanced in degree.

**Morbid Anatomy.**—The kidney of active congestion is slightly enlarged, swollen, and, after removal of the capsule, brown or mottled. On section, the cortex is wider and darker than in health, the blood-vessels are overfull, the Malpighian bodies are distended, and the cells are the seat of cloudy swelling. The medulla is less markedly red and sharply defined from the cortex.

**Symptoms.**—There are none except a scanty urine of high specific gravity and high color, sometimes small albuminuria, with a few hyaline and pale granular casts.

#### PASSIVE CONGESTION OR CYANOTIC INDURATION.

**Etiology and Pathogeny.**—While any agency which obstructs the movement of the blood through the kidney may cause passive congestion, the causes encountered in actual practice are mostly limited to valvular disease of the heart and chronic pulmonary disease involving extensive areas of the lung, such as emphysema, interstitial pneumonia, and pleurisy,

with extensive effusion or marked adhesions. Tubercular phthisis is a less common cause, because of the impaired nutrition and small quantity of blood. Pressure on the renal veins by tumors, the pregnant uterus, or ascitic fluid acts similarly.

In any event the mechanism of its production is the same. The blood is crowded into the venous side of the vascular system. In mitral insufficiency the blood is regurgitated from the left ventricle into the corresponding auricle, and thence into the lungs; the latter organs become engorged, and again resist the entrance of blood from the right side of the heart, whence it is backed into the right auricle and valveless vena cava. The smaller veins of the extremities at first resist the encroachment by means of their valves, but the veins of the abdominal viscera, including the liver and the kidneys, are without valves, and are first, therefore, to receive the brunt of the stagnation, and they become engorged with blood. In pulmonary or pleural disease the obstruction begins in the lungs instead of in the heart, but the mechanism is the same. Pressure by tumor on the renal vein is even more direct.

**Morbid Anatomy.**—The kidney of cyanotic induration or passive congestion is hard, firm, and bluish-red as to its external surface. In the earlier stages it is enlarged simply from the presence of the large amount of blood detained in its vessels. The stellate veins are unusually distinct. The capsule strips off easily, and on section the enlargement is found to involve the cortex, but the veins of both cortex and medulla are engorged, that of the straight veins causing the medulla to appear darker in hue than the cortex. The Malpighian bodies, on the other hand, are not always engorged. The cut surface of the kidney is moist and succulent, but the microscope reveals no further changes either in the cortex or the medulla, the epithelium being unchanged.

After some duration the kidney is slightly if at all larger than the normal organ, though rarely smaller. The other superficial characters of hardness, smoothness, and bluish-red color, however, remain. Sometimes there appears a slight tendency to lobulation. At this stage the capsule does not strip off quite so easily as usual, but may drag small portions of the parenchyma with it. There may then be seen some shallow depressions. On section, the vessels are less turgid, and the relations of the cortex and medulla are not much altered. There may be a slight overgrowth of interstitial tissue and a small-celled infiltration between the tubules. The malpighian bodies are sometimes shriveled, and the epithelium of the tubules is granular and slightly fatty.

**Symptoms.**—These are primarily those of the diseases of which it is the consequence, of which I will emphasize only *anasarca*, because of its importance. To such is superadded *scanty urine of high specific gravity*, containing usually a small amount of *albumin* and a few *small hyaline casts*.

The dropsy first involves the lower extremities, in the area drained by the inferior vena cava. There also occur, however, effusions into the pleural sac and peritoneum, and the hands and arms may be involved.

The *urine* is scanty and of high specific gravity, often 1030 to 1035, and even higher. It is turbid with urates, depositing a copious sediment

of them and of uric acid. The albumin is usually small in quantity, but may become larger if the obstruction to the movement of the blood is great. The casts are small, transparent, or faintly granular, and not numerous—indeed, often absent. Blood is rarely present, while its presence may be considered evidence of a superadded nephritis. The solids are secreted in normal amount. In fact, such kidneys can apparently be restored to their normal function at any time by proper treatment. *Uremia is exceedingly rare.* Very rarely does it happen that an interstitial nephritis is produced.

**Diagnosis.**—Passive congestion exists to a certain degree in all cases of valvular heart disease without compensation, but higher degrees may be suspected when the urine becomes scanty and albuminous, and when all the symptoms of the cardiac affection become aggravated. When the physician sees the patient after the symptoms of passive congestion have become marked, it is often a nice question to decide which of the two conditions is primary, the cardiac or the renal condition; but this subject will be further considered in treating of the relations between kidney disease and heart disease.

**Prognosis.**—With the addition of the renal complication, the inconveniences and annoyances of the cardiac disease become greatly aggravated, while the difficulties in the way of successful treatment are greater. Yet the results which sometimes follow appropriate and energetic treatment and the substitution of favorable for unfavorable hygienic surroundings, such as succeed the admission of a neglected outcast to the wards of a hospital, are often astonishing. Under these circumstances it is not unusual for the dropsy to decline, the albumin and casts to disappear, and the patient to be restored to comparative comfort, without, however, any change in the original lesion, which, upon the slightest provocation, may reexcite all the symptoms.

**Treatment.**—As intimated under prognosis, the substitution of favorable for unfavorable hygienic surroundings, if the former exist, is the primary requisite. Shelter, warmth, rest, and good food are indispensable. After this digitalis is the sheet-anchor, for evident reasons. We have here to deal with a dilated, weak, failing heart, unable to drive the blood forward. Its power must be increased, and we have a remedy capable of doing this in digitalis. Sufficient doses must, however, be given, whether of the tincture, powder, or infusion. A 1/2 ounce (15 c.c.) of the infusion may be given every six hours to an adult; of the tincture, not less than 10 minims (0.65 c.c.), or 20 drops, to be reduced when diuresis sets in. Under such doses, if the cardiac disease is not too advanced, the quantity of urine may increase, become clear, its albumin and casts diminish, and with these also the dropsy, dyspnea and restlessness, sleepless nights. All that has been said under the treatment of cardiac valvular disease of substitutes for digitalis is applicable here, and the reader is referred to that section.

Due attention must also be paid to the bowels, for the sake of securing prompt action of the diuretics, as well as the elimination which their free action accomplishes. The hydragogue cathartics, such as elaterium and the salines, are often excellent adjuvants.

## ACUTE PARENCHYMATOUS NEPHRITIS.

SYNONYMS.—*Acute Nephritis; Acute Diffuse Nephritis; Acute Desquamative Nephritis; Acute Tubal Nephritis; Acute Bright's Disease; Acute Catarrhal Nephritis; Croupous Nephritis; Albuminous Nephritis; Hemorrhagic Nephritis; Acute Albuminuria; Acute Renal Dropsy.*

**Definition.**—Acute parenchymatous nephritis is an acute inflammation of the kidney, the tubular, vascular, and interstitial tissues being simultaneously involved in different degrees in different cases. In the majority of cases, the parenchyma, or secreting structure, is first and most invaded, whence the term parenchymatous nephritis.

**Etiology.**—Most cases of acute parenchymatous nephritis are caused by some poison of endogenous or exogenous origin which is carried by the circulation. Instances of the former are the toxins of scarlet fever or diphtheria, whence, therefore, it is frequent in children. A certain number originate in exposure to cold, especially cold and dampness, while the body is warm and perspiring. The latter cause is particularly potent if the person be fatigued or exhausted. When acute nephritis supervenes on scarlet fever, it is usually not until the end of the second week, often when convalescence is well established. It may occur as early as the tenth day, seldom, if ever, later than the 31st.

Other grave infectious diseases, as small-pox, acute endocarditis, and acute articular rheumatism, typhus and typhoid fevers, pneumonia, and malaria are also occasional causes. Measles, erysipelas, pyemia, jaundice, and diabetes have been known to cause it. Skin diseases, as well as extensive burns of the skin, are acknowledged causes: the former rarely, but the latter almost always if the burns be sufficiently extensive. Simple follicular tonsillitis is also a not infrequent cause, while the graver forms whether due to streptococcus or the Klebs-Loeffler bacillus, may be followed by correspondingly severe nephritis. I have known an abscess in the thigh, succeeding the lodgment of a splinter in the toe, to be followed by typical acute nephritis. Pregnancy is the cause of a good many cases of acute parenchymatous nephritis, to which, in turn, most cases of puerperal convulsions are due.

Most cases of acute nephritis due to other causes than scarlatina, diphtheria, cold, and pregnancy are mild in degree; and even in cases due to pregnancy, if the patient is once safely delivered, recovery is usually rapid. In looking for the evidence of nephritis in acute infectious diseases, it must not be forgotten that intense febrile movement may cause albuminuria, independently of any structural change in the kidney due to the toxic agent. When thus caused, the albuminuria is always small.

Of exogenous causes certain specific poisons of vegetable and mineral origin are capable of producing acute nephritis. Among the best known of these substances are cantharides, turpentine, oil of mustard, wormseed oil, and phosphorus; in a less degree, the mineral acids, arsenic, nitrate of silver, lead, and mercury. Very large quantities of alcohol, when swallowed, have caused acute nephritis.

The microbic origin of nephritis has also been invoked. Apart from

analogy, which, with our present knowledge of bacterial agency, renders such cause highly probable, pathogenic organisms have been found in the urine of cases, pure cultures from which, by Mannaberg, produced intense nephritis when injected into the blood of animals. Oertel claimed, 15 years ago, that in renal diseases following diphtheria he found "great numbers of micrococci and exuberant proliferations of the same," both in the renal tubes and Malpighian bodies; Heller, that he had repeatedly found the blood-vessels and their branches in acutely inflamed and swollen kidneys from cases of pyemia greatly dilated and plugged with masses which, under low powers, presented a peculiar grayish-yellow appearance, and with high powers were found to consist of extremely minute, highly refracting granular particles. These particles he considered spherical bacteria, and the resulting masses bacteria emboli. It is, therefore, now commonly conceded that the bacteria responsible for the acute infectious diseases are also the agents which produce the complementary nephritides in all of them.

As may be inferred from the etiology, acute nephritis is often a disease of early age, although when due to cold or any one of the causes named except scarlatina, it is as much more likely to affect adults as these latter are more frequently subjected to such causes. It is rare after 40, almost unknown after 50. More males are attacked than females in adult life, evidently because they are more frequently exposed to the causes. But even in childhood there is a slight preponderance of cases in boys affected, which can hardly be thus accounted for.

**Morbid Anatomy.**—This varies with the stage of the disease, as well as its severity. In the first place, as ordinarily caused, the disease is symmetrical, both organs being alike involved. In the fully developed stage the kidneys are more or less enlarged, in the latter stages always so, sometimes to more than twice their normal volume, and they may weigh from eight to 12 ounces (240 to 360 gm.), those of children reaching the former, and those of adults the latter.

The capsule strips off easily, without dragging any of the parenchyma with it. Bereft of its capsule, the kidney itself is softer, inelastic, and doughy. Its surface is smooth and exhibits a peculiar mottled appearance, which is due to the fact that the little circlets of veins which form the boundary of the lobules are distinctly injected, while the area surrounded by each circlet is paler than in health, and in the more advanced stages even yellowish-white in color. This "irregular mixture of congestion and anemia," as Sir George Johnson early called it, is further contributed to by the injection of other veins indistinct in health. Spots of hemorrhagic extravasation may also be found scattered over the surface.

*On section*, it is evident that the enlargement is due to change in the cortex and the interpyramidal convoluted portion. The cut surface is smeared over with a dark red or chocolate-hued blood, but on scraping or washing it away the vessels are found injected like those of the surface, and between them the same paleness or yellowish-white hue is seen. The Malpighian bodies are enlarged and distinct, dark red, sometimes pale. Punctiform hemorrhages may also be present, as on the surface of the organ. The pyramids are dark red.

*Minute Changes.*—These are confined almost solely to the labyrinthine structure. They by no means always correspond in degree with what would be expected from the symptoms, being often entirely inadequate to explain them. The changes are *tubal*, *glomerular*, and *interstitial*.

1. *Tubal Changes.*—These vary a great deal with the stage of the disease. The earliest change assumed by the cells is cloudy swelling, a result of increased nutritive activity. In this state the cells are swollen and “cloudy” from a deposition of albuminous granules, which may obscure the nucleus. Although kidneys removed after death from cases of acute parenchymatous nephritis have, as a rule, advanced far beyond this stage, yet it is often possible to find points at which cloudy swelling exists alongside of more advanced stages, while alongside of these, again, may be tubes in which the epithelium is normal. As a result of the cloudy swelling, the cells are larger, and the tubes are therefore distended, broader than in health, but a stage later they are still more distended with granular cells, granular debris, and often red-blood disks and leukocytes. Under a low power, the tubules appear as black, more or less opaque lines. A closer examination of the *cells* at this stage, as obtained by scraping, shows them to be granular in various degrees. In some the nucleus is still visible, in others demonstrable by the aid of staining fluids only, and in others still entirely obscured. Occasionally a few fat drops may be present. In other situations the cells are so closely packed in the tubules that they cannot be differentiated, being apparently fused in one continuous, dark, granular mass. It is to these tubules, distended with granular cells and their debris, dark by transmitted light, but white by reflected, that the pale or white color seen between the injected blood-vessels is due. Casts of the uriniferous tubes are also found *in situ*, usually blood casts or small hyaline casts. Minute extravasations of blood, visible to the naked eye, have been referred to. They occupy the tubules, and in the “hemorrhagic” form the interstitial tissue.

2. *Glomerular Changes.*—In all cases in which the nephritis is due to a toxic substance which enters the blood the glomerule suffers first. The capillaries of the *tuft* are distended with blood, which bursts through into the Malpighian capsule, distending it with red blood-corpuscles and leukocytes. In a more advanced stage, the glomeruli may be paler, in consequence of the proliferation of the cells lining the capsule and covering the glomerule (glomerulonephritis).

These glomerular changes are present in almost all cases. They include swelling and desquamation of the capsular epithelium, and an accumulation of cells in the interior of the capillaries, probably due to a proliferation of their endothelial lining or an accumulation of white blood-cells, or thickening and hyaline degeneration of the capillary walls. These are especially frequent in nephritis after scarlet fever or diphtheria.

3. *Interstitial Changes.*—In mild cases there is no interstitial change, no formation or deposit of new material between the tubes. In others there is a serous transudate, with a few leukocytes in most cases, and red blood-disks. In severer cases there is a large outwandering of cells, and a small-celled infiltrate settles itself between the convoluted tubes and around the capsules. In cases of extreme severity, a diffuse nephritis

involving both tubes and intertubular tissue may be present from the outset. In such event, the latter is uniformly infiltrated or pervaded more intensely in certain places by leukocytes.

The epithelial lining of the straight tubes of the pyramids is unchanged, but the tubes themselves often contain cellular and granular material which has descended from the convoluted tubes.

Serous infiltration and effusion are present in various tissues when the patient is dropsical at the time of death. Among other tissues sometimes thus infiltrated are the membranes of the brain, constituting what is known as edema of the brain. The mucous membrane of the pelvis of the kidney may be injected, but is otherwise unchanged.

**Symptoms.**—The mode of onset of acute nephritis is not uniform, but among the symptoms earliest noticed is slight *swelling* or *puffiness in the face*, below the eyes, associated with more or less *falling off in urinary secretion*. This *edema rapidly extends* to the upper extremities and trunk, and thence, if the disease does not abate, into the lower extremities and abdominal walls. In the male, the scrotum and prepuce are favorite seats of swelling. The great serous sacs are the last to fill with fluid in acute nephritis, although in bad cases ascites not infrequently occurs, while there may also be transudation into the pleural and pericardial cavities. The degree assumed by the general anasarca is sometimes enormous, resulting in the extremest distortion. The eyes may be actually closed by the swelling, and movement of the lower limbs rendered almost impossible. Dropsy does not always follow the order here named. Much depends upon the position of the patient. Thus, if he be upon his feet, the latter may be the first to swell, or if he be lying in the recumbent position, the back may be the seat of the first swelling. While dropsy is a very frequent symptom in acute nephritis, it is not, however, always present. It is more particularly in the nephritis after scarlet fever and exposure to cold that it is a decided and almost invariable symptom. After the other infectious diseases it is frequently absent.

Not infrequently the disease is ushered in by *nausea* and *vomiting* and very rarely by uremic symptoms (see p. 756).

*Changes in the Urine.*—Simultaneously with, and sometimes earlier than, the dropsical symptoms are *diminution in the quantity and alteration in the quality of the urine*. The former may amount to actual suppression. The urine is darker than natural, and often smoke-hued from the effect of the natural acid reaction on a small quantity of blood. Should the urine become alkaline, the color becomes a brighter red. The hue is more positively red if the quantity of blood is large, which is not often the case; but here again the peculiar tint returns if the blood is allowed to subside. The blood may disappear, to return again.

The *specific gravity* of the urine at first is high—1025 to 1030—mainly due to the diminished quantity, while the solids remain nearly normal. Later, if the symptoms abate, the specific gravity diminishes with the increase in the quantity; or, if the disease lasts for any length of time or passes over into the chronic form, a similar reduction in weight occurs; this may result in a specific gravity as low as 1010.

The chief alteration is the *presence of albumin*. This is generally

copious, the urine often solidifying on the application of heat and acid, while it constantly contains more than half its bulk. This albumin is derived in part from the extravasated blood, and in part is a result of the inflammatory action. If estimated by weight, it will equal 0.5 to 1 per cent., and, in rare instances only, 1.5 per cent.

Next in importance is a reduction in the 24 hours' secretion of *urea*, which is invariable until convalescence sets in. The percentage remains as high or higher than in health, but the 24 hours' quantity is diminished. There is a good deal of range within the limits of health in the quantity of urea eliminated in 24 hours—from 300 to 600 grains (20 to 40 gm.) in adults, and it varies with the amount of proteid food ingested. More frequently the amount is reduced to one-fourth or one-half the normal. The phosphates and chlorids are also reduced.

As to *sediment*, the urine of all cases of acute parenchymatous nephritis deposits a sediment which, in the early stages at least, is copious and brownish or reddish-brown in hue; later, it may diminish in amount and assume a lighter color. *Microscopical examination* reveals this deposit to be made up mainly of casts of the uriniferous tubules, free cells from these same tubules, blood-corpuscles, red and colorless, and very constantly crystals of uric acid, together with granular urates. The casts include the varieties known as epithelial casts, blood casts, hyaline casts, waxy, and dark granular casts. Pus casts and numerous leucocytes are also sometimes present. The hyaline casts are probably pure fibrin. The epithelial casts consist of the same material, to which epithelial cells of the tubules are attached, and blood casts have blood-corpuscles caught in the coagulated exudate. The epithelium thus attached, as well as that which is found free in the urine, is variously altered. Some of the cells are merely the seat of cloudy swelling, others are decidedly granular, while others again are converted into compound granule cells or granular fatty cells by complete fatty degeneration. These arise as the disease advances. Casts containing a few oil drops may also be present, but much oil is not found until the case has continued for some time—in fact, become chronic.

Along with the diminished quantity of urine is often met a disposition to *frequent micturition*, the efforts at which are only partially successful, resulting in the emission of from a few drops to a tablespoonful. This frequent desire to pass water is a purely reflex symptom, the bladder being free from disease. It sometimes precedes, in point of time, all other symptoms. It is by no means constant.

*Fever* is not a marked symptom in acute nephritis; indeed, it is generally absent, unless as a part of the disease causing it. To a less degree the same is true of *pain*. It is mostly absent, and when present amounts only to a dull ache, as a rule. *Chilliness* and *rigors* sometimes introduce the disease. *Nausea* and *vomiting* are not infrequent in the beginning. Sometimes these symptoms usher in the disease. The *pulse* is quite characteristically altered. While not materially changed in rate, it exhibits, especially in sphygmogram, a decided increase in tension, as shown by the broader apex and diminished dicrotic element. Blood-pressure is increased, but much less than in chronic nephritis.

*Uremia*.—At almost any time in the course of an acute nephritis the patient is liable to *uremia* while the *train of nervous symptoms* usually known as *uremic*, and ascribed to the accumulation of excrementitious substances in the blood, is not confined to this form of Bright's disease, and is by no means invariably present. Its causes and phenomena, so far as known, were considered under general symptomatology, page 756. When present, however, it adds a phase of extreme gravity.

*The duration* of acute nephritis is variable—from a few days to several months, while the acute form may become chronic. The former class of cases are fatal, for none which recover do so in a few days. The most rapid usually require a month. As to the cases of longer duration, the possibility of recovery at any time cannot be denied, but nothing is better determined than that the longer the duration the more difficult the cure. Of course, such cases are no longer acute.

**Complications.**—These are not numerous in acute, as contrasted with chronic Bright's disease, and some which are described as complications are not really such, but local symptoms. Thus, *edema of the lungs* occurs as a part of the general tendency to dropsy, and may be a grave symptom, resulting in death by suffocation. It is not the result of an intercurrent bronchitis. *Pneumonia*, on the other hand, is an occasional true complication. *Inflammation of the serous membranes* is more truly a complication, but not every case in which there is effusion into a serous cavity is inflammatory. Such effusions may be local dropsies. The exudate may become purulent, thus also increasing the gravity of the case. Pleurisy is the most frequent form, pericarditis next, and peritonitis next. The tubercular origin of the graver forms of pleurisy occurring in Bright's disease has been suggested.

*Hypertrophy of the left ventricle* is not a frequent complication of acute nephritis. It is a well-recognized one of chronic Bright's disease. Time is an essential condition to its production. It is not, therefore, until the nephritis has existed for some time that it commonly occurs. It does occasionally happen earlier. Thus, Dickinson reports a case recognized at eight weeks, and von Leube one at ten days succeeding the first symptoms. The infallible sign of hypertrophy is sharp accentuation of the aortic second sound, with or without demonstrable enlargement of the normal area of dullness.

Allusion has been made to *gastric symptoms* which very commonly attend acute nephritis, especially after scarlet fever. Samuel Fenwick<sup>1</sup> and Wilson Fox<sup>2</sup> have shown that these may be associated with organic changes in the stomach. Fenwick ascribes them to gastritis, as evidenced by increased vascularity of the mucous membrane, distention of the tubes by a confused mass of cells and granular matter, and occasional thickening of the basement membrane. To these, Fox has added thickening of the intertubular tissue.

Notwithstanding the frequency of convulsions in acute nephritis, structural *alterations* in the *brain* are almost unknown. Apoplectic effusions are rare, probably because of the integrity of the blood-vessels of the

<sup>1</sup>Samuel Fenwick, "The Morbid States of the Stomach and Duodenum," 1868, p. 177.

<sup>2</sup>Wilson Fox, "Medico-Chirurg. Transac.," vol. xli., p. 361.

brain in the young, in whom the disease mainly occurs. Nor is the blindness which is not infrequently a symptom of uremia attended by retinal changes, nor does albuminuric retinitis occur in acute parenchymatous nephritis, except with the extremest rarity.

**Diagnosis.**—The diagnosis of acute parenchymatous nephritis is ordinarily quite easy. The previous history, the usually easily recognizable cause, the suddenness of the attack, the scanty and bloody urine with its high specific gravity, the copious albuminuria, the blood and epithelial and dark granular casts, the blood-corpuscles, free epithelium, and granular cells in the urine—these are a combination of symptoms which admit of only one interpretation. At a later stage, the absence of one or more of these symptoms may somewhat increase the difficulty, but it is scarcely possible to err if those which remain are duly considered. It must be remembered, also, that an acute condition, such as this described, may supervene upon any one of the chronic forms of *Bright's disease* to be described, and this may give rise to some difficulty of diagnosis, but if there be hypertrophy of the left ventricle, it is likely that there was chronic disease before; in the latter case, too, there is apt to have been anemia existing for some time, previous edema, headache, and other symptoms of chronic Bright's disease.

*Febrile albuminuria* is quite often mistaken for acute nephritis by those who have had little experience, though the distinction is easy. In pure febrile albuminuria, the quantity of albumin is very small, and while there may rarely be a few hyaline casts, there are no blood-disks and no epithelial casts. The absence of dropsy is of no significance, for in the acute nephritis of the infectious diseases, except scarlet fever and diphtheria, there is seldom dropsy. There may also be febrile albuminuria in scarlet fever which is quite different from the nephritis occasioned by this disease. It occurs early, and in this stage the other features of febrile albuminuria are present, while the scarlatinal nephritis does not come on, as already stated, until after the end of the second week.

While the glomerular changes referred to are more usual in scarlatinal nephritis, there is no certain way of recognizing such condition, and the term glomerulo-nephritis, which is applied to the nephritis associated with these changes, is scarcely justified from the clinical standpoint, because there are no symptoms by which it can be recognized.

The diagnosis of *uremia* commonly easy, is sometimes difficult. This is especially the case when, instead of the usual complex list of symptoms detailed on page 757, there are but one or two. By no means every nervous manifestation coincident with Bright's disease is uremic, and I am inclined to believe that some are ascribed to it which should not be. On the other hand, localized convulsions and hemiplegias, commonly ascribed to some anatomical lesion in the brain, are often uremic in origin. Given, however, a case of sudden convulsions or coma, or even muscular twitching, if it is associated with scanty urine and greatly diminished urea excretion, it may be ascribed to uremia, provided there is no cause which will explain it more satisfactorily. Uremia has been mistaken for *opium* and *alcohol intoxication*, and it must be admitted that the coma in all three is very much alike. But one need only be forewarned to

prevent such error. In opium-poisoning the pupils are contracted, in alcoholism they are dilated, in uremia they vary.

**Prognosis.**—Grave as this disease is justly considered, recoveries from it are numerous and the prognosis is generally favorable. Even without treatment, cases may recover, and more recoveries follow a judicious treatment. The prognosis should, however, always be guarded, as insidious causes may produce death when it is least expected. Among the most important of these is uremia.

Bartels said that death from uremia in acute nephritis has never occurred in his experience, except when the disease has resulted from scarlatina or diphtheria; but Dickinson narrates a fatal case resulting from exposure, in which death was preceded by coma and other symptoms of evident uremic origin, and I am certain I have seen similar cases.

Pulmonary edema is a cause of sudden death, the patient drowning, as it were, in his own secretions. Its onset is characterized by shortness of breath, frothy expectoration, and abundant small râles. Purulent exudation into the serous cavities may also precipitate death, very rarely.

The symptoms of gravest import are, therefore, those of uremia, manifested in any one or all the various ways, the presence of any of the complications alluded to, and especially suppression of urine. Cases should not, however, be despaired of, even when there is complete suppression of urine. Always, however, this is the gravest of symptoms, and death generally ensues within a couple of days after it sets in. The possibility of sudden death should always be borne in mind, and mentioned to the relatives of the patient, although the number of cases in which this occurs is not very great. Of course, the longer the duration of the case the less the likelihood of recovery.

**Treatment.**—Many cases of acute nephritis recover under the conditions of *rest, quietude, and warmth*, and it is further certain that, whatever other means of treatment are used, these three conditions are absolutely necessary to recovery. A patient with acute Bright's disease, therefore, whatever its mode of origin, should be put to bed, kept quiet, and covered warmly.

The *dict* of patients with acute Bright's disease should be of the simplest and easiest of digestion, and should contain a minimum of proteids. The irritability of the stomach in this disease has been alluded to, and it is important that food should be adapted to it. Milk may be considered the typical food, not merely because of its easy assimilation and nutritious character, but because there is abundant testimony to prove that albuminuria diminishes under its use, while the amount of nitrogen contributed to the blood is less than by animal flesh. The combination of lime-water, and still better of carbonated water or Vichy, with milk, is an eminently suitable one. Koumys, Zoolak and buttermilk are also suitable. While solid animal food is not to be recommended, weak animal broths may be permitted, to break up the monotony of a pure milk diet. *Beef-teas and extracts should be prohibited as harmful.* Rice and farinaceous preparations generally are suitable adjuvants to the milk diet.

We should seldom, however, be satisfied with this treatment alone.

The selection of other measures will depend somewhat upon the severity of the case. If the urine be suppressed, *dry cups*, or, in severe cases, cut cups to the loins may divert the blood and relieve the stagnation which always exists in the acutely inflamed kidney. Cups should be followed by a *warm poultice* to the same region, which, indeed, should be used under any circumstances, whether the cupping is necessary or not. Dry cups should not be allowed to remain on one spot longer than to secure a bright redness, after which they must be withdrawn or moved to another spot in the vicinity. By allowing them to remain too long, the blood is stagnated in the capillaries, its onward movement prevented, and there is, therefore, no derivation of blood from the involved organ.

The foregoing measures have for their object the direct relief of the congestion of the kidney. This is further accomplished by *purgation*, which supplements the action of the kidney. But a purgative is early employed not more for this purpose than to promote the action of other remedies. Absorption is slow when the blood-vessels are congested and there is a sluggish current. The cathartic relieves this turgor, and after its effect prompt absorption and action of other remedies may be looked for. The purgative most suitable is a saline. A simple dose of bitartrate of potassium, simple magnesia for children, citrate of magnesium, or Epsom salts for adults will be sufficient. The indication is to get a watery stool as soon as possible. In view of the fact that the stomach is often sensitive, it is desirable to use an aperient which is not nauseous or irritating, and to this end some one of the delicate effervescing preparations so common in modern pharmacy may be used.

Next, or simultaneously, the action of the skin should be promoted. This is done by maintaining warmth and avoiding cold, as already insisted upon. But we are not confined to these protecting measures. The skin may be made to do the work of the kidney itself, and thus one of the most alarming dangers of Bright's disease, uremic intoxication, averted, while at the same time the congestion of the kidney is also relieved. The class of remedies which produces this action are diaphoretics (the warmth described is one of these), and of the simple remedies, none is better than the ordinary sweet spirit of niter, especially if it be combined with neutral mixture and small doses of ipecacuanha. If more active measures are required, some one of the preparations of jaborandi may be used, the dose varying with the effect it is desired to obtain. If moderate diaphoresis only is desired, doses of from 10 to 15 minims (0.65 to 1 gm.) of the fluid extract may be given to adults every two hours, and increased, if necessary, until the effect is brought about. To children, from 5 to 10 minims (0.3 to 0.6 c.c.) may be given in the same manner, or pilocarpin may be given in doses of from 1/24 to 1/12 grain (0.0027 to 0.0054 gm.). The further use of this important remedy will be again referred to in treating uremia.

Another method of accomplishing the same end is by *warm baths*, or, better still, by the warm pack, in which the patient is wrapped in a wet sheet and then enveloped in a sufficient number of blankets. Perspiration is thus copiously induced, and when thus caused is agreeable and never attended by the faintness which sometimes follows the use of

the hot-air bath. In an ordinary severe case of acute Bright's disease, a single pack of this kind will often remove all urgent symptoms and happily inaugurate the convalescence. It may, however, be repeated daily, if necessary.

*Diuretics* are, perhaps, the first means thought of by most practitioners in the treatment of Bright's disease, and they are indicated where there are dropsy and scanty urine. They should, however, be deferred until the measures just described have been employed. *Digitalis* is the diuretic most to be relied upon. It is necessary, however, to have a reliable preparation, and unless one is sure of the quality of the tincture, it is best to use a freshly prepared infusion. I have already explained, on page 642, why I believe more efficient results are obtained from the infusion than from the tincture.

*Digitalis* should, therefore, be given in sufficient doses— $\frac{1}{2}$  to 1 fluidram (2 to 4 c.c.) of the infusion to children, and 2 fluidrams to  $\frac{1}{2}$  fluidounce (8 to 16 c.c.) to adults—repeated every four hours, until an appreciable effect is produced on the rate of the pulse, when it should be diminished. Not until then can we look for a diuretic action. I prefer at first to give it alone. Later it may be combined with acetate, citrate, and bitartrate of potassium. The diuretic action of these salts probably depends upon the impetus they give to osmosis of fluids holding them in solution, thus filling the blood-vessels, which, in their turn, give out water to flush the kidney. To adults, 20 grains (1.3 gm.) of either may be given every two or three hours, freely diluted, because water itself is an excellent diuretic; from 5 to 10 grains (0.32 to 0.648 gm.) to children, as often. An important object, too, is to maintain an alkaline urine, which tends to dissolve exudates. For this purpose, the alkaline-mineral waters are also useful, or what is commonly known as cream-of-tartar tea may be drunk instead of water. A teaspoonful of potassium bitartrate is put into a pint of boiling water, and taken cold as drink is wanted.

Another admirable diuretic combination, including all of these elements, is Trousseau's diuretic wine, which consists of:

℞ Junip. contus,	5 x.	40 gm.
Pulv. digitalis,	5 ij	8 gm.
Pulv. scillæ,	5 j	4 gm.
Vin. xerici,	O j	$\frac{1}{2}$ liter
Macerate for four days and add		
Potas, acetatis,	5 iij	12 gm.
Express and filter,		
Sig.—Tablespoonful three times a day for an adult.		

Infusion of *digitalis* may also be used in the shape of fomentations. Cloths wrung out in hot infusion and laid over the abdomen of the patient have been known to produce diuresis when all other measures have failed.

Theobromin is also a diuretic which should not be forgotten in the treatment of renal dropsy, although it is better adapted to cardiac dropsy. The same is true of caffein; also diuretin and acet-theocin, which are combinations, the first of theobromin and salicylate of sodium, and the latter of acetate of sodium and theobromin. The latter I have found an excellent diuretic in doses of 6 grains (0.4 gms.) every six hours. Diuretin given in doses of 5 to 15 grains (0.3 to 0.6 gms.) every four hours is uncer-

tain, but sometimes very efficient. For the method of administration of caffeine and theobromin see treatment of cardiac dropsy, page 646. None of this group is as efficient in nephritis as in the dropsy of heart disease.

*Treatment of Acute Uremia.*—The alarming and dangerous character of the symptoms of this condition demand a separate consideration of the measures required in their treatment. The treatment which has just been described is such as would be called for by an ordinary case of acute nephritis of a decided character. The tendency of it will be to prevent the retention of those effete matters, whatever their precise nature, which constitute the cause of uremia. But all efforts in this direction sometimes fail, and we are called upon to contend with convulsions or coma, or, more frequently, both in alternation. How shall they be met? The indication has already been explained. Elimination is demanded. The kidneys are not acting, and the secretion of urine is suppressed. There remain, therefore, but the bowels and skin to operate upon. But the patient is unconscious and cannot swallow voluntarily. Such remedies, must, therefore, be used as do not require his cooperation. These are *croton oil* and *elaterium*. Of the former, 2 drops, slightly diluted with plain oil or glycerin, may be carried into the back part of the throat, or, in case of extreme necessity, undiluted, may be introduced into the mouth, whence it is quickly absorbed. Its operation may be facilitated by a rectal injection. Of *elaterium*, a quarter of a grain (0.0165 gm.) in solution may be administered by the mouth.

In like manner, the skin may be made to substitute the action of the kidney. The *vapor or hot-air bath or hot pack* should at once be availed of. The vapor may be conveyed by a pipe two or three inches in diameter, carried from a vessel containing water, under which a spirit-lamp is placed, under the bed-clothing, the patient being well covered with a mackintosh and blanket, excepting the head. An ordinary rain-spout may be used. Hot air may be similarly conveyed, but does not act so quickly. Its action may be favored by moistening the skin. The hot pack is also very efficient and perhaps less enervating.

*Jaborandi* or its active principle, *pilocarpin*, may be used, the latter preferably, because available hypodermically. One-third grain (0.02 gm.) of the muriate may be thus administered, and if perspiration does not set in in a half-hour, it may be repeated. Its action is also greatly facilitated by warmth applied to the patient. A freshly prepared infusion may be injected into the rectum with almost equally prompt results. Four ounces (120 c.c.) of hot water should be poured on a dram (4 gm.) of *jaborandi* leaves, and, when sufficiently cool, strained and injected. The doses here mentioned are intended for adults. When less urgency is required, a fluidram (4 c.c.) may be inspissated and made into a suppository. Should edema of the lungs occur, it may be overcome by the hypodermic injection of atropin, 1/60 grain (0.001 gm.).

If the convulsions continue, *blood-letting* may be practiced, or it may be done at once if the patient is not very feeble. No one doubts the efficiency of bleeding in puerperal convulsions, and if puerperal convulsions are uremic, as they are with few exceptions, then bleeding should be of service in the uremic convulsions of acute Bright's disease.

The *hydrate of chloral* should not be forgotten; indeed, it is one of the most valuable remedies for the convulsion and should be one of the first measures tried. In the case of an adult, a dram (4 gm.) in solution may be injected into the rectum; 15 to 30 grains (1 to 2 gm.) for a child. Its use is sometimes followed by the promptest favorable results. *Chloroform* may also be used to control the convulsion while the eliminating measures are acting.

The *use of opium* requires mention. The caution which has always been suggested in its use I believe to be, in the main, a wholesome one, and I should prefer to produce hypnotic, sedative, and antispasmodic effects by chloral and the bromids whenever it is possible. At the same time there can be no doubt that opium is less harmful in acute nephritis than in chronic, and especially chronically contracted kidney, and when other measures fail to control convulsions, it may be used cautiously. It was in the convulsions of acute nephritis that the late Professor Loomis, of New York City, recommended it, although its wider use has grown out of this suggestion. His practice was to treat cases of uremic convulsions in acute nephritis with hypodermic injections of large doses of morphin— $1\frac{1}{2}$  grain (0.033 gm.) or more.

The same measures which have been detailed, excepting the general blood-letting and chloral, may also be employed in the treatment of suppression of urine or of obstinate dropsy without uremic symptoms, with such modifications as circumstances may suggest, due regard being paid to the strength of the patient. They will be further referred to when discussing the treatment of the chronic forms of Bright's disease.

Sooner or later, also, in the treatment of acute parenchymatous nephritis supporting measures are rendered necessary to repair the losses which the blood suffers by the albuminuria, and to some extent also by the depleting measures of treatment. These effects should indeed be anticipated by proper diet, tonics, quinin, especially iron, wine, malt liquors, whisky, or brandy, as indicated. These measures will also be more particularly alluded to in the treatment of chronic Bright's disease.

*Treatment of Complications.*—Complications should be treated by remedies called for by such conditions independent of the renal cause. Effusions into the pleural cavities and abdomen are often best relieved by paracentesis or aspiration; pneumonia and bronchitis by counter-irritation.

## CHRONIC PARENCHYMATOUS NEPHRITIS.

SYNONYMS.—*Chronic Diffuse Nephritis; Chronic Tubal Nephritis; Chronic Catarrhal Nephritis; Large White Kidney.*

**Definition.**—A chronic diffuse hyperplastic process in the kidney, involving the epithelium, glomeruli, and interstitial tissue.

**Etiology.**—This cannot always be traced. While it is frequently a continuation of acute nephritis, more frequently it originates *de novo*. To cases in the former category scarlatina and pregnancy contribute the greater number. To the second class belong insidious cases, the cause

of which is often not traceable. Habitual exposure to cold and dampness, such as residence in damp, cold houses, may cause some. Tubercular disease of the lungs is an undoubted cause. Great stress is laid by German writers upon malarial poisoning as a cause. In this country it is not a frequent cause. One of two pretty well-founded cases, with others of doubtful authenticity, include my experience with this cause. S. C. Busey, I. E. Atkinson, and William Sydney Thayer have, however, also assigned this as a cause in special papers devoted to the subject. It may be the case in more southern parts of the United States, where malarial poisoning is more intense than in the Middle States. Alcohol is a cause, and the nephritis of confirmed drunkards and the employees of breweries may be thus accounted for, though it cannot be denied that the exposure to which some of the former class are subjected may be responsible. Males, and of these young adults, are the more frequent subjects. Sepsis in prolonged surgical affections may produce chronic nephritis.

**Morbid Anatomy.**—There are two distinct stages in the morbid anatomy of chronic parenchymatous nephritis if the disease is of sufficient duration—viz., the stage of enlargement, represented by the *large white kidney*, and that of contraction, or the *fatty and contracting kidney*. A special variety is *chronic hemorrhagic nephritis*.

1. *Stage of Enlargement.*—There are few more striking objects in morbid anatomy than a typical example of the *large white kidney*. The kidney is large, smooth, white, or slightly tinged with yellow; weighs generally from seven to ten ounces (217 to 310 gm.), but is often much heavier. It is usually doughy, and sometimes elastic in consistence. The capsule, which may be thinner than in health, strips off easily, but occasionally drags a little of the parenchyma with it. When the smooth white surface thus uncovered is examined, the little capillary circlelets bounding the lobules in the normal organ are in some places indistinct, in others conspicuous; the same is true of the stellate veins of Verheyen. Numerous yellow specks are seen scattered over the surface. Hemorrhagic extravasations are also occasionally present, but very much more rarely than in the acute form. Alongside of these the greater translucency of more nearly normal areas results also in a characteristic mottled hue. *On section*, it is evident that the enlargement resides altogether in the *cortex*, which is also anemic, its intense white contrasting strongly with the pink hue of the cones, which, though paler than in health, are much less so than the cortex. Closer examination of the cut cortex reveals the same yellow specks as found on the external surface. They contribute, with similar less decided alterations, to form a series of dull white striæ which alternate with somewhat broader, translucent striæ radiating toward the surface; the former correspond to the area of the convoluted tubules and Malpighian bodies—the labyrinth—the latter to that of the medullary rays.

The pelvis of the kidney in chronic parenchymatous nephritis is the seat of catarrhal swelling and a slight degree of hyperemia.

**Minute Change.**—Microscopic examination of thin sections shows the involvement of both *tubes*, *blood-vessels*, and *intertubular substance*. Of the former, many are found choked with granular cells and the granular débris of cells, causing them to appear, under the microscope, as black,

opaque lines by transmitted light, very similar, indeed, to the tubes in acute nephritis. In other situations the tubules are filled with fat globules and fatty cells. In places the lumen of the tubes is preserved, in others not. Other cells are the seat of hyaline change. Others still are nearly normal. The parts presenting a yellow tinge are those in which the fatty elements have replaced the normal, and this is the composition of the yellow specks already alluded to as visible to the naked eye. They represent a coil of tubules filled with oil drops or fatty cells.<sup>1</sup> Certain tubules contain casts, usually of the waxy kind. Sometimes, indeed, they are very numerous. Rarely, hemorrhagic extravasations are also found in the tubules.

The *capillaries* of the cortex are completely or nearly empty of blood, which has been expressed from them by the distended tubules. To this and to the fatty cells is due the extreme whiteness of these kidneys, whence the name by which they are known. Many of the glomeruli are enlarged, their capsules thickened, their vessel-walls thickened and hyaline, their capillary and glomerular epithelium proliferated and degenerated.

The *pyramids* in chronic parenchymatous nephritis are more changed than in the acute form, but the changes in them are quite secondary. They are sometimes a little paler, owing partly to a granular and fatty alteration in the cellular lining of the straight tubules, and partly to the presence of cells pushed down from the convoluted tubules above them. On the other hand, they may be congested and darker in color. The straight tubes of the cones as well as the looped tubes of Henle often contain waxy casts.

In chronic parenchymatous nephritis the *interstitial tissue* is always altered, and, it may be said, as a rule in proportion to the duration of the disease. It has already been said that sooner or later interstitial overgrowth always presents itself, although it is difficult to say when this overgrowth begins in any given case. Langhans reports a case in which death occurred five weeks after the appearance of the first symptoms, directly traceable to a thorough wetting, in which the stroma was *markedly thickened*. And in a case of Dickinson's already alluded to, intertubular cellular formation, "though approximating as much to pus as to fiber," was found within six weeks of the onset. Again, cases of much longer duration may be entirely without it. Interstitial *fibrosis* may, however, be considered as a superaddition of chronicity, and whenever a case is distinctly chronic, it may be inferred, with tolerable certainty, that it is present. In this overgrowth the quantity of the connective tissue between the tubules varies extremely, being sometimes so slight as to be discoverable only on microscopic examination of thin sections; at other times it is appreciable to the naked eye. Minute examination shows the thickened trabeculae to consist of numerous round and oval nuclei, between which may be homogenous or more or less distinctly fibrillated intercellular substance.

2. *The Stage of Atrophy—The Fatty and Contracting Kidney or Small White Kidney.*—The interstitial new formation previously referred to

<sup>1</sup>No satisfactory explanation has yet been offered of the great differences in the degree of fatty degeneration in the different kidneys of chronic parenchymatous nephritis or in different parts of the same kidney. Dickinson says the cells have a greater tendency to be fatty when cold is the cause.

possesses the properties usual to new connective tissue. Produced primarily to replace destroyed tubular structure, it shrinks and gradually contracts the previously enlarged organ, while obliterating in turn a certain amount of the same structure. The extent of contraction varies greatly, increasing with the duration of the process. The kidney may continue as large and even larger than the normal organ, though smaller than the large white kidney, and its surface is uneven, lobulated, rough, and granular. Its capsule does not strip off easily, as from the large, smooth organ, but drags with it considerable of the tubular structure. The capsule removed, however, the surface of the kidney exhibits between the constrictions the same pallid, speckled appearance, distinct stellate veins, etc., already described; and on section the cortex exhibits the same anemic appearance, but may be narrowed. Microscopically, sections exhibit the same alternation of groups of normal and choked tubules already described, alongside of other places in which the tubules, together with the Malpighian bodies at their extremities, are obliterated. Between them is found a large amount of interstitial tissue, and the Malpighian bodies are surrounded by concentric layers of the same. Even minute cysts, the result of obstruction of tubules by the constricting tissue, are found. The secondary origin of this form of kidney is not conceded by everyone. An independent primary origin is claimed for it.

3. A special form of this stage is *chronic hemorrhagic nephritis*. In this form brown hemorrhagic foci are scattered throughout the cortex between and into the tubes. The organ is still larger than normal, and presents in other respects the histology of this stage.

It not infrequently happens that along with the changes constituting chronic parenchymatous nephritis are found also those of *lardaceous disease*. Thus, in a large white kidney the Malpighian bodies will often strike the mahogany-red reaction with iodine characteristic of this condition, although the alternation may not be recognizable by the naked eye. Occasionally the change may even affect the afferent and efferent vessels.

**Symptoms.**—There are few distinctive symptoms of chronic parenchymatous nephritis. When not a sequel of acute nephritis it often begins insidiously, and, after a variable period of indescribable ill health, including, however, often *digestive derangements*, an *anemic, waxy appearance* develops, with *puffiness of the face* and *swelling of the feet*. Ultimately, the *anasarca* may become general, involving the face, hands, feet, legs, thighs, and trunk. The serous sacs also frequently contain fluid, almost always in severe cases. The swelling may be confined to the extremities or to the face, and may even be limited to more unusual situations, as the scrotum. Indeed, dropsy is often entirely wanting, but as a rule it is manifest sooner or later, and no symptom gives the patient so much inconvenience. In advanced degrees his legs and thighs are twice their normal dimensions. They are so heavy he cannot lift them, while they are often excoriated and moist with exuding serum, and smarting with irritation. Very frequently, as the result of spontaneous rupture of the skin, the discharge of serum is profuse, saturating the bed-clothing and even dropping upon the floor; occasionally, often, with relief to the patient.

Another very constant symptom is *anemia*, producing a peculiar

translucent waxy appearance, quite characteristic and often alone sufficient to suggest the disease. But there may be very slight degrees of it which are not at all peculiar. Again, the *debility* of those suffering from advanced degrees of this condition is very striking. If able to walk at all, they soon get out of breath—are soon exhausted. *Dyspnea*, especially on exertion, is therefore a frequent symptom, and sometimes is extreme. Locomotion is often impossible in consequence of the extreme swelling, even if the strength otherwise permit it.

*The Urine.*—The urine is diminished to about 10 to 40 ounces (300 to 1200 c.c.), although somewhat variable in quantity. It is often turbid, reddish-yellow, specific gravity normal or below, highly albuminous, and deposits often bulky, cloudy sediment. At other times the sediment is scanty. The quantity of urine also increases as the patient improves or as the stage of contraction is entered upon, so that it may even exceed the normal. The *albumin*, while also large, varies as to its percentage amount with the quantity of urine passed—from five-tenth to two per cent., or from one-half to three-fourths of the volume of the urine tested. The amount of albumin lost in the urine is sometimes very large. It has even occurred that the percentage proportion of albumin in the urine has exceeded that in the serum of the blood from the same patient. The quantity of albumin has very little effect upon the specific gravity. Indeed, the lighter urines are generally those which have the larger amount of albumin, because highly albuminous urines often contain little urea.

The *sediment* is made up of variously granular casts, among which the dark granular are conspicuous by their numbers and size, and especially their width. There are also found oil-casts and casts containing entire and fragmentary epithelial cells, which are likewise granular and oily. Finally, yellow waxy casts are found. Casts vary in number, being sometimes scanty, but, as a rule, they increase with the development of the disease and grow less as it mends. Occasionally they are entirely absent for a time, even in this form of Bright's disease, sometimes as the result of treatment, when such absence may be considered a favorable sign. Sometimes, on the other hand, the tubules are choked with them, and they do not descend into the urine. Compound granule (granular fatty) cells and other forms of fatty renal cells are often numerous. Leucocytes are also often very numerous, while red corpuscles may be present and in the hemorrhagic form are very numerous.

The normal constituents of the urine are *generally diminished* in quantity. The most important of these is *urea*, though less important than formerly regarded. To the reduced amount of solids, and particularly of urea, the reduced specific gravity is due.

Notwithstanding the small proportion of urea which is excreted in this affection, *uremia is infrequent in chronic parenchymatous as compared with acute nephritis* and contracted kidney. It is more frequent after the stage of contraction is reached.

*The Stage of Contraction.*—Are there any symptoms by which we can recognize the stage of secondary contraction, which takes place sooner or later, provided the patient lives? The most reliable evidence that this has occurred is the presence of hypertrophy of the left ventricle and ac-

centuation of the aortic second sound, although the possibility of an earlier hypertrophy cannot be denied. The increased vascular tension, mentioned as presenting itself even in acute nephritis, continues in the chronic variety to stimulate the heart to more forcible contraction, which must sooner or later result in hypertrophy. As already stated, time is required to reach this stage, and by the time hypertrophy is developed, contraction of the kidney is likely to have occurred. Long duration of the disease also affords presumptive evidence that contraction has taken place. If a case of undoubted parenchymatous nephritis continues under observation for a year or more, the process of contraction is likely to have commenced.

The *dropsy* diminishes and may disappear as the stage of contraction is entered upon. So, also, the *urine* changes in its properties. The quantity, previously small, is increased, while the specific gravity falls below normal—1010 to 1015; the quantity of albumin is also much smaller than during the stage of inflammation. In these respects—absence of dropsy, larger amount of urine, and smaller amount of albumin—it resembles the true contracted kidney of interstitial nephritis, with which, indeed, it may be confounded in the absence of a previous history. But the casts continue to be quite numerous, and exhibit much the same character that they do in the stage of enlargement, although they too may be few; and if we have not a knowledge of previous history, the diagnosis between contraction secondary to previous enlargement and primary contraction the result of interstitial nephritis may be impossible. Uremia is more common in the stage of contraction than that of enlargement.

In the hemorrhagic form the urine almost constantly contains blood. The quantity varies somewhat and is diminished while the patient is in bed, but reappears the moment he arises.

The *duration* of chronic parenchymatous nephritis is variable. Many cases terminate unfavorably within a year after they have been established, but I have one case now under observation in the stage of contraction which I have known to exist for 16 years at least. Others, especially mild forms, last a long time, causing comparatively little inconvenience.

**Complications.**—The complications of chronic parenchymatous nephritis are the same as those of acute. Edema of the lungs, bronchitis, pneumonia, and inflammation of serous membranes are all liable to occur. Hypertrophy of the left ventricle is more common than in acute nephritis, for the reasons already referred to, but still very much less so than in interstitial nephritis. Derangements of digestion are very frequent, probably due to a more advanced stage of the structural changes described under acute nephritis. The acute blindness, unattended by retinal changes, described as occurring in the uremia of acute nephritis, rarely occurs here, while retinal changes are rather more frequent, but still uncommon compared with interstitial nephritis, under which they will be described.

**Diagnosis.**—Many cases are very easy of diagnosis. The extreme pallor of the patient, the diminished urine of medium specific gravity, the usually large amounts of albumin, the numerous dark granular, oil and waxy casts of large diameter, free fatty cells, and fatty granular cells, especially if we are able to trace a history of long duration, all point

to the disease; and if there is an antecedent history of scarlatina or exposure to cold, pregnancy, or long exposure, probability becomes certainty.

The symptoms of *amyloid* or *lardaceous kidney* very closely resemble those of the large white kidney, and it has been mentioned that the same causes are capable of developing both. It is often impossible to say which form of disease is present. It has usually been considered that if there is enlargement of the liver and spleen, or persistent diarrhea, and the cause is one which may produce lardaceous disease, it is certain that the latter condition exists; but observation has shown that the first two, at least, may be present, together with all the causes and other symptoms which are regarded as favoring lardaceous disease, and yet the disease be parenchymatous nephritis;<sup>1</sup> while the usual causes of lardaceous disease may operate to produce it in the liver, leaving the kidney intact. As a rule, there is not so much dropsy in lardaceous disease, casts are more scanty, and generally hyaline, granular, and waxy; hypertrophy of the heart and uremia and albuminuric retinitis do not occur. Often, too, the two forms of disease coexist, either as the result of the same cause, or the amyloid disease may be the result of long-continued parenchymatous nephritis.

The stage of contraction is more difficult of recognition unless we have had the case for some time under observation and are able to trace its continuation with the stage of inflammation. The resemblance to the *contracted kidney* of interstitial nephritis may otherwise be very close. But here, again, the albuminuria is likely to be larger, and the casts more numerous, and to include the numerous varieties mentioned instead of the scanty, small hyaline casts which attend interstitial nephritis. In the latter the quantity of urine exceeds the normal, while in the former, although the quantity is larger than in the stage of enlargement, it is still less copious than in true interstitial nephritis.

**Prognosis.**—This is unfavorable so far as recovery is concerned. Well-marked cases terminate usually within two years, and sometimes within a few months. Many cases, however, may be very much prolonged by treatment, and if prolonged to the stage of contraction, the patient may be tolerably comfortable for some time—seems, indeed, to have another lease upon life. But sooner or later the dropsy returns, the heart fails, and the patient dies of exhaustion, or some one of the complications of uremia intervenes to carry him off. Of the former, edema of the lungs or of the glottis and pneumonia are particularly dangerous. In the stage of enlargement, uremia, while it is of rare occurrence, is also less apt to end fatally than in the stage of contraction.

On the other hand, it is to be remembered that there are many mild cases of chronic parenchymatous nephritis with correspondingly mild symptoms wherein the progress of the disease is slow and may extend over many years.

**Treatment.**—While it occasionally happens that spontaneous recoveries from acute nephritis occur, this is not the case with the chronic form. Here the expectant plan of treatment does not suffice. The patient

<sup>1</sup>See an article by Paul Furbringer, "Zur Diagnose der amyloiden Entartung der Nieren," "Virchow's Archiv," Bd. lxxi., 1877, S. 400.

with chronic parenchymatous nephritis, if left alone, grows steadily worse, and although measures of treatment may not frequently result in recovery, they often, if judicious, cause marked improvement and long avert the fatal end. There is always an intermediate stage between that of acute nephritis and the condition of the large white kidney, from which recovery often takes place, which calls for a modification of the treatment described for the acute, or some additions to it.

The chief indications in the treatment of chronic parenchymatous nephritis are two:

1. To improve the quality of the blood, which may have become anemic and contaminated with urea, purin bodies and allied excrementitious matter.

2. To combat the symptoms and complications which form a source of great inconvenience and danger to the patient.

1. The first of these indications is chiefly fulfilled by the use of iron, quinin, and strychnin, nourishing food of a suitable kind, a proper hygiene. Iron is regarded by many as almost a specific in chronic parenchymatous nephritis, and is prescribed constantly in the most reckless and thoughtless manner. *Large doses of iron should not be given.* They are useless, lock up the secretions, cause headache, and increase the danger of uremia. The well-known Basham's mixture is a great favorite. It is really a solution of acetate of iron, and, being made by adding to tincture of the chlorid of iron acetic acid and solution of the acetate of ammonia, has the advantage of at least tending to diuresis, while it is also a roborant.<sup>1</sup> But the tincture of the chlorid of iron alone is an efficient preparation which is always accessible, and when combined with the sweet spirit of niter and freely diluted, is perhaps as efficient as Basham's mixture. Only a few drops should be given. To either one the quinin and strychnin may be added, if desired, while to the iron the infusion or tincture of quassia makes a compatible addition.

With regard to *diet*, while it is true that a sufficient amount of food of good quality is desired, those articles should be selected which contain a minimum of nitrogen. Experience has shown that when the appetite is good and large quantities of meat are eaten, uremic convulsions have been more frequent, whereas when the appetite has been bad and little food taken, uremic convulsions in chronic nephritis are very rare. While, therefore, it is not necessary to omit all such food, it is desirable to limit it to moderation, and, while drawing upon the vegetable kingdom for food, to make up the deficiency in meats by the free use of milk. The good results of the milk treatment in cases of chronic nephritis are now generally acknowledged and are evidenced in the diminution of albuminuria, decline in dropsy, increase in the quantity of urine passed, and general amelioration of symptoms. Of the different methods of employing milk, the pure milk diet has been most satisfactory. From 2 1/2 to 3 1/2 quarts (2.5 to 3.5 liters) a day meet the requirements of an adult male, and less is often sufficient. The milk should not be skimmed, but

<sup>1</sup>The more usual formula for Basham's mixture is as follows: R Tinct. ferr. chlorid., f 5 ij (7.4 c.c.), Acid. acet. destillat., f 5 ij (7.4 c.c.); Liq. ammon. acetatis, f 5 iij (90 c.c.); Curacoe vel syrapi simpl., Aque; aa q. s. ad f 5 vj (180 c.c.). M. et Sig. Teaspoonful or dessertspoonful twice a day, in half a tumbler of water. If the mixture becomes turbid, it is probably because some of the acetic acid has evaporated, when a few more drops may be added to clear it up.

diluted, for by retaining the cream the casein or proteid constituent is maintained in smaller proportion. Rich milk is not desirable—indeed, it is better taken diluted with Vichy water or carbonated water and at stated intervals, say from 6 to 8 ounces every two hours. It is not, of course, always necessary to confine the patient to a pure milk diet, but it should at all times constitute a large part of the food. In the matter of diet the patient with chronic nephritis is not to be judged by the same standard as one with acute nephritis.

Next to diet, rest is a most useful measure to ameliorate the symptoms of chronic nephritis, and an albuminuria reduced to a minimum while the patient is up may often be further reduced by putting him to bed. The beneficial effect of rest upon edema due to any cause is too well recognized to require other than an allusion. The advantages of rest in bed are, however, sometimes more than counterbalanced by the disadvantage to the patient of confinement and want of fresh air and outdoor life. These, of course, must be weighed, and that one adopted which serves the patient best.

Under hygienic measures is included suitable clothing. That next the body should be of wool, for it must be remembered that, on the one hand, the skin is a powerful adjuvant to the kidney in its eliminating operations, and, on the other hand, any interference with or suppression of the action of the skin must throw more work on the kidney. Cold is the agent which produces such suppression, and warmth the means by which the action of the skin is encouraged, and no texture prevents the former or secures the latter more effectually than wool. For the same reason, while the maximum amount of fresh air is desirable, cold and dampness should be avoided or sufficiently guarded against.

2. The second indication is to combat the symptoms and complications which cause inconvenience or jeopardize life. These symptoms are those of dropsy, effusions into the serous cavities, and congestions. The patients suffering from them are usually confined to the house, or go out of it at so great inconvenience as to make it intolerable to do so. Of dropsy, there is abundant evidence to the naked eye.

With regard to purgatives and diuretics, nothing need be added to what has already been said under acute nephritis (p. 774). But as to measures which promote a decided action of the skin, I desire to add the warm bath, the Turkish bath, warm-pack bath, and the hot-air or vapor bath already alluded to. Any of these may be used as convenience or the patient's choice may determine, while the frequency with which they should be used depends on the urgency of the case.

The "warm" or "cold pack" is a very pleasant form of bath. The patient is wrapped up in a wet sheet, either warm or cold, and further enveloped in a sufficient number of blankets. A very comfortable sweat generally ensues, which is continued for an hour. In the use of the warm bath the patient is immersed at a temperature of about 104° F. (40° C.), and kept there for from half an hour to an hour. He is then removed and wrapped in blankets. It has been said under the treatment of acute parenchymatous nephritis that these effects are more conveniently and as efficiently brought about by the use of jaborandi and its derivative,

pilocarpin. The directions for their use, given in connection with acute nephritis, need not be repeated. They may be used about as often as the baths, usually on alternate days, occasionally daily, with advantage.

The judicious use of aperients is an efficient means of depleting the blood and reducing dropsy. The selection must depend on the urgency of the case, as sufficient has been said in connection with acute nephritis. But in many cases of chronic nephritis a stage is finally reached at which all treatment of the kind described fails to relieve the dropsy, which becomes eventually the sorest burden of the malady. The body becomes greatly increased in weight, the integument of the extremities is stretched almost to bursting, and sometimes it does rupture, followed by leakage, which, although in one way inconvenient, is in many senses a great relief to the patient by diminishing the tension referred to. Acting upon this, physicians have long been in the habit of puncturing the swollen parts to produce the required leakage. It is a common practice to make a number of minute punctures with a needle or sharp-pointed bistoury, but free incisions may be made on the inner or outer side of the ankle of each leg. Free drainage is thus secured, often with great relief; or Southey's tubes may be used at convenient places. They are introduced by means of a little trocar and after this is withdrawn fine india-rubber tubing is attached to the little cannula and carried to a suitable vessel outside the bed. Some remarkable recoveries have followed incisions. Great care should be taken to keep the tubes clean, as they are liable to become dirty and clogged.

Bearing in mind the effect of chlorid retention on renal dropsy successful treatment would naturally be favored by the elimination from the diet of articles rich in chlorids, seeking thus to reduce the chlorids ingested to two or three grams daily. This is accomplished by a diet including eggs, unseasoned meat, unsalted butter and milk, bread without salt, fresh-water fish, potatoes, rice, fresh vegetables, fruits and chocolate.

The treatment of the complications is in no way different from that of the same conditions under other circumstances. The point to be impressed is the importance of being constantly on the lookout for them. Effusions into serous cavities are probably the most important. Edema of the glottis requires especial allusion, as a complication most alarming and threatening to life. Inhalations of steam may be tried, but prompt punctures or incisions are the only certain means of relieving the patient and saving life.

I know of no measures directly curative in acute or chronic nephritis—that is, remedies which by their direct action remove the morbid state—and I believe none exists unless it be the operation to be next described. All that can be done is to place the patient in a condition most favorable for nature's kindly offices, which are always exerting themselves toward cure. This is accomplished by the measures recommended, which also eliminate the mechanical and poisonous products which interfere with recovery.

**Operative Treatment.**—Decapsulation of the kidney as a cure for chronic nephritis was proposed by the late George M. Edebohls, the suggestion growing out of some results of operation for floating kidney in per-

sons who happened to have coincident chronic parenchymatous nephritis. His results were published in the "Medical News," April 22, 1899. His first thought was that the cure of Bright's disease was due to correction of the displacement of the kidney, and it was not until after three secondary operations upon kidneys which had been anchored some time previously, that he discovered the essential condition underlying the cure to be decapsulation, or decortication. The last paper of Edebohls read before the Section on Surgery and Anatomy of the American Medical Association, June 19, 1908,<sup>1</sup> was based on a total of 102 cases, of which 33 were claimed to be complete cures, 21 received no benefit, and 48 experienced amelioration short of cure. Of the 21 not benefited ten died soon after the operation, from the effects of the operation. In 29 cases he operated on both kidneys at one sitting. The operation consists in stripping off the capsule and cutting it away entirely, close to its junction with the pelvis of the kidney.

The success of the operation is seemingly due, as Edebohls suggests, to arterial hyperemization of the kidney, whereby an increased and adequate blood-supply is furnished the organ which permits an absorption of interstitial and intertubular inflammatory products, thus relieving the tubules and glomeruli from the pressure previously interfering with function.

Several cases have passed under my observation and the following is a typical one of the kind likely to be benefited—one of severe chronic diffuse nephritis succeeding upon scarlet fever. The patient was a little girl aged ten. The case had lasted over four years and there was general anasarca as well as ascites. At the time of operation she was so weak that my colleague Chas. H. Frazier feared to operate on both kidneys at the same time. One only was therefore decorticated. The result may be truly called marvelous. The secretion of urine which under the most favorable circumstances before operation did not exceed 30 ounces (900 c.c.) rose rapidly, and on the fourth day after operation over 100 ounces (3000 c.c.) were secreted, and in ten days she was free from dropsy and ascites and a month later seemed perfectly well. There continued, however, to be a large albuminuria and there were numerous casts. On March 14, 1903, the second kidney was operated upon. She did well, but as there was no dropsy there did not succeed the large increase in the secretion of urine. In a few days, however, the quantity of albumin diminished decidedly and she remained seemingly well for a year, at the end of which time after exposure she suffered a relapse and died in a short time.

### CHRONIC INTERSTITIAL NEPHRITIS.

**SYNONYMS.**—*Contracted Kidney; Chronically Contracted Kidney; Renal Cirrhosis; Cirrhotic Kidney; Granular Degeneration; Granular Kidney; Red Granular Kidney; Gouty Kidney; Renal Sclerosis.*

**Definition.**—Chronic interstitial nephritis is a chronic process resulting ultimately in a shrunken kidney, in which there has been extensive

<sup>1</sup>Published in the Jour. American Medical Association, Jan. 16, 1909. The paper was read, on account of Edebohls's illness, by Samuel Lloyd. Edebohls died Aug. 8, 1908.

destruction of the tubular substance and overgrowth of interstitial connective tissue.

**Etiology.**—Of the recognized forms of Bright's disease, interstitial nephritis shares with chronic parenchymatous nephritis a large number of instances in which the cause is undiscoverable. There are, however, some well-determined causes. Among the most tangible of these is gout. *Gout* is associated with so many cases of contracted kidney that the term gouty kidney has become a well-recognized synonym for the product of interstitial nephritis. There are probably no cases of gout which have continued for any length of time which are not accompanied by interstitial nephritis. Uric acid and allied substances in the blood are probably the exciting cause. Another well-recognized cause is *lead* in lead-poisoning, the absorbed lead acting like the poison of gout. Hence painters, glaziers, workers in lead in any form, are frequent victims. Dickinson considers it safe to assert that of painters at least one-half eventually die of granular degeneration of the kidneys. This is certainly not the case in this country. *Alcohol* has always been assigned an important rôle in the production of chronic interstitial nephritis. It is probably true, especially if associated with a habit of overeating proteid foods. The latter habit alone I believe to be a frequent cause of chronically contracted kidney. It is almost incredible how much some persons eat—persons, too, who are inactive in mind and body. Such persons must overwork the kidney and gradually bring on a condition of chronic nephritis, which does not, however, usually appear until after middle life. On the other hand, I believe alcohol alone is responsible for more cases of chronic parenchymatous nephritis. Henry F. Formad, who, as coroner's physician for many years in Philadelphia, made an enormous number of autopsies on drunkards, always held this view, and claimed that the kidney was peculiar enough in shape to be called the "pig-back" kidney.

Long-continued *cystitis*, especially following gonorrhea, is a cause in a few instances, the inflammation traveling up the ureter to the pelvis of the kidney and thence to the intertubular tissue. The more usual result of such extension is suppurative nephritis.

Among the causes the operation of which cannot be so directly proved are *anxiety* or *business care* and *worry*. Clifford Allbutt, quoted by Robert T. Edes,<sup>1</sup> goes so far as to attribute "24 out of 32 cases in private practice to some long-continued anxiety or great grief." This also is contrary to my experience. It is true that this disease very often exists for a long time undiscovered in business men who have lived under a state of constant mental tension. The effect of this cause is augmented if its subjects combine too liberal eating and drinking with the hard work and anxiety.

*Hereditary influence* is occasionally a cause of contracted kidney. A remarkable instance of this has occurred in my own practice. I was consulted by a man, aged 30, who had granular kidneys. His father and mother both died of Bright's disease, aged 56 and 63 years, respectively. The mother had convulsions. A brother died of Bright's disease, without convulsions, at the age of 37. Two children of this brother had Bright's

<sup>1</sup>Robert T. Edes. "Some of the Symptoms of Bright's Disease," "Boston Med. and Surg. Jour.," vol. ciii, No. 2, July 8, 1880.

disease when four and seven years of age, respectively. A second brother died at the age of 29 with convulsions. A third and fourth brother, aged 23 and 32 years, respectively, have had Bright's disease for six years. A sister, aged 36, has had Bright's disease for five years. A brother, aged 26, and a sister, aged 34, have as yet exhibited no signs of Bright's disease. A maternal cousin died of undoubted Bright's disease, and other members of the family belonging to previous generations died with symptoms which suggest Bright's disease. The patient, himself, has undoubted granular kidney, discovered in August, 1880. An examination of his urine in 1876 revealed no evidences of the disease. There is no gout in the family. Dickinson also relates the history of a family in which a hereditary albuminuria existed independent of gout.

Prolonged *passive congestion*, due to valvular heart disease, may become a cause of granular kidney. The same may be said of *stone in the kidney* causing numerous attacks of nephritic colic. I have known typical chronic interstitial nephritis ensue on such attacks of nephritic colic.

*Pregnancy*, so frequently a cause of acute parenchymatous nephritis, is rarely, if ever, a cause of interstitial nephritis or chronic parenchymatous nephritis. It is true contracted kidney is sometimes found in autopsies of women dying of puerperal nephritis, but I believe it more frequently precedes than follows the pregnancy.

Interstitial nephritis is commonly a *disease of middle age*, the majority of persons in whom it is discovered being past 40. A few cases occur under 30. The youngest patient whom I have ever had was 26. Still younger cases are reported.

It must be remembered that there is a tendency to overgrowth in the interstitial tissue of the kidney, as of other organs, in old age. Hence the term, *senile atrophy of the kidney*. It is not safe, therefore, to call every instance of atrophied kidney met in the postmortem room a case of interstitial nephritis. The clinical history, or some one of the well-marked symptoms of the disease, as albuminuria or uremic symptoms, should have preceded to sustain the diagnosis.

As to *sex*, nearly twice as many males have the disease as females, because of the more frequent exposure of the former to the causes of the affection.

**Morbid Anatomy.**—In interstitial nephritis, both kidneys are involved, but there is often a marked difference in the extent of the disease in each.

Macroscopically, the organs are evidently smaller than in health, often less than half as large. I have seen them less than five centimeters (2 inches) in length. Next to this reduction in size, the most striking feature of the contracted kidney is its uneven or granular surface, which is, however, not always recognizable until after the capsule is removed. Very characteristic also is the presence of cysts with more or less clear watery or gelatinous contents, often visible through the capsule. These are not invariably, but quite frequently, present. The capsule, itself thickened, strips off with difficulty, dragging portions of the secreting structure with it. Owing to the resistance which the blood meets in its passage through the kidney, a larger portion of it passes out of the organ by way of the

capsule; hence the blood-vessels of the latter are dilated, as are also the lymph-spaces.

Bereft of its capsule, the kidney is hard, granular, tough, and usually darker than in health, whence one of its names, the "red granular kidney." This color is in strong contrast to the white or slightly yellow tinge of the fatty and contracting kidney, and although it is not always marked, and sometimes even substituted by a paleness, it is still easily distinguished from that of the contracting kidney of parenchymatous nephritis. The granules on the surface of the contracted kidney are distinct round and oval elevations of the surface, ranging in size from that of a pin's head to that of a pea, or from  $1/25$  to  $1/5$  inch (1 to 5 mm.). Those of smaller size are most numerous, and at first correspond with the lobules, the bases of which are visible on the surface of the normal organ. The larger ones result from the coalescence of two or more of the smaller. The granules themselves are of a lighter color than the depressed circlets between them, which are tinted with vascularity and have a purplish or faint red hue. The *cysts* already referred to are now more distinct (after removal of the capsule), and vary greatly in size. While equaling in minuteness the smallest of the granules, some of them are as large as a walnut. The larger are apt to be ruptured on stripping off the capsule.

*On section*, it is at once evident that the reduction in size of the kidney is largely due to a narrowing of the cortex, although the medulla is also contracted. The former may not be more than from  $1/8$  to  $1/6$  inch (3 or 4 mm.) in width, and exhibit every degree between this and the normal. The Malpighian bodies are smaller, less numerous, and can scarcely be detected by the naked eye, while the small arteries are more prominent from the thickening of their walls. Increased density and firmness of the organ are apparent. In a gouty subject, linear chalk-marks of sodium urate may be present, more particularly in the pyramids of straight tubules, and are contained within; as well as between, the latter. The little cysts referred to as seen on the surface may also be scattered throughout the section from cortex to papillæ, but they are more numerous in the former. They are not always present. The pelvis of the kidney may be unaltered. It is sometimes enlarged, and the calices are elongated from retraction of the pyramids. On the other hand, if the kidney is very much reduced in size, the capsule may be pursed up and proportionately smaller.

*Minute Structure.*—Minute examination of thin sections through the cortex clearly reveals the condition to be an excess of connective tissue, with destruction of the tubules and blood-vessels. The process is best studied if the sections include the capsular edge, as the disease progresses from without inward. In such sections may be seen extensive tracts of connective tissue separating the tubules, which, in healthy kidneys, are closely in contact without appreciable intertubular substance. The *tubules* themselves appear in places quite normal; in others they are represented by fragmentary portions in which the cells are still unchanged; in others, again, the cells exhibit a granular degeneration; some tubes are evidently dilated; others still are completely shriveled, while it is evident from the larger areas of connective tissue that many have completely disappeared. In a few tubules waxy casts are present. The Malpighian bodies are sur-

rounded by concentric layers of nucleated connective tissue. Many of them are shriveled and atrophied, and an attempt to inject them with colored injecting fluids fails either partially or completely. Some thus altered lie detached from the tubules, with which they should be continuous. The granules on the surface of the kidneys are resolvable by the microscope into tubules, some of which are in a tolerably perfect state, some decidedly dilated.

The *cysts* originate partly in dilatations of obstructed segments of the uriniferous tubules and partly in dilated Malpighian capsules. Proof of the latter mode of origin is found in the fact that compressed capillary tufts are sometimes found lying up against one side of the wall of the cyst. The same overgrowth of connective tissue may be seen in the pyramids, but it appears later, extends more slowly, and never reaches the degree found in the cortex.

The *blood-vessel* of the contracted kidney is the seat of important changes. In the first place, it shares with the tubules the compressing effect of the contracting new formation. As the result of this, a part of the capillary system is destroyed, and in the part thus destroyed are many capillary coils in the Malpighian bodies. Hence, as many afferent arterioles send their blood directly into the second capillary network, which is also cut down by the pressure. The vessels which remain are often sclerotic, dilated, and twisted, and in consequence of the destruction of numerous Malpighian bodies send much of their blood out through the capsule of the kidney. The intima is thickened, and the media and adventitia are invaded by hyperplastic connective tissue, but always to a less degree. Even arterioles whose walls have thus been thickened become involved in the atrophic processes affecting the glandular tissue of the organ, and ultimately disappear.

Associated with these changes are a *general arteriosclerosis* and *hypertrophy of the left ventricle* of the heart, sometimes also of the right. The final effect of these alterations is to produce a brittleness in the arteriole walls, which disposes them to rupture on very slight increase of intravascular pressure. Hence the frequent fatal termination of cases of interstitial nephritis by apoplexy, also the frequent nasal and retinal hemorrhages which characterize the disease.

The *retinal changes*—*retinitis albuminurica*—symptoms of which form so important a part of the symptomatology of chronic interstitial nephritis, are various and vary with the stage of each case. Many cases are first diagnosed by the ophthalmic surgeon. The changes include serous swelling of the disk and surrounding retina, hemorrhagic extravasations, dirty white splotches, representing fatty degeneration, and dilatation of the veins and capillaries, with fatty degeneration and sometimes hyaline thickening of their walls.

**Symptoms.**—The great obscurity as to the origin of a large majority of cases of contracted kidney is only equaled by that of the insidiousness of their approach. The beginning of the disease is certainly not characterized by any distinctive symptoms; and its progress is often unmarked by any, until those of uremia point to the beginning of the end. To the observing physician some obscure symptom may suggest an examination of

the urine; or the peculiar tense and bounding pulse of hypertrophy of the left ventricle, or the more tangible symptoms of a slight swelling of the feet or ankles, recognizable only at night or through the unexpected tightness of a boot, may lead to the same examination. An accidental recognition of greatly increased blood pressure may suggest the disease.

*Changes in the Urine.*—Attention being called to the *urine*, it will be found to present characters which are more or less distinctive and lead easily to a diagnosis. When freshly passed, it is acid in reaction, copious, often exceeding the normal amount, and never scanty, except in the last stages of the disease. The quantity is often 60 (1800 c.c.), and may reach 90 ounces (2700 c.c.). The patient very commonly must rise at night, probably not more than once or twice, to void urine. There may be corresponding thirst. Consequently, the urine is light in color and of low specific gravity—1005 to 1015—and contains a trifling or moderate flocculent sediment. It is generally albuminous, but the albumin is small in amount and may be temporarily absent, or it may be absent before a meal and present after it. Later, however, the albumin becomes constant. It seldom exceeds one-tenth the bulk of fluid tested, and is very constantly a great deal less, showing a delicate line of white by Heller's nitric acid test. Tube-casts are present, but not usually numerous. They are almost solely hyaline and pale granular. Some of the hyaline casts are delicately so, requiring delicate illumination for their detection; others are distinct and sharply cut; others still contain two or three glistening oil drops. Casts may at times be absent and again reappear, as is the case with albumin. Toward the termination of cases of interstitial nephritis the urine diminishes in quantity, the specific gravity increases, and the casts become much more numerous, and include among them highly granular or dark granular and occasionally even blood-casts in addition to those mentioned, and there are sometimes a few blood-disks earlier. The *urea* is also diminished, sooner or later, and in this manner the lower specific gravity is contributed to. This fall becomes marked toward the close, accounting for the uremic symptoms which often first announce the disease. It may be as low as 15 grains (1 gm.), and may range anywhere between this and the normal 24 hours' quantity, which may be put down at from 308 to 617 grains (20 to 40 gm.) in an adult, being largely influenced by the kind of food ingested. All the remaining normal constituents may be said, in general terms, to be diminished.

As to the other symptoms, a feeling of *unaccountable weakness* or of being tired is very often present, but it is a symptom which occurs in many conditions, and should only be considered as suggestive. *Slight edema* about the feet and ankles is often present, being so slight as to escape detection, or it is discovered accidentally. When present it is significant, but it is often entirely wanting.

*Hypertrophy of the left ventricle* of the heart without valvular disease is so constant as to be alone suggestive of the disease. No case of interstitial nephritis has existed for any length of time without this condition supervening, and as few cases are discovered until they have existed for some time, few are found without hypertrophy. In more than one-half of cases, at least, hypertrophy is evident. It is recognized at first not so much

by the resulting enlarged percussion area as by the sharp accentuation of the aortic second sound. Corresponding to this, the *pulse* is hard and resisting, indicating high tension and thickening. These two symptoms have, therefore, great diagnostic value. *Sclerosis* is distinguished from tension by obliterating the blood-current by pressure and feeling the artery beyond this point. The sclerosed vessel continues tangible; that of simple high tension disappears. A symptom of this stage is often an uncomfortable *pulsation* felt in the head and even in other parts of the body.

It is not easy to estimate the exact number of cases of pure interstitial nephritis associated with hypertrophy of the different cavities of the heart. The observations of Hasenfeld, in 1897, and von Hirsch, in 1900, found hypertrophy of all chambers in over 75 per cent. Von Buhl's results are essentially the same. Recently some attempts were made to settle this question by Nathaniel Bowditch Potter<sup>1</sup> and Horace Oertel, of the New York City Hospital, resulting as follows:

286 Autopsies, 151 Cases of Nephritis.

	Per cent. of Hyp. of L. V.	Per cent. of Hyp. of L. & R. V.	Per cent. of Normal or Atro. Heart.
66 chronic interstitial	30.5	11.5	58
22 arteriosclerotic interstitial,	27	9	64
25 chronic parenchymatous,	12	4	84

These observers did not follow Müller's accurate method or it is probable they would have found a larger proportion of cases in which the left ventricle and both ventricles were enlarged. Of the cases of atrophic or normal hearts generally associated with deficient nutritive power they found a number in which there was reason to believe the heart was originally hypertrophied and became later atrophic.

An increase of blood-pressure as recognized by the sphygmomanometer is a very characteristic and diagnostic sign, the measure being anything above 160, to 200 and 220 millimeters of mercury.

The causes of these changes in the vascular system will be considered when treating of the relation of heart disease and kidney disease.

As the disease becomes more advanced there are added *cardiac symptoms*, including dyspnea, palpitation, and reduplication of the first sound. The last is probably due to a want of synchronism in the systole of the two ventricles. There is usually no murmur, because there is no valvular disease. The latter may be present. The patient may have had valvular disease prior to the renal malady, or the latter itself, by its long continuance, may have produced endocarditis and atheroma with an aortic systolic murmur. There may be a mitral murmur due to relative insufficiency. Valvular disease is, however, unusual. The hypertrophy of the heart is conservative, and all goes well as long as the power of the heart lasts. When the latter begins to fail and dilatation appears, the blood-pressure diminishes, and with it begins a train of symptoms, among which diminished secretion of urine and dropsy are the most conspicuous, along with gallop rhythm, dyspnea, palpitation, and dizziness. These symptoms may again be averted for a time by *hypertrophy* of the *right ventricle*, which is

<sup>1</sup>"Cardiac Hypertrophy as Observed in Chronic Nephritis," by Nathaniel Bowditch Potter. "Journal of the American Medical Association," October 27, 1906.

a symptom of disturbed compensation. Among derangements of breathing must be included Cheyne-Stokes breathing, commonly toward the end of the disease.

*Dimness of vision* due to retinitis albuminurica, already described on page 790 is a characteristic symptom. It is often the first recognized, and hence the diagnosis is frequently first made by the ophthalmologist. It is a serious symptom, generally considered a sign of advanced disease, as, indeed, it usually is. Some assign two years as the limit of life after its recognition, but this is too unfavorable a prognosis. The atheroma of the blood-vessels is the cause of another symptom which frequently determines the mode of death—rupture of a blood-vessel in the brain: in a word, *apoplexy*. This accident is more usual late in life, but Dickinson reports a case in which cerebral hemorrhage occurred in a girl of 12. The proportion of cases of recognized interstitial nephritis in which this happens is not large, but many cases of apoplexy are directly traceable at autopsy to unsuspected renal cirrhosis. Dickinson believes that of fatal cases of apoplexy, one-half are preceded by this form of disease. Hemorrhages in other situations are referable to this same altered state of the blood-vessels, as, for example, into the retina, from the nose, and even into the stomach. *Sudden blindness*, in addition to the dimness of vision due to retinitis albuminurica, is a symptom which occasionally presents itself. Amaurosis and amblyopia also occur, and may disappear, but dimness of vision due to retinitis albuminurica is a permanent symptom, though I have seen it improve under treatment. Auditory disturbances also occur, such as ringing in the ears, with dizziness and more or less deafness.

The termination by *uremia* occurs more frequently in this than in any other form of Bright's disease. Bartels says that nearly all patients he has seen die in the extreme stage of atrophied kidneys sank under the symptom of chronic uremia. He is probably correct, and it is frequently the first intimation of the existence of any derangement, manifesting itself in any one or more of the forms already described under acute nephritis. Headache, drowsiness, convulsions, stupor, delirium, maniacal excitement, renal asthma, *restlessness*, nausea, vomiting—any one of these symptoms may usher in the dreadful train which is so likely to be fatal. E. C. Seguin especially has called attention to occipital headache as a symptom of uremia.<sup>1</sup> Von Leube considers that even the intermittent headaches which occur in this disease, and which very closely resemble migraine, are probably due to uremia. Temperature follows the same rule in uremia as in other forms of nephritis. The *convulsion* is commonly associated with a rise of temperature. *Dyspeptic symptoms*, with obstinate vomiting, particularly in the morning on rising, are apt to usher in a chronic uremia. *Diarrhea* is less common, but also sometimes occurs toward the close, when it may be very difficult to control.

*The duration* of this form of renal disease is indefinite. Always a chronic process, it may last for years undiscovered, and when discovered before it is too far advanced, the knowledge of its presence will suggest measures of precaution and treatment which may so prolong life that it

<sup>1</sup>"Archives of Medicine," vol. iv., No. 1, New York, August, 1880.

need only be determined by its natural limit or some other disease. Yet complete recovery from well-established interstitial nephritis is probably unknown.

**Complications.**—These include bronchitis, pericarditis, pleurisy, pneumonia, and, more rarely, endocarditis, peritonitis, intertubular gastritis, and even inflammation and ulceration of the bowels. But all inflammatory complications, except bronchitis, pleurisy, and pericarditis, are less frequent than in acute nephritis. The older authors emphasize bronchitis as a frequent complication, according to W. Howship Dickinson, 33 per cent. and according to Sir T. Grainger Stewart seven per cent. My own experience accords more nearly with the latter. Pericarditis is the most serious complication, occurring to Dickinson in 25 per cent. Pleurisy and pneumonia are also of tolerably frequent, Stewart finding the former in 15 per cent. of his cases and pneumonia in seven per cent. Acute endocarditis and peritonitis occur, but very seldom.

**Diagnosis.**—The diagnosis of an interstitial nephritis is usually easy, if in any way an examination of the urine is suggested. The increased quantity, the low specific gravity, small albuminuria, delicate hyaline, pale granular casts, and hypertrophy of the left ventricle, even in the absence of other symptoms, are sufficiently distinctive. The conditions which should suggest such an examination are a feeling of constant weariness, slight swelling of the feet, drowsiness, frequent headaches, confused intellect, dyspeptic symptoms, obstinate nausea, delirium, coma, and convulsions. High arterial tension should always suggest examination of the urine.

The special condition from which it is most difficult to distinguish it is the milder form of *chronic diffuse* or *parenchymatous nephritis*, especially if the latter has reached the contracting stage. In fact, the symptoms are often identical, and unless the history helps us, it may be impossible to decide. The evidences of decided fatty change, such as the oil-cast or free fatty renal cell in the urine, settle the question in favor of chronic diffuse nephritis.

It is important, if possible, to distinguish between interstitial nephritis with secondary arterial sclerosis and *general arterial sclerosis with secondary contracted kidney*, but it is not always easy to draw a sharp line between these two conditions. Both are equally insidious, in both there is the absence of dropsy except in the very last stages of the form with primary renal sclerosis, though here it is also rare, while it is wanting throughout in general arterio-sclerosis. In both there is a scanty albuminuria with very few hyaline casts, but if the opportunity presents to study urine for a time I should say the albumin and casts appear earlier in the primary renal cases. Indeed, in general arterio-sclerosis there is often no albuminuria whatever although hyaline casts may be present. In general arterio-sclerosis there are often brain symptoms due to anemia and imperfect circulation, namely, vertigo, tinnitus and amaurosis. In the latter condition retinal changes occur early, but they are not those of retinitis albuminurica and hemorrhage into the retina. As pointed out by de Schweinitz, there is thickening of the arteries which compress the veins where they cross them. These changes may occur early. Retinitis albuminurica, hemorrhages, and more serious derangements of vision occur only when the kidney lesion is primary. An important symptom characteristic of general arterio-

sclerosis is a tendency to emaciation and loss of weight, a change of color, a pallor, and loss of vigor which is characteristic. The condition of the arteries interferes with an adequate nutrition and the patient wastes as well as grows weaker and anemic. Alfred Stengel holds that this anemia is apparent rather than real, since the blood in the vessels is simply obscured by the thickened vessel-walls. Perhaps the most characteristic difference is found in the blood-pressure. In general arterio-sclerosis blood-pressure may be increased, but not nearly as much as in renal sclerosis where the systolic pressure is often 170 to 220 mm. as contrasted with an average normal of 115 to 140 mm. An important etiologico-pathological difference is claimed by Gull and Sutton in the kidneys. According to them, the destruction of renal tubules is due to the contraction of new connective tissue, the formation of which is due to the arterial changes. In primary contracted kidney the renal parenchyma dies first and is replaced by the connective tissue secondarily.

I have attempted to tabulate these differences between the two conditions as follows:

*Primary Chronic Interstitial Nephritis.*

1. Causes of chronic interstitial nephritis, such as overeating and drinking, gout, diabetes, syphilis, lead intoxication, etc.
2. Characteristic insidious onset, including digestive derangements, small albuminuria, few casts, with little or no evidence of arterial change at first.
3. Edema, never at first, later unusual.
4. Arterial pulsation often very annoying.
5. Vertigo infrequent.
6. Albuminuric retinitis and hemorrhages into retina.
7. Hypertrophy of one or both ventricles rather more frequent, say 42 per cent.
8. High blood-pressure and high arterial tension before vascular change, is evident.
9. True uremia.

*Primary General Arterio-sclerosis.*

1. Same causes.
2. Early appearance of arterial changes.
3. Edema frequent and often marked.
4. No pulsation in head or elsewhere.
5. Vertigo common.
6. Retinal changes, but not hemorrhage, nor retinitis albuminurica.
7. Rather less frequent, say 36 per cent.
8. Moderate or lowered blood-pressure, moderate arterial tension.
9. Simulated uremia.

Strictly speaking, all nephritis is primarily parenchymatous or tubular, but in what is known as chronic interstitial nephritis the changes are slower and the replacement by connective tissue more prompt and rapid, so that the interstitial element predominates and the cells are destroyed more rapidly.

*Diabetes insipidus* is comparable to contracted kidney in the increased quantity of urine of low specific gravity, but there is no albumin, casts are absent, and the quantity of urine is much greater.

**Prognosis.**—The prognosis is unfavorable as to recovery, but favorable as to prolongation of life if the diagnosis be made sufficiently early. Cases with casts and small albuminuria may continue under observation for ten or more years. If not made previous to the setting in of uremic symptoms, little may be expected. But even at this stage, energetic treatment may still avail to avert the immediate danger and prolong the patient's life. The possible sudden occurrence of convulsions and coma, and of death therefrom, should always be remembered and impressed upon the relatives

of the patient. These constitute unfavorable symptoms, to which, toward the end, Cheyne-Stokes breathing may be added.

**Treatment.**—From what has been said under prognosis, it is evident that the most hopeful result to be expected from treatment is the protection of the patient from the consequences of his malady, rather than the restoration of the kidney to its normal condition. Our power in the former respect depends largely upon the stage at which the disease is discovered. If detected at a period in which the urine is abundant, the albuminuria small, the casts few, and there is no edema, the indications are:

1. To maintain the integrity of the blood, by preventing the accumulation of urine—toxins in the blood.

2. To treat, as they arise, the accidents and complications which are often so dangerous to the patient.

The first of these is best accomplished by dietetic and hygienic measures, aided by the use of a few remedies. First, as to *food*, all that was said under chronic parenchymatous nephritis is applicable to interstitial nephritis, because the appetite is still good, and a suitable selection can be exercised. As the urea has its chief source in the azotized elements of food, it is plain that the larger the quantity of such food consumed, the larger is the accumulation of urea to be eliminated by the kidneys. Now, while it is not possible nor, perhaps, desirable to exclude all nitrogenous food, it may be largely reduced. This is accomplished by the substitution of all or a part of animal flesh by milk, while drawing the elements of a mixed food from the vegetable kingdom. The so-called vegetarians have proved conclusively that it is possible to live and maintain good health upon milk and an otherwise exclusively vegetable diet, and, while this diet may not be compatible with the highest mental and physical development of which man is capable,<sup>1</sup> which is not all proved, the resulting life is perfect enough for all its objects, and will doubtless be acceptable to those who prefer to live. On such a system I have known the patient with contracted kidney to maintain apparently perfect health for many years.

With regard to habitual beverages, the use of strong alcoholic drinks is harmful, and brandy, whisky, champagne, sherries and ports should be prohibited. The light wines, and especially the red wines and lighter alcoholic drinks, as lager beer, porter, etc., may be used in moderation. I have already referred to the very great value of the alkaline mineral waters, such as those of Vichy, Vals, and Kissingen; to these a little claret may be added at dinner.

What has been said of clothing, fresh air, and exercise in connection with chronic parenchymatous nephritis is even more applicable to interstitial nephritis. Warmth of the body, maintained by woolen garments next the skin to encourage its action, and the avoidance of damp and cold, which check it, are peremptory. The wetting of the body by rain, or of the feet alone, has frequently been the exciting cause of a fatal uremic attack. India-rubber overshoes should be worn in damp weather.

In this connection, sea-bathing requires mention. It is well known that sea-bathing sometimes induces albuminuria in normally constituted

<sup>1</sup>See Carpenter's "Physiology," seventh English edition, 1869, p. 77.

persons, or, at least, in individuals at other times free from albuminuria. This is probably due to a temporary congestion of the kidney, from introversion of the blood kept up by the duration of the bath. Still more mischievous, therefore, must be the effect of prolonged sea-bathing upon one whose kidneys are already damaged and incompetent to perform their office. Sea-bathing, therefore, or any form of cold bathing, should be interdicted to the patient with contracted kidney, or, indeed, with any form of chronic nephritis. Sea-bathing is especially mentioned because it is considered healthful, and persons remain in the water so long at a time. On the other hand, a daily warm bath at bedtime, and especially an occasional Turkish bath, is advantageous.

For the same reason residence in a warm, equable climate is often of signal service in interstitial nephritis; and cases are reported in which the albumin has disappeared and symptomatic recovery taken place during such residence.

Prolonged bodily or mental fatigue should also be avoided by these patients, as they have been known to be the exciting cause of uremia and death; especially are they so when associated with free eating and drinking. The patient should live a life as easy and as free from any of these causes which have been considered as his circumstances will permit.

As to drugs, they are of limited utility. The moderate use of *tonics*, including quinin, strychnin, and iron, is useful to combat the tendency to anemia and weakness, which sooner or later follows. In this form of Bright's disease, even more than in chronic parenchymatous nephritis, is the indiscriminate use of iron to be guarded against. Iron in contracted kidney, as often used, is a harmful drug. It locks up secretions, causes headache, and increases the danger of uremia. Only when there is evident anemia should it be used, and then only in very small doses. I hold that so long as iron blackens the stools or constipates the bowels, the doses are too large, and they should be reduced until the effect on the stools is very slight or not noticeable. Elimination is favored by stimulating the secretion of the skin, and this is best accomplished by an occasional warm bath, or, especially, a Turkish bath, with thorough friction and protection from cold by woolen underclothing. The Turkish bath is an admirable remedial measure, especially before the disease is too far advanced.

*Diuretics* are not indicated in the earlier stages, because the secretion of urine is already free. The bowels should be kept regular by the use of the natural aperient waters, the Hunyadi, Friedrichshalle, Apenta, Veronica and Rakoczy, or an occasional blue pill, or a dose of magnesium sulphate. Of course, later in the disease, when the heart begins to fail and the urine is scanty, both diuretics and purgatives are indicated. The same principles are to govern us in using them as have already been laid down under acute nephritis. Very high arterial tension sometimes demands treatment. A certain amount is a result of the conservative train of symptoms, beginning with hypertrophy of the left ventricle, and is necessary; but when a resulting throbbing is unpleasantly appreciable, especially if there is throbbing headache with flashes of light at each pulsation, tension should be lowered. The remedy which excels all others is nitroglycerin, which should be given in doses of 1/100 grain (0.00066 gm.) and upward

every three hours or oftener. The best preparation is the one per cent. alcoholic solution, of which one drop represents  $1/100$  grain (0.00066 gm.), the granules being more convenient, but less reliable. The dose should be rapidly increased until the physiological effect is obtained, and then reduced to what is found best to effect its purpose. Either the susceptibility of different persons varies greatly or the drug varies greatly in quality. I have repeatedly given it every two hours for days together in doses of  $1/100$  grain (0.00066 gm.). It may be associated with digitalis, with which it cooperates by relaxing the arteriolar spasm which digitalis produces, and which interferes with its happiest effects. Sometimes nitroglycerin fails of its purpose when small doses of tincture of aconite make an admirable adjuvant or substitute.

The second indication mentioned, the *treatment of the complications and accidents* incident to the condition, resolves itself into the treatment of the bronchitis, the pericarditis, the pleurisy, pneumonia, endocarditis, gastric and intestinal disorders, which have been named as occurring, and especially of the most serious calamity of all, uremia. The treatment of the complications is that of the same conditions under other circumstances. Paracentesis is a measure which is often of signal service in effusions into the chest, and occasionally of the pericardium.

Dyspeptic symptoms are best treated with pepsin and acids, and such other remedies as may be symptomatically required. *Opium* should be cautiously employed, if at all, not only in the gastro-intestinal disturbances, but under all circumstances, as it undoubtedly increases the dangers of uremia. This has been abundantly proved. It need not be discarded altogether, for there is sometimes no substitute for it in certain bowel affections and conditions of severe pain, but it should be given in smaller doses than usual and its effects watched. In like manner, hypnotic, sedative, and antispasmodic effects, when desired, should be produced by sulphonal, trional, vernal, chloral, and bromids, if possible.

Finally, as to the treatment of uremia, the measures described in the treatment of uremia in acute nephritis are to be used. Apoplexy, which is not an infrequent termination of the disease, in consequence of the atheromatous state of the blood-vessel walls, is recognizable by the paralysis, general or partial—most frequently hemiplegia—which accompanies the unconsciousness. Remedies are here generally futile, but such may be used as are indicated for apoplexy. The upright position, bleeding, counterirritation, and, if the patient survives the immediate accident, iodid of potassium, with a view to promoting absorption of the extravasated clot, may be used. Hemorrhages in other situations, as from the nose or alimentary canal, are treated by the same measures as when they occur under other circumstances. The close resemblance at times of the symptoms of uremia to those of apoplexy should be remembered.

As to special treatment, or treatment directed to the removal of the interstitial overgrowth in the kidney, there is none. Theoretically, the iodid of potassium ought to be of service. Unfortunately, the peculiar requirements of its administration—viz., the length of time during which the patient must take the remedy before any results may be expected, and the consequent difficulty in accumulating a sufficient number of cases—are

such that it is almost impossible to determine whether it can be of any service or not. Owing to these difficulties, it is doubtful whether its exact possibilities have as yet been determined. There can be no disadvantage in administering it, if the dose is so small as not to derange the stomach. Very rarely can more than a few grains daily be given. I believe I can say, however, of the bichlorid of mercury, that I have seen its long-continued use in doses of, at first,  $1/24$  grain (0.0027 gm.), and later  $1/50$  grain (0.0013 gm.), kept up a long time, followed by improvement. I have also seen improvement in the impaired vision of albuminuric retinitis follow its use. Certainly, in the event of a clear syphilitic origin, the iodid of potassium should be used. I have also used the biniodid of mercury with apparent happy results, in doses of  $1/24$  to  $1/16$  grain (0.0027 to 0.0040 gm.) a day.

*Operative treatment* by decapsulation has been applied in contracted kidney as well as in chronic parenchymatous nephritis. Indeed, some believe it more indicated in chronic interstitial nephritis, but my experience has been different. See treatment of chronic parenchymatous nephritis, p. 785.

## LARDACEOUS DISEASE OF THE KIDNEY.

SYNONYMS.—*Amyloid Disease; Albuminoid Disease; Waxy Kidney; Depurative Disease.*

**Definition.**—A morbid state of the kidney in which its structural elements are more or less infiltrated with a substance of albuminous composition and of bacony luster, best recognized by the deep mahogany-red color it strikes when treated with a solution of iodine.

**Etiology.**—The most frequent cause of lardaceous disease is profuse and long-continued suppuration, such as occurs in chronic bone disease, whether tubercular, syphilitic, or traumatic in origin; or such discharge as constitutes the expectoration in cases of chronic phthisis and chronic bronchitis with bronchiectasis. Syphilis itself, independently of the tertiary conditions which it produces, is a frequent cause of lardaceous disease. Cachectic states of any kind, chronic dysentery, ulceration of the bowels, and chronic albuminuria are possible causes.

Either sex is equally subject to lardaceous disease, but as men are more frequently exposed to its causes, it is in them rather more common. Very young children are rarely affected, for evident reasons, but in young persons from 11 to 30 it is most frequent. After 30 it grows gradually rarer. Tubercular hip disease in children, especially, is a cause.

**Morbid Anatomy.**—The incipient stages seldom present alterations recognizable by the naked eye, unaided by reagents. But if, after section of the kidney, the cortex be treated by a solution of iodine and iodid of potassium,<sup>1</sup> numerous mahogany-red points make their appearance; or if by a solution of violet anilin, as many red or pink points. These are the Malpighian bodies, whose capillary tufts are the first to be affected by the

<sup>1</sup>*The Iodin Test Solutions.*—The best test solution for macroscopic purposes is one made by dissolving  $2\frac{1}{2}$  grains (0.16 gm.) of iodine by the aid of five grains (0.32 gm.) of iodid of potassium in one fluidounce (30 c.c.) of water. The solution contains about one-half of one per cent. of iodine. For microscopic preparations a solution weaker than the foregoing, or a one-quarter of one per cent., of iodine dissolved by twice the quantity of iodid of potassium, is more suitable, and sometimes a solution containing as much iodine as water alone will take up answers best.

change. The kidney, in this early stage, is normal in size or very slightly enlarged. Its capsule strips off readily, leaving an organ which exhibits no changes, or a paleness or translucency which readily escapes notice, but may be recognized at the edges of a thin section. Very often, too, they are completely overshadowed by other alterations, for amyloid kidney is most frequently a superadded event in the course of chronic diffuse nephritis while the same event may happen in interstitial nephritis. The large white kidney of chronic parenchymatous nephritis is especially apt to exhibit a slight degree of lardaceous change, which may altogether escape notice unless iodine is used. Hence, *iodine should be tried upon all kidneys removed at autopsy.*

In a more advanced stage of uncomplicated lardaceous change the kidneys are both enlarged, usually symmetrically, but the extreme degrees of enlargement are commonly associated with fatty degeneration of the epithelium. Such organs were a pair weighing 23 ounces (715 gm.) which came under Dickinson's<sup>1</sup> notice. Johnson<sup>2</sup> refers to a case in which the two kidneys weighed 28 ounces (870 gm.). Rindfleisch<sup>3</sup> has seen a single instance of that very rare condition, complete lardaceous infiltration—that is, in which the basement membrane of the uriniferous tubes, as well as the capillaries, was infiltrated—in which the kidney was enlarged to nearly twice its normal size. In the uncomplicated forms of lardaceous disease the capsule is not adherent, but if interstitial changes coexist to any extent, it is adherent. It leaves the surface of the kidney pale and anemic; occasionally, the stellate veins are conspicuous. The characteristic translucency may even be recognized in the organ in bulk, but in sections it is more striking. When the change is present in high degree, the edges of a thin section are almost as translucent as a similar section of bacon. On laying open the kidney the cortex is seen to be enlarged; it is pale, anemic, waxy, firm, and resisting. The pyramids are normal in hue and area. The iodine solution added to such a kidney produces its peculiar coloration not merely in the Malpighian capillaries, but also in the afferent and efferent vessels and the vasa recta of the pyramids. In a still later stage, that of atrophy, the kidney becomes contracted, diminished in size, rough, and even distorted in shape. The capsule is adherent, and on section the cortex is found narrowed, sometimes as much so as in the contracted kidney of interstitial nephritis.

*Microscopic Changes.*—To microscopic examination in the first stage, in which the naked eye often fails to detect anything abnormal without the aid of iodine, the Malpighian bodies exhibit a lustrous or waxy appearance. They are also enlarged and the capillary walls thickened. At this stage there is no visible alteration in the tubules or in their epithelium. In the second stage larger vessels are involved, the vasa afferentia and efferentia in the cortex, and also the vasa recta of the cones; also the second capillary network of the cortex, and an exudation occurs into the tubules of a glistening material which forms casts. This is undoubtedly at times the amyloid material, for such casts sometimes strike the mahogany reaction. At other times they have the composition of ordinary hyaline casts. It

<sup>1</sup> Dickinson, *op. cit.*, p. 249.

<sup>2</sup> Johnson, *op. cit.*, p. 104.

<sup>3</sup> Rindfleisch, "Path. Histology," "New Syd. Soc. Trans.," 1873, vol. ii., p. 167.

is to be remembered, too, that similar waxy casts are found in the tubules in other forms of chronic and even acute renal disease.

The arteriole walls are thickened by an involvement of both interna and media. This thickening is attended by an extraordinary distinctness of the muscular fiber-cells of the circular coat. Later, the basement membrane and epithelial lining may also be invaded, the cells being swollen, translucent, and apparently fused. It is also quite usual for the epithelium of the cells to be fatty, and the capillary walls to contain aggregations of fat globules, while the urine in the later stages contains oil casts and fatty cells.

In what has been called the third or contracting stage of lardaceous kidney, but which may be the ordinary contracted kidney on which the amyloid change has been ingrafted, minute examination reveals, in addition to the appearances described, the hypernucleated intertubal overgrowth. Cysts are occasionally present for the same reason that they are found in the granular contracted kidney, and the surface assumes also a certain degree of granulation.

**Symptoms.**—An individual who has had syphilis, or who has phthisis, bone-necrosis, or other affection causing an exhaustive drain, may acquire this form of kidney disease without appreciable addition to his symptoms. There may be a growing frequency in micturition, but this symptom may be totally absent. A somewhat copious albuminuria may be accidentally discovered. At first the urine may be quite clear, and no casts are met, or they are exceedingly scanty and hyaline or faintly granular. Later, a slight edema of the feet may appear while the patient is up and about, but it disappears during the night while he is in bed. The albuminuria is now copious, but still varies, and casts may be more numerous, or may still be scanty and continue hyaline or faintly granular. The urine is now decidedly increased in quantity—53 to 80 ounces (1600 to 2500 c.c.); its specific gravity is low—1005 to 1015. More rarely the urine is scanty. A cachectic anemic condition develops. There is sometimes a peculiar fetor of the breath, but it is doubtful whether this is characteristic of this more than of other forms of chronic kidney disease. Still later all these symptoms increase; the dropsy is persistent, the urine loaded with albumin, and, in addition to the ordinary delicate hyaline casts, it may contain the glistening waxy casts.

Senator announced some years ago that *serum globulin* is increased in the urine of amyloid kidney. Some winters ago I was enabled to make some observations which make me confident that he is right and that it is quite a valuable diagnostic sign. Fatty casts and free fatty epithelium from the tubules of the kidney may be superadded, as well as free oil drops. Epithelial casts are rare, as is blood. Edema of the lungs may also occur as a serious complication. Toward the close of the disease, the urine, which had been increased, becomes diminished in quantity, but is seldom suppressed. Of the chemical constituents, it may be said of all that they are, as a rule, slightly diminished, but not sufficiently to influence the course of the disease. It is in consequence of this that uremia is almost unknown in lardaceous disease, the urea and extractives being eliminated in sufficient amount to avert this evil. Nor do we find hypertrophy of the left ventricle or high arterial tension.

But lardaceous disease of the kidney almost never occurs alone. It is always accompanied by similar changes in the liver, spleen, and often of the intestinal canal. Hence, evidences of alterations in these organs are more or less marked. Thus, the percussion areas of the liver and spleen are almost always enlarged, and the blood-vessels of the stomach and intestines are often involved. In the former event obstinate vomiting, and the latter equally obstinate diarrhea, results. The latter is far more frequent than the former.

As to *duration*, the disease generally runs a very chronic course, which is limited only by the malady of which it is a complication. As such it is always of shorter duration than interstitial nephritis, and may be shorter than chronic parenchymatous nephritis, although the latter affection and lardaceous disease more closely resemble each other in respect to duration. When obstinate diarrhea and vomiting supervene, the end is usually not remote.

**Diagnosis.**—There are some instances in which lardaceous disease is easily recognized. If a patient has had syphilis with secondary and tertiary symptoms, or has long been a victim to phthisis, and he is discovered to be edematous and to have a large albuminuria, with an increased amount of serum globulin, with waxy hyaline and fatty casts and an enlarged liver and spleen and obstinate diarrhea, there can be little doubt but that there is lardaceous disease. But when neither of these two general diseases is present, or the phthisis has not existed a very long time, or there is not decided evidence of enlarged liver and spleen, we cannot be certain. While it is never safe to diagnose lardaceous disease without the presence of enlarged liver and spleen, such enlargement on the other hand, even when associated with large albuminuria does not necessarily imply amyloid kidney. The symptoms and course of the disease, particularly in its latter stages, are so like those of *chronic parenchymatous nephritis* that it is often impossible to separate the two. Further, there is every reason to believe that chronic nephritis is sometimes caused by the same dyscrasic conditions as produce the lardaceous disease. In such cases, too, therefore, a diagnosis is impossible. Finally, the two conditions may exist jointly.

The only other form of renal disease which it is at all possible to confound with lardaceous disease is *interstitial nephritis*. But in this we have the almost total absence of dropsy, small albuminuria, and scanty sediment, in which granular and hyaline casts are found. While the quantity of urine is increased in both these forms of chronic Bright's disease, the quantity is larger in interstitial nephritis. Hypertrophy of the left ventricle, an almost invariable symptom in contracted kidney, is very rare in lardaceous disease, while enlargement of the spleen and liver is common and does not occur in interstitial nephritis. Contracted kidney may also be associated with lardaceous disease.

**Prognosis.**—In the matter of prognosis much depends upon the presence or absence of the original disease causing the amyloid change. If the former cannot be cured, the effect of the latter can only be to hurry on the unfavorable termination, although it is subject to abatements as well as exacerbations. If the original disease is curable and the patient young, there are no limits to the possible improvement,

although it is scarcely likely that the diseased structures are ever restored to their normal state. But as it is unlikely that all the renal vessels are involved in the change, and the organ itself, is one capable of assuming an extraordinary degree of supplemental function, it is not impossible that there may be practically complete restoration of function. If the patient be past middle life, even if the original disease has disappeared, the probabilities of recovery are small, while a decided improvement is not impossible. If the stage of alteration of the blood-vessels of the stomach and intestines, as attested by obstinate vomiting and diarrhea, is reached, the disease is necessarily rapidly fatal.

**Treatment.**—Of the lardaceous disease it may be said with greater emphasis than in any other renal disease, “an ounce of prevention is worth a pound of cure.” A due appreciation by surgeons and syphilographers of the causes of lardaceous disease would prevent the occurrence of many cases, the timely amputation of a limb long the seat of suppuration and the thorough treatment of syphilis being all that is necessary to accomplish this. To this end also frequent examinations of urine should be made by the surgeon in charge of cases of the kind so often referred to, and the slightest indication of albuminuria should be the signal for prompt interference, if such be possible, while the possibility of the occurrence of this renal complication should always be before the surgeon’s mind. Especially watchful should be he who is in charge of children with hip-disease.

In syphilis the faithful and persistent use of remedies for a sufficient time after all the symptoms of the primary and secondary affections have disappeared is essential. To this end the “continuous,” rather than the “intermittent,” treatment of syphilis by small doses of mercurials long continued is the plan most likely to secure the eradication of the disease, and this should be kept up for at least six months after the disappearance of all syphilitic symptoms. (By small doses are meant doses of from  $1/50$  to  $1/25$  grain (0.0013 to 0.0026 gm.) of the bichlorid.)

If the causing disease continues to exist, the treatment of the amyloid disease is the treatment of the former—if it is syphilis, iodid of potassium and mercurials; if phthisis, cod-liver oil, iron, creasote and creasotal, quinin, an abundance of nourishing food, in which milk and cream should be conspicuous, alcohol, and restorative measures generally, together with fresh air and suitable exercise. Supposing the original disease to have disappeared, the measures of treatment indicated are precisely those of chronic parenchymatous nephritis, for the details of which the reader is referred to the section on that disease.

### SUPPURATIVE INTERSTITIAL NEPHRITIS AND PYELONEPHRITIS.

SYNONYMS.—*Septic and Pyemic Nephritis; Interstitial Suppurative Nephritis; Surgical Kidney; Abscess of the Kidney.*

**Definition.**—Suppurative nephritis, due to invasion of the kidney or its pelvis by pathogenic bacteria, either by way of the circulation or the urinary tract. A milder nonsuppurative grade of this disease, characterized by

cicatricial-like markings on the capsule of the kidney and sometimes by firm adhesions between the capsule and its fatty surroundings, may be named *capsulitis* or *perinephritis*.

Most frequently this form of nephritis starts in the pelvis of the kidney as a pyelitis, and thence extends into the interstitial tissue of the organ. Such a condition is preeminently a *pyelonephritis*. It may also happen that the nephritis starts in the interstitial tissue of the substance of the organ as the result of infectious embolism or traumatism or obstruction of the tubules by concretions. In either event both the kidney and its pelvis are sooner or later involved, and it is scarcely possible to separate the two conditions in diagnosis, and I do not, therefore, separate the two diseases.

**Etiology.**—The most frequent medium of invasion by *bacteria* is *retained* decomposed urine. Retention may be due to stricture of the urethra or even phimosis, to stone in the bladder or ureter or pelvis of the kidney. Perhaps there are always bacteria ready to avail themselves of sufficiently favorable conditions, but a favorite route of introduction is by unclean catheters. In many of these cases inflammation of the bladder is an intermediate state. Calculous concretions in the substance of the kidney also furnish conditions favorable for the action of bacteria of suppuration.

*Infectious emboli* cause a small number of cases of suppurative nephritis. The emboli are usually derived from the valves of the heart in cases of ulcerative endocarditis, but they may also arise in putrid wounds, stumps, or other seats of putrid inflammation. The abscesses found in the kidney in common with other organs in pyemia are thus produced. *Tubercle bacilli* are also causes, entering by either of the routes named, producing tuberculous pyelonephritis. Among the organisms found in the urine and held responsible are, besides the tubercle bacillus, the *bacterium coli commune*, the *protus Hauser*, the streptococcus and staphylococcus. *Parturition* is not an infrequent medium of introduction of pathogenic bacteria, while the infectious fevers are recognized causes.

*Traumatic agencies* such as blows, kicks, or penetrating wounds in the neighborhood of the kidney, or falls from a distance and striking upon the sharp edge of a fence or similar object, may also cause suppurative nephritis.

Suppurative nephritis may occur at any age subject to the operation of the cause. The youngest patient I ever had was two years old.

**Morbid Anatomy.**—The appearances vary necessarily with the stage of the disease and also somewhat with the cause. In an earlier stage, if the inflammation pass from below upward, as is most frequently the case, the mucous membrane of the pelvis is first affected, being swollen and dirty gray in color, sometimes visibly congested. Later, the pelvis and calices may be dilated and the papillæ flattened. The distention may go on at the expense of the kidney until the whole organ is converted into a *pus-sac* bounded by a varying remnant of renal tissue. Such sac may be a constant source of pus, or if complete obstruction occurs, the pus may become inspissated and *cheesy*. The ureter is also often dilated, sometimes resembling, in consequence of such extreme dilatation, the intestine.

In tuberculosis extending *via* the urinary tract the *apices* of the cones are also invaded, it may be from the mucous membrane by continuity, or by direct lodgment of the bacillus. Successive portions of the kidney substance

break down, and the ultimate product will be the same, a sac filled with liquid pus or *cheesy, putty-like substance*.

In other instances, especially when the kidney is invaded by way of the vascular or lymphatic system, as in *pyemic abscess*, foci of suppuration a millimeter and upward in diameter are scattered in the cortex and separated by sound renal tissue. They are surrounded by an intensely red border, are often visible through the cortex, and may be ruptured by dragging off the capsule. On section at an early stage, linear streaks of pus may be found in the medulla.

At a later stage these little collections of pus unite to form larger ones, these again to form others still larger, destroying the tubular structure of the kidney as they encroach upon it, and it is at this stage that cases of pyelonephritis not infrequently terminate unfavorably and the specimens come under observation. At first each of the abscesses thus formed is confined to the region of a single pyramid, and it not infrequently happens that a kidney is partitioned off into spaces corresponding with these. Before this occurs, however, the abscess bursts through the papilla and calyx into the pelvis of the kidney. Thus, in an opposite direction from that first described, the kidney may again be converted into a purulent sac, but these cases generally terminate fatally long before this stage is attained.

When the *abscess is embolic* in origin, its seat is at first occupied by an area of intense hyperemia, resulting in *hemorrhagic extravasation*, which takes place also into the tubules, causing bloody urine. To this succeeds suppuration. The size and number of the abscesses depend upon that of the plug obstructing the blood-vessels, which is usually one of the interlobular arteries or a vas afferens. The embolic abscesses may also be multiple, in consequence of the breaking of the embolus into a number of minute fragments. When the cause is *traumatic*, the process is not so easily defined. Circumscribed abscesses may occur, or the kidney may be converted into a soft, pulpy mass, a mixture of pus, blood, and broken-down renal substance.

In the variety described as *capsulitis*, cicatricial markings or adhesions to adjacent tissue constitute its morbid anatomy.

**Symptoms.**—The symptoms of this condition are not numerous and, apart from the characters of the urine, are not very distinctive. In milder degrees of pelvic inflammation before the kidney is invaded there may be none. *Pain* and *tenderness* are the most constant, but considerable inroads may be made upon the structure of the kidney before pain results. On the other hand, it is often very severe, while the *tenderness* over the region of the kidney is pronounced. This tenderness is the most distinctive and valuable symptom. Usually the severest pain is in the renal region, whence it radiates toward the front of the abdomen and groin, and may be accompanied by retraction of the testicle. When the condition is the result of impacted calculus, the seat of the impaction is the primary seat of pain. It may be between the umbilicus and the pubis when the stone is low down in the ureter. The pain is always intermittent to a degree, sometimes totally so, but generally it is more or less constant, increased paroxysmally. Various positions are assumed by the patient with a view to easing the pain, among which lying on the face is not infrequent.

A distinct *tumor* may sometimes be discovered in the region of the kidney by palpation and percussion. This implies an enlargement of the organ, due either to its conversion into a purulent sac, or an augmentation of its size owing to the distention of its pelvis with pus or calculi or both. Very frequently it is due to perinephric invasion.

*Fever* is also a remittent symptom. Possibly in a very few latent cases it may be altogether absent, but except in these there is always elevation of temperature, with corresponding frequency of the pulse. These latter at times become decided, and in advanced stages the fever is septic, being followed by profuse *sweats*. In acute cases, especially pyemic, the beginning of suppuration is often marked by a *chill* and *high fever* or succession of chills, but in other instances it is quite impossible to recognize the beginning of the suppurative stage.

The *characters of the urine*, as intimated, are more distinctive. Except in acute infectious cases, the urine almost invariably sooner or later contains pus, and unless it does contain pus, no certain diagnosis can be made. *Blood* is also a very constant constituent from cases of suppurative nephritis, but while such urine is scarcely ever examined by the microscope without discovering a few blood disks, the quantity is often not large enough to be recognizable to the naked eye. The quantity of *pus* varies greatly. While it may be so copious as to produce a heavy white opaque deposit one-sixth to one-fifth the bulk of urine, it may be represented by little more than a trace. This variation will occur at different times in the same case. Pus from the kidney and its pelvis is usually distinguished from that formed in the bladder by the absence of that glariness so characteristic of the latter, due to admixture with mucus and decomposition products. Pus from the pelvis of the kidney is rarely fetid, as compared with pus from the bladder.

The urine is usually *diminished in quantity*. Complete suppression is not uncommon toward the close of cases presenting extreme degrees of destruction. Notwithstanding such diminution, the color may be pale and the specific gravity low, owing to the small proportion of urea present, the range of specific gravity in a single case being from 1003 to 1016. In reaction the urine is faintly acid, neutral, or alkaline, and though often prone to rapid decomposition, this is a much less characteristic feature than in cystitis. *It is always albuminous*, but the quantity of albumin is never very large, and varies generally *pari passu* with the quantity of pus and blood. When more albumin is present than is thus accounted for, it is likely that the parenchyma of the kidney has become involved. Such cases, are, therefore, more serious. In such cases, too, *tube-casts*, ordinarily rarely found in suppurative nephritis, may appear.

It sometimes happens that there is a sudden increase in the quantity of pus in the urine, followed by a gradual diminution, or the urine, previously clear, may suddenly become loaded with pus. Such occurrences indicate the probable period of *rupture of an abscess* through a papilla and a pouring out of its contents into the pelvis of the kidney, or of the removal of a temporary obstruction to the descent of the pus. It may happen that a small portion of the substance of the kidney is thus discharged, when it may be recognized by microscopic examination, which will discover the tubules and glomeruli of the kidney. Occasionally, also, the abscess, instead of

rupturing into the pelvis of the kidney, perforates into the perinephric tissue, burrowing in different directions and producing fistulous openings. Perforations may thus take place posteriorly in the lumbar region, or anteriorly at the groin, into the colon, and more rarely into the lungs and liver, and even into the peritoneal sac.

The *course* and *duration* of suppurative nephritis vary greatly. Traumatic cases are comparatively rapid, either toward recovery or death. Pyemic cases may run their course in 48 hours, and are invariably fatal. But cases due to other causes—viz., impacted calculus, tuberculosis, stone in the bladder, or cystitis—may be prolonged indefinitely, while some terminate without being discovered. Sooner or later the patient generally succumbs to exhaustion, but life may be sustained for years with paroxysms of the severest suffering and a surprising degree of destruction of the kidneys. The *greatest danger to those thus affected is intercurrent illness* which is always more serious and more apt to terminate unfavorably. It is then that the kidneys, previously surprisingly sufficient in eliminating power, give way in this respect, the symptoms of uremia supervene, and the patient dies of this complication. It is well known that the operation for stone is much more likely to be followed by a fatal result when the patient happens to have a surgical kidney.

There are no *complications* peculiar to suppurative interstitial nephritis save those mentioned as causing it; or as resulting from unusual accidents, such as rupture and perforation into neighboring organs, or uremia.

In capsulitis the resemblance of the symptoms to those of stone in the kidney is often very striking, and has led to the diagnosis of nephrolithiasis with operation.

**Diagnosis.**—The diagnosis of suppurative nephritis may be easy or difficult. It is easy when there is the history of a traumatic cause followed by hematuria, and later purulent urine, with tenderness and pain over the region of the kidney. If the urine contain pus constantly or intermittently, and in addition to this there be pain or tenderness in the renal region, suppurative nephritis may be averred with reasonable certainty. I know of no distinctive cellular elements from whose presence in the urine it may be asserted that pus comes from the pelvis of the kidney or ureter, for though the little columnar or pear-shaped cells are referred to these sources, they also come from the urethra and bladder. This question is now settled by catheterization of the ureters.

As to differential diagnosis, the only certain means of recognizing the *tuberculous form* is by finding the *bacillus* in the purulent urine, at the present day greatly facilitated by the use of the centrifugal apparatus. Should the symptoms described occur in a case of tuberculosis of the lungs, the tubercular nature of the nephro-pyelitis becomes quite probable.

*Pyelonephritis* is distinguished from *paranephritis* by the more circumscribed shape of the tumor, the absence of edematous infiltration of the lumbar region, and by the presence of purulent urine, unless it happens, as it rarely does, that the paranephric abscess breaks into the kidney and discharges by the ureter. Pain on flexing and rotating the thigh is characteristic of paranephric abscess, because of the involvement of the psoas muscle. Pyemic abscesses of the kidney may be suspected if a pyemic

process is present, and a chill supervene, followed by any or all of the renal symptoms described.

**Prognosis.**—Operation has done much to improve the prognosis of late years. Yet so far as recovery is concerned, it is still in most cases unfavorable. Traumatic cases may recover if the injury is not too extensive, while very grave injuries are usually rapidly fatal. Recovery, too, ensues on cases succeeding infectious fevers and pregnancy. Cases due to obstruction of the ureters cannot get well so long as the obstruction and irritation continue, and as their removal is often impossible, such cases gradually grow worse. On the other hand, their fatal termination may be delayed indefinitely. It is often a matter of astonishment, on viewing the postmortem appearance of cystic purulent kidneys, that the patient has lived so long with such extreme structural changes present, the barest remnant of secreting structure being sometimes found. It is impossible to say how far repair may take place if the cause can be removed. Conditions of this kind occur when a stone has been removed after having been long present either in the bladder itself or in the kidney or ureter. It is scarcely necessary to say that such persons are in imminent danger from the effect of cold, acute disease, or other cause which tends to suppress the action of kidneys already crippled in function.

**Treatment.**—As *operation* offers the best chance of cure in many cases, a surgeon should be called early. There is no curative treatment by medicine for suppurative nephritis without a *removal of the cause*, and as the latter is often impossible, it follows that medicinal measures are mainly palliative. One of the most frequent indications is the *relief of pain*, which is often so severe as to call for powerful anodyne measures—opium and its alkaloids being absolutely essential. Hypodermic injections of morphin in doses of from  $1/8$  to  $1/3$  grain (0.008 to 0.022 gm.), repeated, if necessary, are favorite and effectual methods of relieving the intense pain, which is often due, not so much to the inflammation, as to the impacted calculus or other cause of obstruction. Suppositories of from  $1/2$  to 2 grains (0.03 to 0.13 gm.) of the extract of opium may be substituted. Hot fomentations and simple counterirritants, such as mustard, are also valuable adjuvants.

The *catarrhal process* in the kidney, its pelvis, and the ureter, and also in the bladder, may be treated with varying success. Diluents are decidedly indicated, and for this purpose any one of the numerous negative mineral waters may be used. The alkaline mineral waters are contraindicated, as they inspissate the pus and make it more difficult to pass. The usual remedies are the balsam, benzoic acid and urotropin. Of the first, I prefer sandalwood oil, because it is better borne by the stomach than copaiba. Given in gelatin capsules, each containing 10 minims (0.65 c.c.), of which one or two may be taken three times a day, a decidedly beneficial effect upon the catarrhal inflammation sometimes ensues, seen in the diminished amount of pus. Benzoic acid fulfills another indication, that of securing an acid reaction of the urine, which is very often either alkaline or so faintly acid that it rapidly becomes alkaline, and thus predisposes to decomposition. The benzoic acid is best given in the form of capsules. For an adult 5 grains (0.33 gm.) four times daily are usually sufficient to keep

the urine acid. Larger doses than these may be given, or benzoate of sodium may be used in 10 grain (0.6 gm.) doses, either alone or in conjunction with the sandalwood oil, the former before and the latter after a meal. To children smaller doses should be given, 1 grain (0.006 gm.) three times a day, increasing the dose. The various vegetable diuretics, as buchu, pareira brava, etc., are of little use in suppurative nephritis and pyelitis.

Urotropin or formin is perhaps the best of the three remedies named. It should be given in 5 grain doses (0.33 gm.) four times a day preferably on an empty stomach in solution or in a capsule.

The constant and inevitable tendency in these cases to run down in general health, in consequence of the drain and wear and tear to which they are subject, demands *tonics*, such as quinin, iron, and strychnin, while milk and other nutritious articles of diet are always indicated. The dangers to which the patient is subject from exposure, cold, and dampness should be averted by suitable care and woolen clothing.

I repeat that many of these cases are saved at the present day by a timely nephrotomy, by which the pus is discharged, the kidney drained, and calculi, if present, removed. I look back upon many cases that were allowed to perish whose lives would at least have been materially prolonged by operation.

### PARANEPHRITIS OR PERINEPHRIC ABSCESS.

**Definition.**—Paranephritis is an inflammation invading the capsule and connective tissue about the kidney, terminating almost always in suppuration.

**Etiology.**—A number of causes may be responsible for perinephric abscess. Thus there may be rupture of a nephric abscess through the capsule of the kidney; perforation of the bowel, most frequently seen in connection with appendicitis; extension of suppurative disease from the spine, as in caries of the vertebræ, or from a burrowing empyema; finally, blows and injuries may terminate in suppuration about the kidney.

**Morbid Anatomy.**—At autopsy the kidney is found surrounded by pus, which is usually posterior to it, rarely in front between the kidney and the peritoneum. The pus has often a fecal odor from contact with the large bowel. It may burrow in various directions, and even burst into the pleura and be discharged by the lungs; or it may work its way to the groin and appear at Poupart's ligament. In turn it may perforate the bowel or rupture into the peritoneum, bladder, or vagina. Occasionally the fatty bed of the kidney is found to be converted into a fibrous capsule fused more or less closely with that of the true kidney capsule. There is a milder degree of this condition which I have called capsulitis.

**Symptoms.**—Most cases are secondary to disease in the neighborhood. *Pain and tenderness* in the region of the kidney are the most constant symptoms. In addition there is a peculiar *edematous* or *boggy condition* in the same locality, giving rise to pitting on pressure. The position assumed is often distinctive, the thigh being flexed to relax the psoas muscle, tension on which, especially in adduction, increases suffering.

The patient, if able to walk, relies as much as possible on the opposite leg, on which he leans, assuming also a stooping posture with the spine fixed. The whole attitude and behavior of the patient remind one of hip-joint disease, while the pain may even be referred to the knee, as in this disease. These symptoms do not, however, appear at once, and the approach is often insidious. At other times suppuration is ushered in by chills, fever, and sweats. The plastic form of fibroid paranephritis is without distinctive symptoms. Various directions of burrowing and seats of perforation were mentioned in treating of the morbid anatomy.

**Diagnosis.**—The diagnosis from *nephric abscess*, with which it is most likely to be confounded, has been considered. The attitude of the patient in lying or standing is like that in *hip-disease*, but the history elicits that in its incipency the pain is much higher up in perinephric abscess, while examination shows that the swelling and tenderness are above the hip and not over the hip-joint itself. As most cases except those due to injury are secondary to disease in the neighborhood, it is not necessary to separate the two classes. Secondary forms are more sudden in their onset, though this is not always the case. Doubtful cases may be settled by the exploring needle.

**Treatment.**—This is by section and free drainage, for though spontaneous rupture sometimes takes place, it is apt to be preceded by destructive and dangerous burrowing, which should be anticipated by operation.

## NEPHROLITHIASIS (STONE IN THE KIDNEY).

**Definition.**—Nephrolithiasis means “stone in the kidney,” but the term is a general one, which covers the presence in the kidney, its pelvis, or ureter of concretions large enough to justify the term “stone,” of smaller masses appropriately known as “gravel,” and fine particles known as “sand.”

**Morbid Anatomy.**—Except in the case of “sand,” which includes particles made up either of pure uric acid or oxalate of lime, gravel and stone, as found in the kidney and its pelvis, always have an organic basis through which are distributed the mineral matters which go to make up their bulk, and which remains as a framework after the mineral matters are dissolved out. The matters thus precipitated, in some one of the shapes named, in the order of frequency are:

- (1) Uric acid and its compounds of sodium, ammonium, and potassium.
- (2) Oxalate of lime.
- (3) The phosphates of calcium and of ammonium and magnesium.

Only in the case of uric acid stones of small size, and of oxalate of lime stones likewise moderate in size, do we have the bulk of the stone made of a single constituent. More frequently it is the case that uric acid or oxalate of lime stone forms the nucleus, and about this aggregate in concentric layers, the phosphates, which make up the great bulk of all large stones as well as some stones in their entirety. More rarely a uric acid nucleus is surrounded by oxalate of lime or the reverse. Not only may the sediments become the nuclei of large stones, but foreign matters, such

as a clot of blood or a fragment of any kind of matter accidentally reaching the urinary passages, may also play a like rôle.

The steps for determining the more precise composition of stones will be found in appropriate manuals on the examination of urine, but the three principal varieties present certain physical characters by which they can with considerable certainty be determined. Thus, *uric acid stones* are usually smooth or lobulated, dark red or reddish-brown in color, hard in consistency, and rarely acquire a size of a centimeter (0.4 inch) in diameter, while many of them are no larger than a lentil. They may be multiple. *Oxalate of lime stones* are very hard and uneven, so characteristically so that they have received the name mulberry calculi, from their resemblance to this fruit. Their hard-pointed projections produce exquisite pain in transit from the kidney through the ureter into the bladder. They attain about the same maximum size as uric acid stones, and are also often multiple. The *phosphatic stones* are white in color or grayish-white, quite soft, easily disintegrated, may often be crushed between the fingers, though at other times they are much harder. They attain the largest size, being often as large as a hen's egg. When stones lie in the ureter rather than in the pelvis of the kidney, they are apt to be more elongated, or sometimes spindle-shaped, and present at times a spiral marking which is characteristic. Others are molded to the shape of the pelvis of the kidney with a prolongation for each calyx, which may be further branched—the dendritic or coral calculi. Rarer forms of calculi are made up of cystin, xanthin, carbonate of lime, and urostealith.

**Etiology.**—The rationale of the precipitation of sediments which aggregate to form concretions is not always the same, and is perhaps not thoroughly understood. In the case of uric acid the deposit takes place either because of the abnormal acidity of the urine, because it contains more than the normal quantity of uric acid, or because, for some reason, the amount of water secreted is abnormally scanty. In either event the uric acid is precipitated in the excretory tubes of the medullary substance or in the pelvis of the kidney, forming minute concretions made up of from five to ten whetstone-shaped crystals, whence they descend in the form of sand or gravel to the bladder. At times the sediments grow by successive additions in the pelvis of the kidney, forming thus true *renal* concretions, whose descent into the bladder, if at all possible, is accomplished with the greatest difficulty and pain. The method in which such concretions form in the calices of the kidney around a papilla is well shown in Fig. 80.

Oxalate of lime calculi form similarly by the precipitation of crystals of this substance immediately after the urine is secreted.

Phosphatic concretions are rarely primary. In order that they may form, the proportion of phosphates must be largely increased, or the reactions of the urine must be permanently alkaline. More frequently phosphates precipitate around nuclei of uric acid or oxalate of lime, or foreign bodies. The effect of these seems to be to cause an alkalinity in the urine immediately about them or, in cases of more general cystitis, in all the urine in the bladder. This alkalinity causes the precipitation of phosphates about the primary nucleus and formation of stone of various sizes. Rarely layers of phosphates and uric acid alternate.

**Symptoms.**—It sometimes happens that a stone is found *postmortem* in the substance of the kidney or in the pelvis which was not suspected, but it is hardly likely that even in these cases symptoms were not present. They were simply overlooked or ascribed to some other cause. The most constant symptom of nephrolithiasis is *pain in the region of the kidney* associated with more or less *tenderness*. Like the pain of stone in the bladder, it is *aggravated by motion*, especially rough motion, and there are certain positions of the body in which the patient is made more or less uncomfortable. Quite often the inflammation caused by the stone proceeds to suppuration, and the whole of the kidney, more or less, is substituted by a pus-sac. The pain is often suddenly aggravated when a large stone so lodges as to plug up the ureter and interfere with the descent of urine, or a small one

FIG. 80.—Hilus of Kidney with a Large and Small Renal Calculus, Showing How Precipitation and Aggregation Take Place—(from *Rindfleisch*).

descends through the ureter into the bladder. Under these circumstances come the attacks of so-called nephritic colic, characterized by pain which may equal in severity any to which man is subject. It has other distinctive features. It radiates downward into the groin and the neighborhood of the bladder and down the inside of the thighs and into the testicle, which is often retracted. Sometimes it extends upward toward the diaphragm, and it is not always easy to separate the pain of nephritic colic from that of hepatic colic when the former is on the right side. It may happen that both kidneys are the seat of impacted stone, though this is a very rare event. There are often nausea and vomiting, a cold sweat appears, and the patient may collapse.

After the pain and colic the changes presented by the *urine* may be highly distinctive, aiding greatly the diagnosis; at other times the urine is

absolutely negative. It very frequently contains blood, though the quantity is commonly small, and may be demonstrable only by the microscope. Especially is there blood in connection with fresh attacks of nephritic colic. Pus is almost always present in small or large amounts. Cyliindroids or mucus-casts may be found, true casts rarely. In some cases, too, uric acid crystals in the shape of red or brickdust-like particles either before or during an attack of nephritic colic point to the uric acid nature of the stone. The same is true of oxalate of lime crystals. In the case of the last two substances the urine is acid in reaction. Phosphatic stones may be suspected if the urine is alkaline in its reaction, as it is only possible for phosphatic sediments to form in the presence of an alkaline or neutral urine while uric acid crystals can only remain permanent in an acid urine. Oxalate of lime, the most insoluble of all crystals, occurs, however, in either acid or alkaline urine. In cases of gravel or sand, as contrasted with stone, there are no symptoms, as a rule, between attacks, as the stone must reach an appreciable size before it produces the constant or almost constant pain characteristic of it. In some cases there is complete suppression of urine, even when the kidney on the opposite side is normal, though more frequently when it is diseased, and death from uremia may occur in consequence.

**Diagnosis.**—It has been intimated that nephritic colic may be confounded with *biliary colic*. Usually the symptoms of each are sufficiently distinctive. Jaundice in biliary colic is almost invariably present and comes on very soon after the obstruction begins. The stools are without bile and grayish-white in color. Usually the pain is more toward the epigastric region as a center, and thence through the upper abdomen and perhaps through to the right shoulder-blade. The urine is also bile-stained, and responds to the tests for the coloring-matter of bile. Other substances, however, besides stone, may produce nephritic colic. Thus, *clots of blood* may obstruct the ureter and give rise to all the pain occasioned by an impacted stone, and in the absence of a history of stone and of hemorrhage there are no symptoms by which the two causes of colic can be separated. In the case of *hydatid cysts* of the kidney, fragments of these, too, may be discharged, and in suppurating kidney *inspissated pus* may occlude the ureter. I have in my possession some striking molds a centimeter in diameter and several centimeters long, composed of inspissated pus, which plugged up the ureter for a time and were subsequently discharged. Renal colic has been mistaken for *intestinal colic*, but such confusion is dissipated as the condition continues. Renal colic is also produced when the ureter is compressed by any cause as a *twist in the ureter* of a floating kidney, or by compression of a tumor. The symptoms of stone in the kidney sometimes closely resemble those of *stone in the bladder*, but the pain in the latter, though it may be felt, to the back, radiates toward both sides; in stone in the bladder the urine contains more mucus and is alkaline or becomes readily so, while in nephrolithiasis the pus is purer and the urine acid. In all cases pointing to the presence of stone in the bladder the sound should be promptly used.

The most invaluable aid to the diagnosis of stone in the kidney is the X-ray examination, and in all cases of suspected stone this measure should be employed. Almost without exception a stone, if present, is disclosed,

and many stones thus recognized have been found at operation which would have otherwise been less searchingly sought. Rarely it has happened that the X-ray has apparently disclosed a stone when none has been found at operation.

**Prognosis.**—The prognosis of stone in the kidney is very much more favorable now than it was 20 years ago, in consequence of the safety with which operations can be performed. The kidney may be exposed, split open, and the parts reapposed and restored with perfect recovery, and whenever the diagnosis of stone in the kidney is made, an operation should be done. When many severe attacks occur without other conclusive evidence, an exploratory operation is sometimes justified for the sake of diagnosis. When the sand or gravel is so small as to pass the ureter, the suffering terminates with its passage into the bladder.

**Treatment.**—It is needless at the present day to say there are no medicines which, when administered, are capable of producing solution of a stone if it be of any size. In cases in which there is no such formation and we have simply to contend with gravel or sand, therapeutic measures to prevent its further formation, and even in some cases to promote solution, may be availed of.

It is, however, a matter of extreme importance before treatment is instituted to know exactly the kind of sediment that is to be dealt with, and to this end the urine should be carefully studied. Thus, uric acid is dissolved by alkalies, and the object of treatment should be to alkalize the urine as much as possible, with a view to keeping the uric acid in solution. On the other hand, to give alkalies to the patient with phosphatic stone or sediment is only adding "fuel to the flame." As to oxalates, they are equally insoluble in both acids and alkalies, but there is reason to believe that they are produced under the same conditions which produce uric acid sediments, and the treatment is therefore the same for either.

The required alkalinity of the urine for the *solution of uric acid* may be produced in any one of a number of ways. Perhaps the most desirable of all is the free use of alkaline mineral waters, represented by the foreign waters of Tarasp, Vals, Vichy, and Ems, and in this country approximated by Saratoga Vichy and Saratoga Geyser waters, which may be termed alkalo-saline waters. It is unfortunate that in this country we have no native sources of alkaline mineral waters, at least east of the Rocky Mountains, and the alkaline waters of the West are so strong that it would not be possible to use them without dilution, while very few physicians seem to have had any experience with them. In the absence of true alkaline waters the numerous negative mineral waters which are so strongly recommended by their owners may still serve a useful purpose as diluents and solvents. They are almost too numerous to mention, but the Bedford, Poland, Waukesha, Buffalo lithia, Geneva lithia, Londonderry lithia and Ballardville lithia waters are among the best known. In a few cases they alone may be sufficient if used freely enough. They may be rendered more active by combining alkaline salts, such as the citrate of potassium and the bicarbonate of potassium and lithia. The lithia waters for sale in this country contain uncertain, and at most very small quantities of lithia. I think it much better, under the circumstances, to add a definite

amount of lithium carbonate or citrate to a glass of water—say from 5 to 10 grains (0.3 to 0.6 gm.). At least 1 quart (1 liter) of any of the true alkaline waters should be used every 24 hours by an adult subject to uric acid sediments, and a corresponding or larger quantity of the more negative waters referred to. *Liquor potassii* of the United States Pharmacopœia is a very excellent means of counteracting acid tendencies. It may be given in doses of from 15 to 30 minims (1 to 2 c.c.), and milk is a very suitable vehicle. Piperazin, a comparatively recently introduced solvent for uric acid, undoubtedly possesses this power outside of the body, and in a few cases it has also seemed to me of service when administered to patients with uric acid gravel. Some assert and others deny its efficacy. Its costliness is in the way of its general use in sufficient quantity to test its real value. All that has been said of treatment of the uric acid diathesis may be applied to that of the *oxalate of lime*.

Much also may be accomplished by *diet*. Persons with uric acid diathesis should limit the amount of nitrogenous food, using a minimum of meat and cultivating the use of milk and vegetables as a diet.

The *phosphatic tendency* is, unfortunately, not so easily combated, as our resources for the purpose of acidifying the urine are very limited. Only two drugs, benzoic acid and boric acid, have this reputation, and they possess it to a slight degree only, while large doses are not well borne by the stomach. From 5 to 10 grains (0.3 to 0.6 gm.) of each may be given three, four, or five times a day, as borne by the stomach. The newer antiseptic medicaments, such as cystogen, formalin and urotropin, also tend to acidify urine. In phosphatic lithiasis, too, there is, of course, the same indication for the free use of diluent drinks, and in these cases the negative mineral waters are as good as any, while, perhaps, distilled water serves as the type of a solvent. When the composition of the stone is unknown, it is best to use this class of waters rather than alkaline waters, lest the stone happen to be phosphatic, in which event alkaline waters would cause further deposit. While the mineral acids cannot, of course, be given in such dose as to produce acidity of the urine, they are still useful in counteracting any tendency to high degrees of alkalinity.

In the matter of diet, too, the phosphatic diathesis requires an opposite treatment. Meats are here indicated, while milk and vegetables may form a less abundant part of the food because of their tendency to alkalize the urine.

In treating the uric acid diathesis with alkalies it is possible to carry the effect too far and cause deposit of phosphates where uric acid sediments were previously precipitated. It is important, therefore, to watch the urine carefully and to avoid such an administration of alkalies as will cause phosphatic sediments to make their appearance. It is well known that stones are found in the bladder, which exhibit alternate layers, now of uric acid and now of phosphates, although the latter substance almost invariably makes up the bulk of calculi which have attained any size. The rationale of this is perhaps as follows: as soon as the uric acid gravel or oxalate of lime gravel becomes large enough to act as an irritant, it increases the organic matter in the urine in the shape of pus and mucus. These matters, it is well known, favor an alkaline reaction, so that the little

stone becomes surrounded, as it were, by a stratum of phosphate-precipitating urine, and the larger it grows, the more apt is this to be the case. When alternate layers exist, it may be inferred that the natural acidity reasserts itself and throws down the uric acid and urates, which in turn form a layer about the stone.

The extreme pain of attacks of nephritic colic must be combated by anodynes, and for this purpose rarely is anything except opium and its alkaloids sufficient, while the hypodermic mode of medication is far the best, both because of its prompt action and the less serious effect upon the stomach. It is rarely the case that less than  $1/4$  grain (0.016 gm.) of morphin thus administered is sufficient, and very frequently this dose must be repeated very soon. It has happened to me that when the pain was less severe, I could control it with full doses of penacetin and acetanilid, or by the aid of these substances render smaller doses of morphin sufficient. For this purpose not less than 15 grains (1 gm.) should be given. Hot poultices are useful to a certain extent in relieving pain when applied to the lumbar region and to the groins, while hot baths are of great service in relaxing spasm and allaying pain due to it.

The escape of the stone from the ureter into the bladder is followed by unspeakable relief, and its discharge from the urethra usually follows sooner or later with little or no pain, although a stone of considerable size may lodge in the urethra and require extraction. When stones are not discharged, they are likely to become the nuclei of larger stones in the bladder, where, of course, the majority of stones acquire their growth.

Stones too large to pass *per vias naturales* should be cut out of the kidney. It must be remembered, however, that after apparent well-founded diagnosis it sometimes happens that no stone has been found on section. Yet, strange as it may seem, it frequently happens that the symptoms do not return after such negative operation. Such cases, on the other hand, may prove to be cases of tuberculosis of the kidney. This is true of some of the conditions I have called *capsulitis* where the relief may be due to splitting the capsule.

## TUMORS OF THE KIDNEY.

**Definition and Application.**—The term “tumor of the kidney” is applied to almost any enlargement of the organ due to morbid growths. Yet there are morbid growths of the kidney which are not sufficiently large to produce appreciable change in its size. Thus, the *adenoma* does not usually exceed  $4/10$  inch (1 cm.) in diameter, though it may be two inches (5 cm.) or more. The same is true of the *angiomata* and *leukemic tumors*, of *fibroma* and *lipoma*, which sometimes form small white nodes in the fibrous tissue near the bases of the pyramids. *Lymph-adenoma* occurs in the kidney associated with similar disease of lymph glands, liver, and intestine. *Villous papilloma* sometimes grows in the pelvis of the kidney. *Syphilitic gummata* also belong to the group of moderate-sized tumors rarely producing symptoms.

*Cysts*, single and multilocular, acquire larger size, producing appreciable

enlargement of the kidney. The malignant tumors, *sarcoma* and *carcinoma*, belong to this category, and with cysts are, clinically speaking, perhaps the chief occasion of the term "tumor of the kidney." On the other hand, *renal abscess*, or pyonephrosis, does not usually earn for the kidney involved the name "tumor," while hydronephrosis does.

**Symptoms.**—Certain local symptoms are produced indifferently by any one of the tumors large enough to become clinically appreciable. In the first place, *renal tumors grow* for the most part *forward* rather than backward, because of the more yielding character of the parts in front of them than behind them, rarely producing posteriorly much more than a fullness of the back, in the course of which there is obliteration of the resonance which may be present between the kidney dullness and the vertebral spines. As this forward growth proceeds, a special effect results from the relation of the bowel to the kidney; as the ascending *colon* on the right side and the descending colon on the left lie *in front* of the corresponding kidney, the effect of enlargement of this organ is to push the bowel in front of it, the hollow viscus being recognized by the tympanitic percussion note. In this respect renal tumor differs from splenic tumor, and less invariably from that of the liver, since the bowel does not intervene between these organs and the abdominal wall, though, rarely, the small intestine may float between the liver and the parietes. Commonly, too, the hand may slide between the renal tumor and the liver on one side and the renal tumor and the spleen on the other, while it never loses the rounded border characteristic of the kidney.

By bimanual palpation with the palm of one hand placed in the lumbar region and the other in front below the ribs, pressure being made in both directions, the tumor may be recognized. In this examination, too, it will be noticed that the kidney permits a much more limited degree of mobility during breathing than does the liver, although it is not totally immobile. The renal tumor, too, commonly resists lateral movement.

Again, *pain* in the region of the kidney is an inconstant symptom. It is often totally absent, at other times exceedingly severe, especially if the vertebræ and spinal cord are encroached upon. It sometimes happens that in consequence of the pressure of the kidney upon the 12th dorsal nerve and branches of the lumbar plexus neuralgic pains in the abdominal walls are produced.

**Diagnosis.**—As to differential diagnosis, both varieties of tumor, viz., *carcinoma* and *sarcoma*, produce hematuria, though it is not a frequent symptom even with them. In the event of its occurrence the blood may be fluid or clotted, and is often molded in the pelvis of the kidney and ureter, an event very rare with blood poured into the pelvis under other circumstances. Hematuria is more frequent in carcinoma than in sarcoma. Both conditions are likely to produce pain. It is sometimes extreme and boring, when it indicates destructive encroachment on the vertebræ. More frequently it is dull, radiating over the flank into the thighs. These tumors also produce cachexia. Very rarely they may be recognized by the presence of distinctive histological elements in the urine. This occurred in my experience in at least two instances. Frequently the urine is altogether negative.

Of sarcoma and carcinoma between which no distinction was made until 40 years ago, the former is now regarded as the more common. Both may be primary or secondary, more frequently secondary. Sarcoma is a disease of early life, in fact, it is often congenital, when it is represented by that form known as rhabdomyoma, which contains striated muscular fibers. In more than half the cases it affects children under ten. On the other hand, renal cancer is not confined to later life, as are other forms of cancer, and it may even occur in children. May not these tumors, too, have been sarcomata? More usually one kidney only is affected. Such organ is uneven, soft, even to a sense of fluctuation. Carcinoma also selects one kidney whence it may invade the pelvis and ureter. It affects the general health more rapidly, hematuria is more frequent and copious, but intermittent. If there be a superficial primary growth elsewhere and a renal tumor is present, the presumption is that it is of the same nature, but no certain diagnosis can be made between carcinoma and sarcoma unless the rare opportunity occurs to examine fragments discharged with the urine. Unfortunately for diagnosis, the urine is too often quite free from any sediment, even of pus. Carcinoma of the kidney is apt to invade the renal veins and even the vena cava, and as such to cause metastasis in the lungs and in other organs as well.

From *ovarian tumors* renal tumors are distinguished by the fact that in the former the intestines lie in the flanks, giving resonance on percussion in that locality, while an enlarging kidney pushes the bowels in front of it. The ovarian tumor also grows from below upward and drags with it the uterus and appendages, as can be recognized by vaginal examination and by rectal touch.

Much more difficult is it to distinguish the renal tumor from *enlargement of the retroperitoneal glands*, as such enlargement also pushes up the intestines in front of it, giving rise to a tympanitic percussion note. Hematuria never occurs in retroperitoneal tumor, while it may or may not be present in renal tumor. The retroperitoneal tumor may press upon the ureter and the renal vessels and thus produce obstruction to the descent of the urine. The central situation of the enlargement in retroperitoneal tumors contrasts with the lateral growth in the renal tumors.

From *tumors of the liver* renal tumors differ in that the former sooner or later cause a bulging of the right hypochondriac region, while the renal tumors rarely reach as high as to alter the configuration of the lower thorax. The sharper border of the liver tumor as contrasted with the rounded edge of the kidney tumor is characteristic, while the freer movements of the liver with the breathing is also of value. *Splenic tumors* are not likely to be confounded with tumors of the left kidney. Splenic tumor protrudes from above downward and toward the umbilicus instead of from the lumbar region forward. It moves more with breathing, and its sharper edge and indentation may be recognized. It is always above or outside of the colon.

**Treatment.**—Renal tumor is beyond curative treatment by the physician. As soon as the diagnosis is made, a surgeon should be called and the question of operation considered.

## CYSTS OF THE KIDNEY.

Reference is here made only to such cysts as produce clinically appreciable enlargement of the organ. They include:

1. *Retention or obstruction cysts*, solitary cysts ranging in diameter from a centimeter (0.4 in.) to ten centimeters (4 in.) and larger. They may be present in one or both kidneys. These are probably primarily the result of stenosis of a uriniferous tubule behind which accumulates first urine, which is gradually substituted by an aqueous fluid in which may be found traces of urinary constituents. A trace of albumin may also be present. These cysts rarely give rise to symptoms.

2. *The congenital cystic kidney*, in which both organs are the seat of numerous round cysts varying in size from  $1/5$  inch (5 mm.) to one inch (2.5 cm.), may produce tumors of large size, so large, in fact, that they have interfered with parturition. They contain a fluid which is at times clear, at others again turbid, colloidal in consistence, and containing albumin, cholesterin, triple phosphates, rarely urea and uric acid, and sometimes fat drops. Persons with these cysts may grow to adult life, and, indeed, such cystic kidneys have been found postmortem when not suspected. Commonly, the subjects die either before birth or shortly after. The exact mode of origin of these congenital cysts is not understood, but they are probably the consequence of a defect in development.

There may be no symptoms beyond that of an enlarged organ, or they may be those of interstitial nephritis with its secondary cardiovascular consequences. There may be a small albuminuria. Blood-disks may be found, but no casts.

3. *Dermoid cysts* are also occasionally met in the kidney, while a *general cystic condition* invading the liver and spleen as well as the kidney is described.

4. *Hydronephrosis* is a monocystic degeneration of the kidney starting in obstruction of the ureter, succeeded by dilatation of the pelvis and gradual wasting of the kidney substance, due to pressure of the accumulating fluid.

The obstruction causing this condition may also be congenital. As such it, too, may be large enough to impede labor. An oblique insertion of the ureter at such angle as to interfere with the easy discharge of the secretion may be the cause of its retention in the pelvis of the organ. Among recognized causes during life are, also, occlusion of the ureter by cicatricial adhesion, by lithiasis, by tuberculosis of the ureter, by pressure, by tumors, by a retroflexed or prolapsed uterus, by bands of lymph in healed peritonitis and by twists in the ureter of a movable kidney. Finally, carcinoma of the bladder and even hypertrophy of the prostate and stricture of the urethra may be causes.

The contents of the tumor may be purely aqueous; more frequently they are slightly turbid; they contain a few pus-cells, more numerous if they are the seat of inflammation; also uric acid, urea, and albumin.

Its symptoms consist of those already described as common to benign renal tumors of sufficient size. An event which is almost pathognomonic is the occasionally sudden disappearance of the tumor simultaneously with

the discharge of a large quantity of fluid from the bladder, followed by gradual refilling of the sac and return of the tumor. This intermittent discharge may be kept up for years. Such an event must be ascribed to a valvular obstruction in the ureter which at times yields to the pressure of the accumulated fluid; or it may be due to the undoing of a twist in the ureter of a floating kidney.

As to differential diagnosis, *ovarian tumor* is the condition with which it is most frequently confounded. I have already (p. 818) called attention to the different relations of the intestine to the tumor in the two instances and other points of difference, all of which need not be repeated. The relative immobility of the renal tumor, as contrasted with the mobility of the ovarian, may, however, be mentioned; also the lumbar origin of the former, as contrasted with the pelvic of the latter, as determined by rectal and vaginal examination. Should the tumor disappear simultaneously with a copious discharge from the bladder, the diagnosis is, of course, conclusive. Aspirations may also be brought to aid the diagnosis, when advantage may be taken of the fact that the characters of the ovarian fluid and that of hydronephrosis are widely different. The dense, colloid fluid of the ovarian cyst, with its numerous cholesterin plates, fatty granular cells, small granular cells, and highly albuminous composition, contrast strongly with the aqueous consistence, the low specific gravity, and the general negative character of the hydronephrotic fluid. Too much stress must not, however, be laid upon these differences, as they do not always exist. The history in the case of ovarian tumor will develop the events of menstrual and sexual derangement, which are absent in hydronephrosis. Hydronephrosis is not likely to be confounded with *ascites*. The changes in the position of the fluid with that of the patient, characteristic of ascites, and its bilateral situation distinguish it at once from hydronephrosis.

From a *circumscribed peritoneal exudate* hydronephrosis is distinguished by the different history, the greater tenderness of the former, and tympany of the subjacent intestine elicited by strong percussion. In renal abscess there is fluctuation, but there are also fever and sometimes chills. The *renal retention cyst* is at times indistinguishable from hydronephrosis. Both may be congenital or due to congenital defects, but should there be intermittent emptying of the sac, with refilling, hydronephrosis may be suspected. The diagnosis from *hydatid cyst*, so far as is possible, follows in the next paragraph.

5. *Echinococcus* or *Hydatid Cyst*.—Hydatid disease of the kidney is a rare affection, and when the enlargement caused by it is sufficient to produce physical signs, they do not differ essentially from those of hydronephrosis and cystic kidney. Only in the event that the microscope recognizes hooklets or scolices, or fragments of the cyst-wall in the urine or in the fluid obtained by tapping or discharge into other localities, such as the stomach, intestines, or bronchi, can a diagnosis be made with certainty. Such discharge into the pelvis of the kidney, if it produce obstruction, may also cause acute hydronephrosis. The presence of hydatids elsewhere, and of the hydatid fremitus, is presumptive evidence. The chemical and physical characters of the fluid from hydatid cysts is given under hydatid disease of the liver (p. 513). Like hydronephrosis and cystic tumor, the hydatid

kidney differs from ovarian tumor by its immobility, unless the disease should perchance invade a movable kidney.

**Treatment of Renal Cysts.**—The treatment of the whole list of affections included under cysts of the kidneys lies in the province of the surgeon, the chief office of the physician in these cases being one of diagnosis and relief of pain.

## ANOMALIES OF FORM AND POSITION OF THE KIDNEY.

**NORMAL SITUATION OF THE KIDNEY.**—The normal situation of the kidney is on the quadratus lumborum and psoas muscles, the inferior end of the left kidney extending a variable distance below the edge of the 12th rib, while the right extends about  $3/4$  inch (20 mm.) lower down, the whole right organ being lowered by the position of the liver. The outer edge of the kidney is often in a line drawn vertically through the end of the 12th rib. Both kidneys descend about  $1/2$  inch (12.5 mm.) during deep inspiration. The kidney, if in its normal situation, is accessible to pressure just below the last rib at the outer edge of the erector spinæ muscle. Sometimes one or the other, more frequently the left, lies on the lumbar vertebra, on the sacrum, or in the inguinal canal.

**CONGENITAL ABSENCE OF THE KIDNEY.**—The total *absence of both kidneys* is possible in connection with extreme abnormalities and defect of development, but is incompatible with life.

*Congenital absence of one kidney* is not very rare, the absent one being usually the left. Such absence may be suspected when over the normal situation of the organ a tympanitic note only can be elicited by percussion. In such event, the remaining kidney supplements the work of the absent one, and serious consequences only follow in the event of disease or lesion of the remaining organ. The ureter and pelvis of the absent kidney are absent also, but sometimes the remaining organ has two pelves and two ureters. Occasionally the rudiment of a ureter is present. Congenital atrophy of one kidney is even more common, but is discoverable only at autopsy.

**LOBULATED KIDNEY.**—The lobulated kidney is the most frequent anomaly of form. It consists essentially in the persistence of the lobulation natural to the organ in the fetal state. This is acquired by the end of the eighth week of fetal life, after which it gradually disappears in normal development, but is still maintained with more or less distinctness throughout the first year after birth. The abnormal lobulation is variously distinct. Usually partial and superficial, the fissures are sometimes so deep as to divide the organ into separate reniculi, of which there may be from seven to 20. This lobulation, a rare event in man, is clearly seen in the kidneys of the lower animals, especially in the sheep and ox.

**HORSE-SHOE KIDNEY.**—The most striking of the anomalies of form is the horse-shoe kidney, in which usually the lower ends of the two organs

are united either by true renal tissue or by a band of fibrous tissue. More rarely it is the middle segments which are united, and more rarely still the upper ends. In either event, this coalescence is usually associated with displacement of the organ, which is then lower down than in the normal condition, usually just above the promontory of the sacrum, more rarely in the pelvis, and at times on one side or the other of the spinal column. In the fused kidney there are usually two pelves, with from two to four ureters. More rarely there is but one pelvis. The ureters pass over the front of the kidney. The renal arteries spring from the aorta at points corresponding to the situation in which the organ is found. Thus, when above the sacrum, the arteries spring from the back of the aorta near its bifurcation or from one of the common iliacs, while the veins enter the corresponding parts of the vena cava or iliac veins.

The horse-shoe kidney is generally first recognized at autopsy, or at operation, but rarely it may be recognized in its abnormal position above the sacrum, especially in thin persons.

#### THE MOVABLE OR FLOATING KIDNEY.

SYNONYMS.—*Ren mobilis*; *Floating Kidney*; *Palpable Kidney*; *Nephroptosis*.

**Description.**—The normal kidney is commonly quite firmly retained in position by its capsule of fat and by a covering of peritoneum. The movable or floating organ exhibits a very different degree of mobility in different instances. The mobility may be so slight that it can be recognized only by the expert manipulator, or so great that the organ may be easily grasped by the hand through the abdominal walls. In the latter condition there is a mesonephron or peritoneal fold loosely attaching the kidney to the spine.

**Etiology.**—The movable kidney is more common in thin persons than in the obese, in women than in men. Indeed, it has been said that one woman out of every four has a movable kidney. It is six times as frequent in the working-classes. The right kidney is far more frequently movable than the left. Repeated pregnancies are assigned causes, as is also mechanical violence, as a fall or tight lacing. It is most likely, however, that the majority of floating kidneys are congenitally loose, and that this looseness may be increased by the conditions named.

**Symptoms.**—The floating kidney often occasions no symptoms. At other times it is responsible for a remarkable train of *nervous symptoms*, mainly reflex in character. These include *obstinate indigestion* of every grade, *flatulence*, *palpitation of the heart*, *cardialgia*, *neuralgic pain* almost anywhere in the body, but especially in the abdomen and cardiac region. Gastric crises identical with those characteristic of locomotor ataxia have been ascribed to floating kidney. *Irritable bladder* and *dysmenorrhea* are also consequences. It is an interesting fact that where the degree of displacement and the mobility are most marked, the reflex symptoms are least so. This is not without a parallel in other diseases, and in illustration may be cited the well-known fact that *prolapsus uteri* of moderate degree often causes decided reflex symptoms, while a complete procidentia produces

often trifling local annoyance. The direct result of the displacement, so far as appreciable, is a sense of *dragging* or weight, which especially manifests itself while standing, walking, riding, or dancing, to which may be added a variable amount of *pain*. More serious symptoms sometimes manifest themselves as the result of *torsion* of the ureter, occasioned by complete rotation of the kidney, in which the renal vessels and nerves are also involved. These are agonizing pain, associated with symptoms of collapse, such as nausea, an anxious expression, and scanty urination. They are caused in part by obstruction to the ureter and the backing of the urine on the kidney. Acute hydronephrosis may also be the result of such strangulation, which may be caused, too, by inflammatory bands. This condition ends sometimes as suddenly as it begins. Both hemorrhage and albuminuria are reported as results. Both are certainly rare. There may be other effects of displacement due to the location of the organ at times, of which irritation due to pressure upon the bladder may be mentioned as one. It is often very uncomfortable for the patient to lie on the one side opposite that on which the displaced organ belongs.

**Diagnosis.**—This is variously difficult. The kidney exhibits some mobility in health, descending also always  $1\frac{1}{2}$  inch (1.3 cm.) with each deep inspiration. Movable kidneys are sometimes so loose and movable that they may be felt with ease through the abdominal walls. Between this ready recognition and that which requires the highest manipulative skill of the examiner there is every degree. At the present day, movable kidney is regarded as a much more frequent condition than was formerly believed. So frequently has the set of reflex nervous symptoms described been found associated with movable kidney that their presence should always suggest an examination for the presence of such an organ. The examination may be made with the patient in the standing posture, or when lying on the back. In the first he bends slightly forward, the hands being placed on a table, and the clothing thoroughly loosened. The right hand of the examiner is then placed in front immediately next the skin, below the hypochondrium, while the left is placed over the lumbar region. The patient is directed to respire deeply and regularly, and to relax during expiration. The region between the two hands is carefully palpated, when, if there is any marked degree of displacement, or rather of lowered position, the organ can be felt as a firm, smooth, oval body, somewhat sensitive to pressure, which produces a sickening pain which is quite characteristic. Most rarely the pulsation of the renal artery can be felt. The right kidney naturally moves with breathing more than the left, being pushed down by the liver. Sometimes the manipulation will be more successful in the knee-elbow position. When in this position, the movable kidney having fallen forward, a resonant note may be obtained by percussing over the normal situation of the organ; or the patient may be placed on the back with the side to be examined toward the edge of the bed, on which the physician may sit. The hands are applied as in the standing position, and manipulation is practiced as described.

The displaced organ is hardly likely to be confounded with anything else. The *spleen*, which corresponds nearly in size, is also sometimes movable. Its shape is, however, different. Its anterior body is sharp

and often notched. Sometimes both the left kidney and the spleen are floating. A *movable pyloric tumor* has been mistaken for a movable kidney. The passage of a stomach tube in case of doubt would clear it up.

**Treatment.**—As may be inferred, many cases of movable kidney require no treatment. In a few instances the symptoms are relieved by improving the general health; in others the patient is comfortable while lying on the back, and such comfort may continue for a time after rising. When decided symptoms attributable to the kidney are present, surgical treatment for fixing the kidney—nephrorrhaphy—has seemed to me the most satisfactory treatment, and this sometimes fails. I have known an operation for removal of the kidney—nephrectomy—to be necessary after nephrorrhaphy had been attempted twice unsuccessfully. The use of pads and supports has been only partly successful in my cases. On the other hand, Charles D. Aaron has recently published a paper on the successful treatment of 442 cases without surgical intervention.<sup>1</sup> Progress has certainly been made in the success obtained by bandages made by skillful persons, and it is advisable to make an effort with a bandage before operation is tried.

### IDIOPATHIC HEMATURIA.<sup>2</sup>

**Definition.**—So-called idiopathic hematuria is a hematuria the origin of which is unknown. In addition to the various causes of bloody urine already referred to in treating diseases of the urinary organs, and, in addition to malarial hematuria, there remains a form of renal hematuria of not very infrequent occurrence, for which none of the causes named will account. To this the term idiopathic hematuria is appropriate.

**Symptoms.**—The characteristics of the urine in this form of hematuria are in no way different from those of renal hematuria from other causes. The blood is intimately admixed with the urine, and is not, as a rule, found in the shape of coagula, as is so often the case when the blood comes from the bladder or pelvis of the kidney or in malignant disease of the kidney. There is the usual smoky hue characteristic of acid urine containing a small amount of blood, becoming brighter red as the urine becomes alkaline, and darker red as the quantity of blood is increased. The microscope reveals numerous blood-disks recognizable by their usual characters, and often blood-casts and casts filled with the débris of red disks, or red disks so closely packed as to make it impossible to distinguish their outline. The urine is, of course, albuminous.

Next to the change in the urine, the most striking feature is the absence of other symptoms. The subject is not ill, is not weak, and complains of nothing. Occasionally a dull ache in the back is felt or supposed to be felt, perhaps because the patient thinks that since there is bloody urine, there ought to be pain in the back. The same may be said of weakness, but these symptoms are not usually complained of, though they may be present. Sir William Gull spoke of such hematuria as a "renal epistaxis." With

<sup>1</sup>" Jour. Am. Med. Assoc." Dec. 5, 1903.

<sup>2</sup>I realize that the subjects hematuria, hemoglobinuria, and chyluria, next to be considered, are not strictly renal affections, but it is difficult to classify them otherwise.

the lapse of time, however, and the continuance of the symptom, positive weakness gradually supervenes.

**Treatment.**—Rest is an important and essential condition in the successful management of idiopathic hematuria. The usual astringents, mineral and vegetable, known to be efficient in the treatment of hemorrhagic conditions elsewhere, are often without effect here, though these substances, including gallic acid, ergot, the persulphate of iron, and acetate of lead, alum, catechu, and kino, may be tried. The persulphate of iron has proved of undoubted value in my hands, in doses of from  $1/4$  to  $1/2$  grain (0.015 to 0.32 gm.) every four hours in a pill. Tincture of the chloride of iron in 30 drop doses four times daily apparently cured in three weeks a boy whom I saw with Charles H. Smith, of Uniontown, Penna., after many other drugs had been tried. The treatment was, however, associated with rest in bed under a trained nurse. The treatment was Smith's own suggestion. The astringent mineral waters, especially the alum waters, as those of the Rockbridge Alum Springs, in Virginia, and the Jackson Spring, North Carolina, have apparently proved curative, but I have also failed with them. A case which I saw in consultation with T. Parry Tyson, of Jenkintown, resisted all measures until Tyson tried the fluid extract of *hamamelis virginica* in doses of 20 minims (1.32 gm.) every three hours, and in 36 hours the hemorrhage ceased and has not recurred. As *hamamelis* contains much tannin and gallic acid, it may owe its efficiency to this constituent. One of my cases, after resisting every other form of treatment, finally recovered after electric baths had been used for 15 minutes every other day for one month.

Gelatin has also been recommended in hematuria, in common with other hemorrhages. As an example, Schwabe injected into each infra-clavicular region, 7 ounces (25 c.c.) of physiologic salt solution containing  $2\frac{1}{2}$  per cent. of pure gelatin, followed by the daily administration by the mouth for a week of a pint of ten per cent. gelatin solution.

## HEMOGLOBINURIA.

**Definition.**—In this interesting condition, the coloring-matter only of the blood is found in the urine; very rarely a few blood-disks or their fragments. In their absence, other criteria of the presence of blood coloring-matter must be sought. To do this, one may take Teichmann's hemin crystals, as directed in the footnote on page 69; or if the spectroscope be available, the filtered and diluted urine produces the absorption bands of oxyhemoglobin between Fraunhofer's line D and E, or more frequently the three bands of methemoglobin, of which that in the red near C is distinctive. Sometimes both are present. The urine thus stained with hemoglobin is dark brownish-red, and even black in color. It is also albuminous, and in lieu of the blood-disks are sometimes found yellowish-brown, irregular, and granular flakes, and sometimes cylindrical masses of hemoglobin.

Hemoglobinuria is always associated with hemoglobinemia, which is, however, less easy of demonstration. The hemoglobin is set free from the corpuscles and imparts a reddish hue to the blood-plasma. The disks

themselves are paler, and yellowish-brown particles of hemoglobin may be demonstrated between the corpuscles. The number of corpuscles themselves may be reduced, falling to 4,000,000 and less.

Hemoglobinemia and hemoglobinuria may easily be separated into two divisions, toxic and simple paroxysmal.

**TOXIC HEMOGLOBINURIA.**—This is produced by toxic substances, which dissolve out the hemoglobin from the corpuscles. Such are sulphureted hydrogen, arseniureted hydrogen, carbon monoxid, carbolic acid, pyrogallie acid, naphthol, nitrobenzole; potassium chlorate in large doses, and the poison of certain mushrooms; also sometimes the poison of the infectious diseases, including scarlet fever, diphtheria, pyemia, yellow fever, typhoid fever, malaria, and even syphilis. The last has sometimes seemed to act as a predisposing cause, subsequently to which so trifling a thing as exposure to cold has caused it. I have seen it associated with pregnancy as a probable cause. Hemoglobinemia and hemoglobinuria sometimes succeed on extensive burns when the poison is probably the retained excretions of the skin. High temperature alone is said to have caused it. In malarial poisoning the hemoglobinemia may be the direct result of the action of the malarial plasmodium. The blood of one animal transfused into the vessels of another, must be added to this group.

**Prognosis.**—This depends upon the dose of the toxin causing it and the other symptoms produced. Recovery is usual, but some cases are rapidly fatal.

**Treatment.**—This is that of the disease occasioning it. The same astringent measures may be tried as in hematuria, and restorative medicines may be given to rebuild the blood. Of these, iron is the most important.

#### PAROXYSMAL HEMOGLOBINURIA.

In this, intermittent attacks occur. They come on suddenly, preceded by chills and fever, headache, and pain in the limbs, the temperature often reaching 104° F. (40° C.). The bloody urine follows in an hour or less, and may last four or five hours, or there may be two or three paroxysms in a day. At other times there is no fever or the temperature is even subnormal. Jaundice is associated with some cases, especially toward the end. At times, instead of the expected hemoglobinuria, there is only albuminuria. Ralfe explains this by supposing that the toxic agent has destroyed only a small number of corpuscles, the coloring matter from which is used up in the spleen and liver, while the globulin goes off in the urine. Von Leube especially calls attention to a swelling and tenderness of the liver and spleen, and says he has met these symptoms in lieu of the expected hemoglobinuria—in lieu even of albuminuria.

The occasional association of hemoglobinuria with Raynaud's disease is very interesting. The probability is that in most cases where the two conditions are associated, the preliminary hemoglobinemia is due to a separation of the hemoglobin from the red disks in the peripheral asphyxiated part of the nose, ears, fingers, or other parts.

As to other causes of paroxysmal form, malaria is undoubtedly one, though perhaps not so often as was once supposed. Another cause is excessive muscular exertion, especially when associated with cold, while cold itself is perhaps the most frequent of all causes. Mental emotion is sometimes a cause. It must be admitted that for the cases not explainable by toxic agency no satisfactory solution has been presented.<sup>1</sup>

**Prognosis.**—The prognosis of the paroxysmal form is commonly favorable, though it may continue to recur for a long time.

**Treatment.**—This depends upon the cause. If it be malarial, the condition is easily curable by quinin. To seek the causes in many cases is to seek the unattainable, and the cases must be treated on general principles. Rest and warmth are essentials. After this, the same astringent remedies as those recommended under hematuria may be tried. As cold seasons and cold weather favor it, a residence in a warm climate should be recommended when the condition persists. Nitrite of amyl is said to have cut short and to have prevented an attack.

## NON-PARASITIC CHYLURIA.

**Historical.**—Chyluria was first mentioned in 1675; later by Müller, Morgagni, Sauvages and Chapotin; the latter in 1812, by Alibert in 1818, by Prout in 1818. It was described by Rayer in his book on Bright's Disease in 1841.

**Definition and Description.**—A state of the urine in which the secretion is admixed with fat in a minute state of division, whereby the urine acquires a milky or chylous appearance.

The proportion of fat varies greatly, being at times only enough to impart a mere opalescence, while at other times the urine is scarcely distinguishable from milk, even the characteristic odor and taste of urine being wanting. The fat, on standing, often rises to the surface, like cream. By the microscope, in addition to this molecular fat and a few oil drops, numerous blood-disks are also found. These are sometimes so numerous as to impart a pinkish tinge to the fluid, and at times a spontaneous coagulation takes place, with the formation of a slight reddish clot, showing the presence also, of fibrin—*hematochyluria*.

**Etiology.**—To produce chyluria there must be brought about in some way a leakage from chyle vessels into the urinary passages somewhere between the kidney and the neck of the bladder. Yet no such communication has ever been found, so far as I know, though W. H. Mastin noticed the patulous mouths of several chyle vessels opening into the serous sac of a testicle which he laid open for the cure of a chylous hydrocele or lymph scrotum. Having ligated them, no recurrence of the hydrocele happened. Supposing such a communication to exist, how is it brought about? In most cases probably by the blocking of lymph channels by prematurely discharged ova or embryos of the *filaria Bancrofti* (*parasitic chyluria*), to be described when treating of animal parasites. Undoubtedly, there occurs, on the other hand, what may be termed, under the circumstances, an idiopathic chyluria, the most searching examination of the blood during life,

<sup>1</sup>It is well known that horses are subject to hemoglobinuria, and that it occurs in them after exposure to cold, especially after having been stabled for several days.

and careful dissection after death, of lymph glands and vessels in certain cases, failing to discover either ova or embryos. On the other hand, by no means every case of filariasis is attended by chyluria.

**Symptoms.**—Few symptoms other than those of the chylous urine are present. It is usually intermittent, but may be persistent. There is sometimes a loss of strength from the draining off of fluid which is undoubtedly nutrient; at other times there is some pain in the back, and at others again painful urination due to obstruction of the urethra by coagula of fibrin, but in most cases the patient feels well and would not know there was anything the matter with him had not his attention been called to the urine.

**Treatment.**—No means have been discovered to destroy the filaria in parasitic chyluria, nor to check the leakage in the idiopathic form, which often persists for years and then subsides spontaneously. Should the mosquito be its cause, the same measures which will ultimately be found for its eradication will apply to the filarial disease.

See also article on Filariasis in section on Parasites.

## THE RELATION OF HEART DISEASE TO KIDNEY DISEASE.

Allusion has more than once been made in the foregoing pages to the relation of kidney disease to heart disease, and the association of lesions in the two organs. Of such importance is a proper understanding of this relation, that a few pages devoted to its consideration may be helpful to the student. The association admits of classification:

1. *Renal Disease Associated with Hypertrophy of the Left Ventricle without Valvular Disease.*—Modern studies have made it quite certain that this form of combined heart and kidney disease may originate in two ways: (a) The heart affection may be secondary to the kidney disease as its direct consequence; or (b) both conditions may result from one and the same cause—viz., arterial sclerosis.

(a) *The Renal Condition Precedes.*—The condition which precedes is commonly the contracted kidney of interstitial nephritis, and its result is hypertrophy of the left ventricle.

How is the cardiac hypertrophy to be accounted for? I will first review the theories which have been given from time to time, for theories alone they must be acknowledged to be. The oldest, which may be termed the "retention" or "chemical" theory, was advanced in its cruder form by Bright himself, whose acute observation had not failed to notice the association of cardiac hypertrophy without valvular disease with the disease so deservedly coupled with his name since 1827. Bright suggested two alternative explanations: "Either that the altered quality of the blood affords irregular and unwonted stimulus to the organ immediately, or that it so affects the minute and capillary circulation as to render greater action of the heart necessary to force the blood through the distant subdivisions of the vascular system." The late Sir George Johnson held this last view, and his pupil, Nestor Tirard, in England, and Senator, in Germany, still entertain it. At one time Johnson held that the hypertrophied state of the

muscular coat was the result of an *effort* of the vessels to aid the onward movement of the blood. More recently he ascribed the thickening of the muscular coat, which exists not only in the kidneys, but in the systemic arterioles generally, to a constant exercise of the normal stop-cock action whose object is to resist the passage of this abnormal blood; while the hypertrophy of the left ventricle is ascribed to an effort to overcome this resistance. Johnson maintained that there is a true hypertrophy of the muscular coat of the general arterial system, associated with thickening of the intima only in the kidneys, but of the adventitia also in the arterioles of other tissues.<sup>1</sup> Recent histological studies, made for Johnson under the direction of Halliburton, confirm this view. Unfortunately, other recent studies by modern methods, notably those by W. T. Councilman and Arthur V. Meigs, to be again alluded to, do not find the changes in the middle coat early described by Johnson and now again by Halliburton. Until lately, experiments which have for their object determining the effect of toxic substance introduced in the blood on the heart and vessel walls have proved negative. More recently a number of experimenters, notably Alfred Croftan, have succeeded in producing increased arterial blood-pressure, arterial spasm, thickening of arteries, and hypertrophy of the heart, as well as granular and fatty degeneration of renal-cells. Croftan used the alloxuric bases xanthin and hypoxanthin, while Ustimovitch, Grützner, von Cavazano, and Robustello injected urea into the blood.<sup>2</sup> It is to be regretted that a histological question seemingly so simple cannot be settled by the refinements of modern histology.

The so-called "mechanical theory" of cardiac hypertrophy was advanced by Traube, whose researches in 1856 gave a decided impulse to clinical study of the subject. According to Traube, the increased arterial resistance was caused by two erroneously-supposed states—the first, an overfullness of the vessels due to the diminished renal secretion; second, a resistance to the admission of arterial blood into the kidney, due to the renal contraction itself. The first hypothesis was erroneous for contracted kidney where the urinary secretion is really increased, while the second is opposed by the fact that even ligation of the renal arteries fails to increase arterial pressure. This is because of the ample vascular space elsewhere for the blood thus diverted. Nor did Cohnheim's further elaboration of the mechanical theory, which located the increased resistance more precisely behind the wasted glomerule, give any more permanent life to it.

I incline to the belief that we should not lose sight of the possibility that the primary changes in the heart may be *compensatory* in their nature, set up with a view to supplementing the gradual loss of renal substance. Such an action is paralleled everywhere in the physical economy. Nowhere do we meet with loss of function which is not at once met by an attempt of nature to compensate it. The dependence of the urinary secretion upon cardiac pressure is well understood, and an increase of cardiac power is the most reliable means available for stimulating the action of the kidneys, when desired, in therapeutics. The diuresis which is so con-

<sup>1</sup>"The Pathology of the Contracted Kidney," by Sir George Johnson, London, 1896.

<sup>2</sup>See Croftan's paper on "The Role of Alloxuric Bases in the Production of the Cardio-vascular Changes of Nephritis," published in the "American Journal of the Medical Sciences," November, 1900, where the reader will find references to papers by the other experimenters mentioned.

stant a symptom of the contracted kidney is acknowledged to be the direct result of a supplemental contraction of the left ventricle, which it is reasonable to suppose is induced for the purpose named, and results in hypertrophy.

This view receives confirmation in the subsequent course of the disease. So long as the free secretion with is the result of the compensatory action of the heart is kept up, so long the patient remains tolerably comfortable, and perhaps even for a time unconscious of the presence of disease. But an organ thus overgrown is sure, sooner or later, to suffer in its nutrition. Especially is this the case if its arteries be the seat of an endarteritis, interfering with the free movement of the blood and producing also fibromyocarditis. And what are the further consequences? The strong propulsive power of the heart declines, the pulse falls away in tension and power and becomes more frequent and sometimes irregular. The urine secreted diminishes in quantity and assumes a darker hue. Fortunate is the patient if the specific gravity of the urine rises inversely with its reduced quantity, as it indicates that the normal excretion of solids is kept up. Too frequently, however, this is not the case, and excrementitious substances accumulate in the blood, laying the foundation for uremia. Headache, nausea, a foul and even a urinous breath may be superadded, and uremia sets in, preceded by drowsiness, or it may be ushered in suddenly with convulsions. Or another set of symptoms may supervene; the patient becomes short of breath, first on slight exertion, and later this very distressing symptom occurs without such exciting cause. This sort of asthma, known as uremic asthma, has been discussed on page 757. For a time this symptom may be averted by whipping up the heart by cardiac stimulants, and the right ventricle even comes to the rescue for a time and hypertrophies in its effort to overcome the now disturbed compensation. Subsequently this, as well as the left ventricle, may become dilated, and edema of the lungs sets in, with annoying cough and serous frothy expectoration, sometimes blood-tinged. Nor does general dropsy continue absent, but ensues sooner or later with the growing heart failure. Our resources are now almost at an end, but are not exhausted, as even these symptoms sometimes subside.

It should be stated that not every case of interstitial nephritis is attended with hypertrophy of the left ventricle. In addition to the cases of contracted kidney from senile endarteritis already referred to, cardiac hypertrophy is apt to be absent in the interstitial nephritis of the weak and cachectic.

(b) *Both the Hypertrophy of the Left Ventricle and the Contracted Kidney are the Result of One and the Same Cause—Arterial Sclerosis or Arterio-capillary Fibrosis.*—It should be stated, first, that a certain school explains all cases of contracted kidney in this way. The changes described in the arteries differ chiefly from those described by Johnson in that they are held to be degenerative, so far as the muscular coat is concerned.

The late Sir William Gull and H. S. Sutton, in a paper which has become classic, announced in 1872<sup>1</sup> that the changes in the muscular coat were chiefly of an atrophic character, and, although the method of these

<sup>1</sup> "Arterio-capillary Fibrosis," "Med.-Chir. Trans.," London, 1872.

observers have been much criticised, the most recent studies on this subject by W. T. Councilman and Arthur V. Meigs go to confirm their conclusions both as to the seat and the nature of the changes. Councilman<sup>1</sup> finds atrophic changes in the muscular coat, including greater or less destruction of the muscular fiber-cells and the formation of a homogeneous hyaline tissue invading both coats, but especially the intima, where it produces decided thickening, and encroachment to a varied extent upon the lumen, sometimes amounting to occlusion. The capillary walls are likewise thickened, and sometimes, especially in the glomerule of the kidney, obliterated. Meigs<sup>2</sup> studies also find these changes for the most part confined to the intima, which is decidedly thickened. To a less extent, the intima of the veins is similarly involved. The picture of the changes thus briefly described may be obtained from a small artery taken indifferently from any tissue or organ of the body—for example, from the muscular substance of the heart, the kidney, or the liver. It is this diffuse form of arteritis, rather than the nodular, which is the link between the hypertrophy of the left ventricle and the contracted kidney. In the nodular form of arteritis the changes are limited to small areas in the aorta and large arteries—atheromatous patches, sometimes calcareous and sometimes fatty, the so-called senile arteritis. The resistance offered the free movement of the blood is evidently less than in the diffuse form.

Of the consequent results of such thickening, the hypertrophy of the ventricle is most easily explained. The resistance in the blood-vessels stimulates the ventricle to increased effort, and there result increased arterial tension and hypertrophy. The degree of cardiac hypertrophy is sometimes enormous, the organ weighing as much as 850 grams (28 ounces), and the average in 27 cases studied by Councilman being over 400 grams (13 ounces), as contrasted with the normal, ten to 12.

According to this view, the alterations in the kidney, which vary greatly in extent, being sometimes scarcely noticeable and sometimes extreme, are the direct result of an interference with its nutrition. The blood-supply to the renal elements being cut off, these gradually waste and ultimately disappear. The cells and tubules thus destroyed are gradually, but irresistibly, replaced by fibrous connective tissue, in obedience to the pathological law elaborated by Weigert, but which was announced, at least so far as the kidney is concerned, 50 years ago by Johnson,<sup>3</sup> that parts destroyed are partially replaced by cicatricial connective tissue. This contracts and reduces the size of the kidney, and perhaps also, in this contraction, further destroys the proper kidney structure, and thus increase the atrophy.

It has been said that in this form of combined kidney and heart disease there is no cardiac murmur. Nor is there, as a rule. It is not impossible, however, for the endarteritis of which we are speaking to creep along the walls of the aorta until it reaches the aortic valves, and so structurally changes them as to make them rough or incompetent and give rise to murmurs.

<sup>1</sup>"On the Relations Between Arterial Disease and Tissue Change," *Trans. Assoc. Amer. Phys.*, vol. vi., 1891.

<sup>2</sup>"New York Record," July 7, 1888.

<sup>3</sup>"Medico-Chirurg. Trans.," 1847.

The causes of this form of Bright's disease are, therefore, the causes of the endarteritis, which have been discussed on page 675. To a less degree, probably, the specific causes of all the infectious diseases must be included in this category—possibly even malaria. The subjects are usually middle-aged men, between the ages of 40 and 55, but they may be younger. Councilman has found these changes more common in the negro than in the white race.

**Treatment.**—The treatment of this form of combined kidney and heart disease is not different from that of interstitial nephritis. Even greater rigidity is necessary in eliminating nitrogenous food, and all food should be reduced to a minimum. A diet of milk diluted with water is the safest of all. Bread and butter may, however, be allowed, and even succulent vegetables easy of digestion, such as rice, potatoes, peas, and string-beans, while simple fruit-juices, as those of oranges and lemons, are allowable. Mental excitement and immoderate muscular exertion must be avoided, and the heart should not be overworked in any way.

The medicinal treatment especially directed to the arterio-sclerosis may be divided into that intended for the cure of the endarteritis and that directed to the relief of symptoms. The only drug from which results may be expected for the former purpose is the iodid of potassium, which should be given a fair trial in doses as large as can be borne without deranging the stomach. For the relief of the symptoms more especially due to the sclerosis—viz., headache, throbbing, and vertigo—the nitrites are often useful. Nitroglycerin should be given in doses of 1/100 grain (0.00065 gm.) every four hours or oftener, rapidly increased to 1/50 grain (0.0013 gm.) if the smaller dose is without effect. The aim should be to produce the physiological effect, which is a sense of fullness or a flushing. The sodium nitrite may be substituted in 3 to 5 grain (0.19 to 0.32 gm.) doses. It has the advantage of being more permanent in its effect, although it is slower in its action.

2. *Valvular Heart Disease Associated with Renal Disease in which the Heart Disease is Primary.*—The heart disease is commonly disease of the mitral valve. The kidney involvement does not occur in connection with aortic valvular disease until mitral insufficiency is superadded. It is well known that in mitral regurgitation as soon as compensation ceases the blood accumulates first in the lungs, then in the right side of the heart, and finally in the venous system, engorging especially the liver, stomach, and kidneys. The effects upon the first two were discussed in treating of heart disease. They generally manifest themselves sooner than the renal symptoms. The result in the case of the kidney is the kidney of passive congestion or cyanotic induration, already described on page 762.

Much more decided are the clinical phenomena resulting from such congestion. It is a well-recognized condition of copious secretion of urine that the blood should move freely through the kidney. A stasis is followed immediately by diminished filtration of water, the 24 hours' quantity being reduced to from 30 to 20 ounces (90 to 60 c.c.), and even to less. The solids at first at least remain the same, the urine is dark-hued, the specific gravity is high, the reaction is markedly acid, and a copious sediment of urates and uric acid makes its appearance as soon as the urine

cools off. There is almost always a small amount of albumin found, but as the congestion increases, albumin becomes copious. Casts are sparsely, if at all, present, and are of the hyaline and faintly granular variety. Both red and white blood-corpuscles are also sometimes detected, as might be expected. This condition of the kidney and the symptoms are the direct results of the cardiac valvular disease. Yet I often see these cases diagnosed as Bright's disease as though it were the primary and principal affection. They may also be produced by any cause producing venous stasis, as pulmonary emphysema, chronic pleurisy, and thrombosis of large veins. Their effect is further to augment the symptoms of the cardiac disease. The circulation, already everywhere obstructed, is further impeded, there is dyspnea, dropsy increases, appetite fails, and there are nausea and constipation. Sleep, already disturbed by dreams, become more so, and a more distressing picture than is presented by such a case is rarely met.

**Treatment.**—Yet these symptoms are often easily amenable to treatment so long as the heart muscle remains capable of being influenced by digitalis. I have seen many a patient, apparently *in extremis* gasping in orthopnea and with legs heavy and almost bursting with dropsical effusion, completely relieved by a few large doses of this drug. But they must be large doses—not less than from 8 to 10 minims (0.5 c.c. to 0.6 c.c.) or from 15 to 20 drops every three hours until an effect is produced. If digitalis fails, the tincture of strophanthus may be given in the same doses, or caffein citrate in 3 grain (0.2 gm.) doses, each every four hours, or spartein sulphate in doses of from  $\frac{1}{4}$  to  $\frac{1}{2}$  grain (0.016 to 0.03 gm.). Theobromine in  $7\frac{1}{2}$  grain (0.5 gm.) doses, and aceto-theocin in 4 to  $7\frac{1}{2}$  grain (0.25 to 0.5 gm.) doses should not be forgotten. Purgation should not be omitted, and should rather be pushed to the production of watery catharsis. The ingestion of fluids should be restricted, and Hay's treatment of dry diet with purgatives is sometimes useful. But I have found a restricted milk diet limited to two ounces every two hours, associated with the drugs previously named, equally efficient.<sup>1</sup>

Such a kidney is, of course, more liable to become the seat of an acute or a chronic nephritis than the normal organ.

3. *Renal Infarct the Result of Heart Disease.*—The next form of kidney involvement secondary to disease of the vascular apparatus, commonly heart disease, is more frequently seen on the postmortem table than recognized in the living subject. It is *embolic infarction*, produced by the lodgment in some branches of the renal artery of an embolus derived from the heart or a blood-vessel. Its most frequent source is a fragment of vegetation or clot from a diseased heart-valve, commonly the aortic. An embolus may also arise from a thrombus in a vein. If from the latter, it must be carried first to the right heart, and thence through the lungs into the left heart, and thence by the aorta to the kidney, and must, of course, be small.

The effect of the lodgment of an embolus in the kidney is a wedge-

<sup>1</sup>See some cases reported by the author in a paper "On the Management of Obstinate Dropsies," *Med. News*, June 21, 1890.

shaped hemorrhagic infarct which at first is dark red in color, standing out above the surface, but which in time whitens, contracts, and is ultimately absorbed, leaving a mere cicatricial mark.

Most frequently a renal infarct occurs without noticeable symptoms. Its occurrence, if looked for by reason of the presence of valvular heart disease, may be suspected if there is the sudden appearance of blood in the urine. A sudden pain in the region of the kidney occurring at the same time with hematuria would go to confirm the diagnosis. No treatment, except rest, is indicated, even if the event is recognized.

4. *Accidental Coincidence of Renal Disease and Heart Disease.*—Finally, kidney disease and disease of the vascular apparatus, and especially cardiac disease, may coincide accidentally, each the result of its own cause, and reacting the one upon the other in various degrees and variously aggravating the symptoms of each, so that it often becomes a very nice question to determine which is the preponderating disease. Fortunately, this difficulty does not always extend to therapeutics, the same remedies which are useful to one affection being commonly indicated for the other. A careful study of each case should, however, be made on its own merits, and due weight assigned to each factor of the disease.

## DISEASES OF THE BLADDER.

## CYSTITIS.

SYNONYMS.—*Catarrh of the Bladder; Vesical Catarrh.*

**Definition.**—Cystitis is an infectious inflammation of the bladder excited usually by different varieties of pathogenic bacteria.

**Etiology.**—Among these are the *bacillus coli communis*, the *gonococcus*, *staphylococcus pyogenes* and *bacillus tuberculosis*. The typhoid bacillus is not an infrequent cause.<sup>1</sup> The causes formerly assigned to such inflammation, though relegated by the above definition to favoring causes, are still very important. They include foreign bodies, such as stone, trauma, obstruction to the outflow of urine by enlarged prostrate or stricture of the urethra. A frequent medium of introduction of bacteria was formerly catheters. The number of cases caused by catheterization has diminished because of the greater precaution taken of late in the care of instruments. Of acknowledged bacterial origin is also gonorrheal cystitis, which, succeeding an attack of gonorrheal urethritis, invades the bladder by extension.

Cold was formerly recognized as a cause of cystitis, especially in women and children, but it is subject to the same conditions as the causes just named. On the other hand, cystitis succeeds upon the introduction of substances in the blood, as cantharides and capsicum. Even the ingestion of certain articles of food has been followed by it. Traumatic agencies may be classed among predisposing causes rather than exciting, furnishing the conditions favorable to the operation of bacteria.

**Morbid Anatomy.**—The bladder of cystitis is a varied picture. There may be degrees so slight as to produce scarcely appreciable change in its appearance. At other times the mucous membrane is hyperemic and bathed with a mucoid or mucopyoid secretion of dirty-gray color. In many cases only the neck of the bladder and the part of the urethra passing through the prostrate are involved. Again, the bladder is "ribbed," a result of straining. During this act the mucous membrane between the muscular trabeculae yields, producing depressions bounded by the more unyielding muscular bands. On the other hand, in chronic cases permanent thickening of the bladder-walls may result. Finally, in the severest forms of inflammation due to pathogenic organisms, such as those associated with putrid urine, the mucous membrane may be covered with patches of false membrane, or the wall of the bladder may be infiltrated and undermined with pus, constituting the so-called phlegmonous or diphtheritic cystitis, from which there may result urethral and perineal infiltration. A further extension of the cystitis into the pelvic connective tissue about the bladder is known as paracystitis; this belongs to the province of the surgeon.

**Symptoms.**—While a division of cystitis into acute and chronic is justified by the suddenness and severity of symptoms in certain cases as

<sup>1</sup>See an admirable paper by Thomas R. Brown on "The Bacteriology of Cystitis, Pyelitis," etc., "Johns Hopkins Hospital Reports," vol. x., 1901.

contrasted with their slow development in others, yet the conditions so constantly verge into each other that a separate consideration of the two forms is not necessary. The first symptom is usually a *frequent desire to void urine*. Such frequency varies greatly in intensity. It may be every few minutes or almost incessant, several times an hour or once in two hours. After the primary frequency of disturbance it usually diminishes somewhat. Such frequency is often attended by painful straining. In severe cases there is always *tenderness* over the region of the bladder above the pubes, and in some cases there is constant *pain*. In these tenderness can also be elicited by pressure from the vagina and rectum, while catheterization is especially painful. In calculous cystitis pain is excited or aggravated by motion, especially such as is communicated to one riding in a wagon over a rough road.

As commonly met, there is rarely fever with cystitis, but the severe forms are attended with *moderate fever* and sometimes, in the diphtheritic variety, with *high fever*. Even when there is fever, the temperature does not exceed 100° to 102° F. (37.8° to 38.9° C.), though it may be higher. In certain acute diphtheritic cases of great virulence there are *chills*, *sweats*, and *high fever*. In advanced stages there may be *sepsis*, due to absorption of retained putrid matter from the bladder.

The *urine* presents striking changes, from which alone the diagnosis can be made. *First*, it contains pus in varying quantities, but it is especially characteristic of the pus of cystitis that it is associated with mucus, which imparts a glairy, stringy character to the urine, that increases the difficulty of its discharge from the bladder. The reaction of the urine when passed is commonly either alkaline or faintly acid, and if acid, it promptly becomes alkaline. This is due to the formation of ammonium carbonate out of the normal urea, the result of the operation of bacteria. The greater alkalinity thus resulting reacts upon the pus and converts it into a glairy matter resembling mucus, thus further increasing the difficulty of micturition. Under the circumstances the pus is loaded with amorphous phosphates of lime and glistening crystals of ammonio-magnesium phosphate. It is so viscid that it will not rise in the pipet, and must be cut with scissors to be manipulated for microscopic study. Blood is an almost constant constituent of the urine in calculous cystitis, and in the grave diphtheritic forms shreds of gangrenous bladder tissue may be discharged.

**Diagnosis.**—Ordinarily, the diagnosis of cystitis is easy, yet there sometimes occur mild forms which it is difficult to differentiate from mild degrees of *interstitial nephritis*, while it not very rarely happens that the two conditions are associated. In contracted kidney there are also sometimes a good many leukocytes. The presence of hyaline casts, even when scanty, points to nephritis, while hypertrophy of the left ventricle and increased arterial tension settle the question. Still more emphatic is the diagnosis if there is retinitis albuminurica.

The question as to whether there is *pyelitis*, separate or associated with cystitis, is still more difficult. It is true that the pus in pyelitis is very much less glairy and viscid than that of cystitis pure and simple. I know, however, no distinctive cellular elements which settle this question,

though some assert there are. Even spasm of the bladder, commonly regarded as peculiar to cystitis, may be present in pyelitis. Rather must we rely upon tenderness in the neighborhood of the kidney on the one hand and in that of the bladder on the other. Marked intermission in the purulent discharge, especially if associated with attacks of nephritic colic, which imply an obstruction of the ureter, point to *pelvic involvement*. Catheterization of the ureters may aid in the diagnosis, pus from the pelvis of the kidney being thus separated from the bladder contents.

*Calculus cystitis* may be suspected when pain in the region of the bladder is excited by motion, as in riding over a rough road, or at the end of the penis after micturition; also when there is blood in the urine or when the stream of urine is suddenly interrupted. These symptoms should immediately suggest the use of the sound, negative results with which must not, however, be accepted without qualification, as the stone may be concealed in a diverticulum.

**Prognosis.**—The medical treatment of cystitis does not furnish a very satisfactory chapter in therapeutics. It includes such treatment as the physician is called upon to use, supposing the exciting cause, such as a stone in the bladder or obstruction in the urethra, to have been removed, whenever possible. Thanks to modern surgery; the enlarged prostate which is responsible for so many cases of cystitis is, in the vast majority of cases, removable without accident even in the old. Many cases due to other causes get well; others are only partially relieved. Some of the most virulent acute cases terminate favorably with rupture into the vagina or rectum if the patient resist the primary attack of the disease.

**Treatment.**—*Acute Cystitis.*—Of this form the treatment is far more satisfactory, at least so far as the removal of the acute symptoms is concerned, than that of the chronic form. Rest in bed is a primary and essential condition. Leeches to the perineum should be applied more frequently than they are. A poultice to this same region and over the lower abdominal region is always useful, while a brisk saline cathartic should never be omitted.

As the feverish state which always accompanies cystitis is more or less constantly associated with scanty urine, concentrated and irritating to the inflamed mucous membrane, it is desirable at once to increase the secretion and thus dilute it. Copious libations of pure water, to which the citrate or acetate of potassium is added, in 15 to 20 grain (1 to 1.3 gm.) doses for an adult, should be allowed. The ordinary spirit of nitrous ether in dram (3.4 c.c.) doses every two hours is an admirable adjuvant, and may be combined with the official liquor potassii citratis, which contains about 20 grains (1.3 gm.) of citrate of potassium to 1 2 ounce (15 c.c.). Formerly, the mucilage of flaxseed or flaxseed tea was much used as a diluent menstruum for the diuretic alkalies indicated, but it is doubtful whether it is any more efficient than a like quantity of water. When there are much pain and straining, as is often the case, especially when cantharides is the cause of the inflammation, opium is indispensable, always in the form of a suppository, 1/2 grain (0.03 gm.) to 1 grain (0.065

gm.) of the extract, or a corresponding amount of morphin. Iced-water injections into the rectum, or pieces of ice similarly applied, are very efficient in allaying the pain and irritation when additional measures are needed. I have recently found injections of cocain into the bladder useful in allaying the intense irritation. Not more than 2 grains (0.13 gm.) of cocain should be introduced into the bladder at one time.

*Chronic Cystitis.*—The successful treatment of chronic cystitis is a much more difficult task, for three evident reasons:

1. The constant presence in the bladder of the urine with its irritating qualities, especially so to an inflamed mucous membrane.
2. The difficulty in getting remedies to reach the inflamed surfaces.
3. The pent-up inflammatory products, which in their decomposition often make the urine still more irritating by exciting in it ammoniacal changes.

There is no doubt that, if the urine could be kept from entering the bladder during the existence of an inflammation, the latter would rapidly heal; that cure would be facilitated by obtaining ready escape for the pus and mucus; while happier results might also be reasonably expected if we could secure readier access for remedies to the inflamed areas. None of these indications can be met entirely. They remain, however, the conditions to be fulfilled, and while none can be thoroughly fulfilled, they may be variously approximated.

First, the irritating qualities of the urine may be diminished by the use of diluents, already recommended in the treatment of acute cystitis. Almost any of the negative mineral waters, so highly recommended by their owners, are useful for this purpose. Just as good is pure spring water, and even better is distilled water. From one to two quarts should be taken daily. If the kidneys are equal to their office, a large quantity of light-hued urine of low specific gravity and relatively weak in solids will be secreted.

When it is purposed to go further and add to the efficiency of diluents, mistakes are often made. While one can scarcely go astray in adding alkalies to the fluid ingested in acute cystitis, it is very different with the chronic form. In this the urine is often alkaline, or ready to become so on the slightest addition of alkali to the blood. Such alkalinity of urine in turn favors decomposition, the effect of which is to convert the pus, if present, into a tenacious, glairy fluid which the bladder cannot evacuate. Notwithstanding this tendency, 'liquor potassæ and other alkalies are sometimes administered under precisely these conditions—adding "fuel to the flame." The indication under these circumstances is to render the urine acid, if possible, although the means to this end are unsatisfactory. Benzoic acid has the reputation of doing this, and it is probably true of it when administered in sufficient doses. It may be given in the shape of a 5 grain (0.32 gm.) capsule, of which at least six must be given in a day to produce any effect. Benzoate of sodium may be given in 10 grain doses (0.6 gm.) every two hours. The same property has been assigned to citric acid, but this is a mistake, as all of the vegetable acids, when ingested, are eliminated as alkaline carbonates.

The second indication is to medicate the inflamed surface. Two ways suggest themselves:

1. By the internal administration of drugs.
2. By the injection of medicated liquids into the bladder.

To carry out the first method, an enormous number of infusions, decoctions, and fluid extracts of vegetable substances have been suggested, the vast majority of which are absolutely useless, except as they serve by their quantity to act as diluents. Among the best known of these are buchu, pareira brava, uva ursi, and triticum repens. I have never known any beneficial results to be obtained from any of them, except perhaps buchu, and seldom prescribe them except as vehicles.

The remedies heretofore most efficient in cystitis through their internal administration are the balsams. Of these, the balsam of copaiba is practically unavailable, because not one stomach in a hundred will bear it in sufficient doses or for long enough time to permit it to be of any use. Sandalwood oil is more easily borne, and is also an efficient remedy. It is best administered in capsules containing 10 minims (0.6 gm.). Contrary to the usual custom of giving these and like remedies after meals, I have given them on an empty stomach before meals. They are as well and even better borne than when given after food, and they pass into the blood much more quickly. It is desirable to impregnate the blood and to impart a balsamic odor to the urine. This is scarcely possible with less than eight capsules a day—two before each meal and two at bedtime. They should be followed by a little milk rather than water.

A valuable addition to drugs useful in the treatment of cystitis is urotropin or formin, and it has been in my hands most efficient. It has seemed to me to be most indicated in subacute and chronic stages. The dose is 5 to 7  $1\frac{1}{2}$  grains (0.33 to 0.5 gm.) in a capsule three to five times a day. I have not found it always superior to sandalwood. Occasionally this balsam is more efficient.

Both boric acid and benzoic acid are useful adjuvants to the treatment of chronic cystitis through their antiseptic effect on the urine, each in 5 grain (0.32 gm.) does, rapidly increased to 10 grains (0.65 gm.). They may be given jointly, as in the following prescription:

℞ Sodii biborat., }	
Ac. benzoic., }	gr. x (0.65 gm.)
Infus. buchu,	f 3 ij (60 c.c.).
Three times a day.	

Resorcin in 3 to 5 grain (0.198 to 0.33 gm.) doses and naphthalin in 2 grain (0.13 gm.) doses are recommended for the same purpose. Salol has become a popular remedy, very large doses being advised—from 15 to 30 grains (1 to 2 gm.) every three hours—but in my experience these doses are not well borne, ten grains (0.66 gm.) being a maximum dose.

The application of remedies to the bladder by injections is best considered in connection with the third indication—the getting rid of inflammatory products, the pus and mucus, and the matters resulting from their decomposition. The latter are not always present, but all who have had much experience with cystitis are familiar with the tenacious, glairy, mucoid matter, which will not drop or rise up in a pipet, glisten-

ing with large crystals of triple phosphate, and exhaling a stinking, ammoniacal odor which quickly contaminates an entire apartment. There is only one way to get rid of this, and that is to wash out the bladder, and often this is too long deferred. Tepid water should be used first, and the injection made through the soft, flexible catheter. Sir Henry Thompson is very emphatic in his directions that no more than two ounces should be thrown in at a time, and that this should be allowed to run out, a like quantity again injected and allowed to run out, and this repeated until the water comes out as clear as it enters. But double this quantity may be used with entire safety, and with such quantity used, a much shorter time is necessary to cleanse the bladder thoroughly. After the capacity of the bladder has been determined, even more may be thrown in, because it is sometimes useful to distend the viscus a little, in order to reach the depressions and inequalities always present in advanced inflammations. These simple injections, practiced once a day, or in severe cases twice a day, often result most happily. After a few injections with plain water some medication may be added. Salicylate of sodium, in the proportion of a dram (4 gm.) to the pint (1/2 liter), is one of the best. Its disinfecting qualities are undoubted. Boric acid, in the proportion of a dram (4 gm.) to the pint (1/2 liter), is also very satisfactory. Sir Henry Thompson's soothing lotion—of biborate of sodium an ounce (30 gm.), glycerin 2 ounces (60 c.c.), water 2 ounces (60 c.c.), and of this mixture 1/2 ounce (15 c.c.) to 4 ounces (120 c.c.) of tepid water—may also be used.

At the University Hospital to-day the iodide of silver has altogether replaced the nitrate of silver. The bladder is first irrigated by a five per cent. boric acid solution. Two ounces (30 c.c.) of five per cent. solution of iodide of silver is then introduced into the bladder and allowed to remain as long as the patient can hold it. The injection is made at first twice daily. If the patient is made more comfortable we apply it daily. The bladder, if previously washed out by boric acid solution, should be irrigated with plain warm sterilized water in order to avoid chemical reaction between the nitrate of silver and the boric acid. For tuberculous cystitis an oil emulsion of iodoform is the best, beginning with a two per cent. emulsion leaving 1 to 2 ounces (30 to 60 c.c.) in the bladder according to its capacity. If well borne it should be increased to five per cent. The bladder should also be previously irrigated with five per cent. boric acid solution.

Alum is an astringent which has been too often overlooked of late in suppurating processes in mucous membranes, and may be substituted for the salicylate with advantage when the pus does not disappear so rapidly as is desired. It should be more cautiously used than the salicylate of sodium. Sufficient of the powdered alum should be first added to a pint of water to give it a distinctly astringent taste, when the bladder should be washed out as described, while a small quantity may be allowed to remain after the last injection.

When there is a foul odor present, the bichlorid of mercury may be used in exceedingly dilute solution—not more than 1 to 25,000 at first—gradually increasing the strength if it is well borne. Carbolic acid may also be used in weak solution—1/4 to 1/2 per cent.—also peroxid of

hydrogen, one part to four or five of water. Among other remedies recommended for use in the same way are acetate of lead, 1 grain (0.06 gm.) to 4 ounces (120 c.c.); dilute nitric acid, 1 or 2 minims (0.06 or 0.12 c.c.) to the ounce (30 c.c.).

Anodynes are indispensable in many cases of cystitis to relieve the patient of extreme pain and of the frequent desire to pass water, which are the result of the same cause. Opium and its alkaloids are the most efficient, and they are best introduced by the rectum. There appears to be no absorbing power in the bladder for opium, and there is no use in attempting to administer anodynes by that channel. Cocain, from which so much might reasonably be expected, is disappointing, though it should not be overlooked. I have injected as much as 2 ounces (60 c.c.) of a one per cent. solution into the bladder, representing 8 grains (0.5 gm.), without effect, except to produce some of the symptoms of cocain poisoning. To avoid this not more than 2 grains (0.13 gm. of cocain should be put into the bladder at one time. Disappointing, too, has been the use of cocain to remove the exquisite tenderness of the urethra which sometimes attends this condition, and is a serious drawback to the use of the catheter; yet it may be tried for both purposes. For catheterizing, a two per cent. solution may be injected into the urethra, allowing two or three minutes to elapse before the catheter is introduced. Then, through the soft catheter itself, a few drops of this solution may be injected in advance of the catheter, which is again pushed a little further; then a few more drops are instilled, the catheter is introduced a little further, and so on until the instrument enters the bladder.

When there is greatly *enlarged prostate*, catheterization is indispensable, and is often attended with the most happy results. It is often too long deferred because of the natural repugnance to the use of the instrument. The patient or his friends should be taught to use the catheter and to wash out the bladder. In these days of refined antisepsicism it is scarcely necessary to say that the greatest precautions should be taken to cleanse the catheter after its use, in order to avoid sepsis. There is nothing better for this purpose than the bichlorid solution, 1 to 1000, in which the catheter should be allowed to lie for a short time after being cleansed with boiling-hot water.

How much can be accomplished by such treatment as that just described? An absolute and total cure in chronic cystitis is a rare event. On the other hand, a life of suffering may be converted into one of comparative comfort, and I have many times seen it. It occasionally happens, of course, that all treatment of this kind fails, and yet the patient lives to be tortured by the discomfort of the situation. In such cases perineal section may be recommended, and I have had the operation done several times with some relief to the patient, although with less than was hoped for. Of late years suprapubic cystotomy has come into favor. The operation of castration, once advocated for enlarged prostate has fallen into disuse. Vasectomy, though a simpler operation, is even less efficient. Prostatectomy or enucleation of the prostate either by the suprapubic or perineal section is the only effectual operation and is now much employed with excellent results.

## STONE IN THE BLADDER.

All that has been said in a general way of stone formation and the treatment of its tendency when treating of nephrolithiasis may be applied to stone in the bladder.

**Symptoms.**—The symptoms of stone in the bladder are practically those of cystitis, already described, aggravated by motion, especially riding over rough roads. \*As further distinctive of stone in the bladder may be mentioned pain at the end of the penis immediately after micturition. The only proof, however, of the presence of stone is its recognition by the sound, which should be used in every case of cystitis.

**Treatment.**—For removal of stone in the bladder medicinal treatment is even less efficient, and operative treatment is, if possible, more imperative.

## NEUROSES OF THE BLADDER.

**Physiology of the Bladder and Its Derangements.**—A proper understanding of nervous derangements of the bladder will be facilitated by a review of its physiology. The control of the bladder over the urine is partly reflex and partly voluntary. The reflex center is in the lumbar enlargement of the cord; the voluntary, in the cortex of the brain. In the lumbar cord seem, however, to be lodged two reflex centers, one for the *detrusor vesicæ* and the other for the *sphincter*. If the bladder be partly filled and at rest, its control is given over to the sphincter, whose striated fibers are reflexly active. As the bladder becomes more nearly full, the unstriated fibers of the detrusor muscle are more and more stimulated, and a time arrives when the sphincter can maintain itself only by the assistance of the will if the subject be in a normal state. In such state, too, under suitable circumstances, the will suspends its control over the sphincter and the bladder is emptied.

## PARALYSIS OF BLADDER.

If the spinal cord is cut above the lumbar enlargement, voluntary power to aid or suspend the action of the sphincter is lost, the bladder is given over to the lumbar cord as a pure reflex center. The urine accumulates as long as the action of the sphincter prevails, but as soon as a sufficient amount accumulates to stimulate the extrusor, the bladder is emptied more or less completely. Thus is produced one of the forms of incontinence, as when there is extensive lesion of the cord above the lumbar region.

If, on the other hand, there is paralysis of the *detrusor* muscle and the sphincter remain intact, there will be retention of urine. If, however, communication with the brain remains intact, by an act of the will the reflex contraction of the sphincter may be suspended and the bladder partially emptied by a straining effort, at least so far as pressure can be exerted by the abdominal muscles. Should the afferent or sensory nerves of the reflex arc be paralyzed either alone or in conjunction with

the efferent to the detrusor, the bladder will become enormously distended; but if the distention continue, a point is reached when the sphincter is paralyzed by overstretching, when incontinence occurs and the urine dribbles away. There is the same effect if there be destruction of the cord at its lumbar enlargement. So long as the cord is intact the patient may partially empty the bladder by abdominal pressure. Again, if paralysis of the *sphincter vesicæ* occurs, incontinence succeeds as soon as urine has accumulated sufficiently to overcome the elastic closure of the bladder

FIG. 81.—Diagram Showing Probable Plan of the Center for Micturition—(Gowers).  
 MT. Motor tract. ST. Sensory tract in the spinal cord. MS. Sphincter center, and *ms* motor nerve for sphincter. MD. Detrusor center, and *md* motor nerve for detrusor. *s*. Afferent nerve from mucous membrane to S, sensory portion of center. B. Bladder. At *r* the position during rest is indicated, the sphincter center in action, the detrusor center not acting. At *a* the condition during action is indicated, the sphincter center inhibited, the detrusor center acting.

orifice. It may also be slightly delayed by voluntary innervation of the sphincter, but is unrestrained during sleep. Hence at such time the patient wets the bed. Such incontinence is also manifested when the patient coughs or when in any way sudden pressure is brought to bear on the bladder. It is often seen in women who are said to have "weak" bladders. Combined detrusor and sphincter paralysis is followed by *dribbling* away of urine as soon as enough accumulates to overcome the elastic closure of the urethra, because there is no contraction of the bladder, and the outflow is a mere overflow.

#### MUSCULAR SPASM OF THE BLADDER—CYSTOSPASM.

**Symptoms.**—In detrusor spasm sudden evacuation of the bladder takes place. This occurs in hyperirritability of the mucous membrane of the bladder or of the reflex center in the cord as soon as a small amount of urine accumulates in the bladder. It may be controlled to a degree by a voluntary impulse to the sphincter, but at other times it is irresistible, and is especially prone to occur during sleep. To this class of cases belong many of the instances of incontinence in children.

In spasm of the sphincter, on the other hand, the orifice is kept forcibly closed, though this closure, too, may be intermitted by action of the will, permitting thus a small quantity of urine to be discharged at a time. As the urine accumulates the discomfort increases still further, when an attempt is often made to empty the bladder by straining efforts. This sometimes reacts on the sphincter, producing further contraction, which may extend to the bulbo-urethral and sphincter ani muscles, causing painful spasm. Such spasm, too, forcibly resists the introduction of a catheter. It may be due to hyperexcitability of the sensory reflex center or to irritation directly in the neighborhood of the sphincter, such as intense inflammation.

A combination of spasm of the detrusor and sphincter muscles may exist, giving rise in high degrees to intense suffering. It may be caused by a simultaneous irritation of the two reflex centers in the cord or by intense irritation of the mucous membrane of the bladder reflected to both sets of muscles.

In addition to the nervous affections, chiefly of the cord, which may occasion these symptoms, modifications in the sensibility of the mucous membrane of the bladder, of the deeper urethra and prostate may also occasion them. These changes may be purely neurotic. R. Ulzmann has refined the subject of neuroses of the genito-urinary system to a high degree, referring many symptoms of the kind described to an "exalted reflex excitability" caused by "overstrained physical, but especially by exciting mental activity," long kept up. Among these he mentions fright, pain, grief, loss of property, and the like, as well as the "gonorrheal process," excess in venery, and masturbation, apart from the organic processes of hyperemia, and even inflammation, which may be due to gonorrhea. The pure neurotic representatives of this class are unattended with changes in the urine, which is normal in every particular. These are not very uncommon, and they are often extremely difficult to treat successfully.

A comparatively frequent representative of this class is due to a hyperesthesia of the vesical mucous membrane, as the result of which the presence of the smallest quantity of urine gives rise to a pressing desire to empty the bladder, which is accomplished with spasm, pain, or other discomfort. As the result of this the patient must empty his bladder often—several times an hour, but much less frequently, if at all, at night. The urine is, as a rule, normal, and though sometimes concentrated, with a proportionate specific gravity, is still no more so than that which is commonly retained with perfect comfort. This occurs also sometimes in women.

Occasionally there is absolute loss of sensation in the vesical mucous membrane, apparently also functional, in consequence of which the urine accumulates without exciting the attention of the patient, and the bladder becomes thus overdistended.

**Treatment.**—Of *Incontinence* or *Enuresis*.—Previous to instituting treatment for these conditions the most careful inquiry must be made as to the cause, and its removal sought. This is often impossible, and treatment must then be empirical.

Incontinence most frequently calls for treatment. If due to disease

of the cord, it is amenable to treatment so far as such disease is, and in the meantime the patient must be protected by catheterization from the overdistention which is so apt to precede incontinence. Incontinence due to weak sphincters demands that this weakness should be treated by full doses of strychnin, which may be advantageously given in gradually ascending doses. Tincture of *nux vomica* may be substituted in ascending doses until 15 minim (1 c.c.) doses or more are attained. Electricity has been highly commended for this form of incontinence, in the shape of faradization, one pole being applied to the lumbar part of the spine and the other in the urethra, in the vagina, or to the perineum, the sittings being continued for a few minutes each day or every other day. Cold douches to the perineum are also useful.

If incontinence is due to hyperesthesia of the mucous membrane or to irritability of the bladder, belladonna is the accepted remedy. It should be given in ascending doses, and toward evening if it be nocturnal incontinence, so common in children. The physiological effect of the belladonna should be produced. The bromids may be combined with it or used separately. If there is irritability of the lumbar cord, ergot commends itself through its effect of diminishing congestion of the cord. The urine should receive attention, since a high degree of acidity or the presence of sediments of uric acid and of oxalate of lime may become the exciting causes of incontinence.

Incontinence in children (which is the most frequent variety met in practice) is a source of great annoyance, but in the majority of cases it subsides spontaneously not later than the 12th year. In its treatment in addition to the measures suggested, close investigation should be made for causes which should be removed. Masturbation especially in asylums and institutions is apt to be a cause of incontinence and should be carefully sought for.

Habit is sometimes a cause of incontinence in children, and encouragement of a cautious practice of holding the water may gradually correct the evil. Children should *not* be punished for incontinence, as the nervous apprehension excited only serves to make matters worse. General ill-health and irregular habits are sometimes responsible, and when these are corrected the patient recovers. Phimosis is sometimes a cause, and should be corrected if present. Indeed circumcision is sometimes a cure even when phimosis is not present.

*Of Retention.*—An overfull bladder should always be relieved by the catheter, and catheterization should be repeated as often as necessary to prevent recurring distention while the cause is being treated. When the retention is due to weakness of the detrusor muscle, strychnin will be of service. Electricity may also be used—one pole being placed behind the pubes and the other applied to the lumbar region.

If retention is due to spasm, the cause should be carefully sought. The same irritations referred to as causes of incontinence may produce spasm, and some of the same remedies are useful to relieve it, as belladonna and the bromids. Warm sitz-baths and full baths and enemas of warm water may be used at a temperature of 95° F. (35° C.) two or three times a day. In the event of failure with these measures, more

powerful anodynes may be used, including opium and morphin. These are best administered in the shape of a suppository containing from  $\frac{1}{2}$  grain to 1 grain (0.033 to 0.066 gm.) of extract of opium, and  $\frac{1}{4}$  grain (0.0165 gm.) of morphin. Ultzmann recommends, in cases of frequent micturition due to hyperesthesia of the prostate, injections through the prostatic urethra by a catheter which just reaches the membranous portion of the urethra. The solutions used are a  $\frac{1}{4}$  to  $\frac{1}{2}$  per cent. of carbolic acid and a  $\frac{1}{2}$  per cent. solution of sulphate of zinc, increasing the strength as it is borne to three, four, and five per cent. These should be used once a day with a syringe holding 4 ounces (100 gm.), and the whole quantity should be thrown into the bladder in the manner prescribed.

Other forms of spasm must also be treated by sedatives, and, strange as it may seem, the passage of a sound will sometimes relieve such spasms.

Unfortunately, the causes of either of these conditions cannot always be ascertained, and a cure must be secured by passing from one remedy to another until the correct one is arrived at.

### HEMORRHOIDAL VEINS OF THE BLADDER.

Excluding all other causes of hemorrhage of the bladder heretofore considered, such as villous cancer, stone, and tuberculosis, there remains a cause of hemorrhage which, by exclusion, resolves itself into a hemorrhoidal state of the veins. Its subjects are only older persons, rarely under 60; it is rather copious and yet rarely fatal—in my experience never so—though fatal cases are reported.

Great care should be taken in the study of cases of this kind in order to make sure that the hemorrhage is not due to the more serious causes already considered, otherwise a grave mistake in prognosis, as well as in diagnosis, may occur. The bladder should be carefully explored by the sound and, if necessary, by the endoscope.

**Treatment.**—Hemorrhages from this source may occur and not be repeated, and it is this favorable termination, in the absence of stone or malignant disease, on which we are sometimes unfortunately compelled to rely for the diagnosis. Should the hemorrhage continue, astringent solutions— $\frac{1}{2}$  per cent. and upward of alum and sulphate of zinc—may be injected into the bladder, always using the soft catheter. Absolute rest in bed should also be insisted upon. At the same time, the astringent drugs and mineral waters recommended under the treatment of hematuria may be tried, but it is hardly to be expected that astringent effects can be produced in the bladder through the route of the circulation by medicines administered by the mouth. In some cases, ergot appears to have been efficient in controlling these hemorrhages.

### MORBID GROWTHS OF THE BLADDER.

The bladder is subject to myoma, myxoma, sarcoma, and carcinoma, especially the variety known as villous cancer or papilloma; also to tuber-

culosis. Carcinoma may be primary, but is commonly secondary. The simplest histoid tumors are not clinically recognizable, one from the other.

**Symptoms.**—*Carcinoma of the bladder* may be suspected if, in addition to the usual symptoms of cystitis, hemorrhage is copious and persistent, if there is carcinoma elsewhere, and if there is rapidly-developed cachexia, and especially if there are other signs of secondary cancer in the vicinity. Occasionally villi of the papillomatous growth are passed in urine and easily recognized. Unless thus fortunate, the only certain means of diagnosis in the male, though not always to be relied on, is the endoscope, which, in the hands of a skillful manipulator, affords valuable assistance. In the case of the female it is easier and quite as satisfactory to dilate the urethra under ether and explore with the finger, though the endoscope may also be used.

The symptoms of *tuberculosis of the bladder* are those of cystitis, and the recognition of the bacillus of tuberculosis by microscopic examination affords the only sure means of differential diagnosis between it and other forms of inflammation of the bladder. It is, however, relatively easily found when present, especially if the urinary centrifuge is used.

**Treatment.**—If the diagnosis of villous cancer can be made early, the life of the patient may be prolonged by scraping the bladder, but in my experience the growth returns, sooner or later. In a few instances in which I have had surgeons operate for me in true cancer of the bladder, the result has been unfortunate—the patient perishing soon after the operation. The palliative treatment is that of cystitis. At the same time the counsel of a surgeon should be promptly sought.

The local treatment of tuberculosis of the bladder is that of cystitis. It demands the same general treatment as tuberculosis occurring elsewhere. See also p. 840.

## SECTION VIII.

### DISEASES OF DERANGED METABOLISM

#### (CONSTITUTIONAL DISEASES).

### RHEUMATISM AND RHEUMATOID AFFECTIONS.

**Historical.**—The term rheumatism was originally used to indicate morbid conditions associated with mucous discharges (Gr. *ῥευμα*, a flux), conditions to which the term catarrh was later applied and for which this term is still used. Rheumatism and gout were originally confounded under the name *ῥευματισμός*, first applied to gout and so used by Hippocrates (B. C. 460–357) and Aretæus (the latter half of first and beginning of second century A. D.), Sydenham (1633) was the first to separate the two conditions and to describe them intelligently.

#### ACUTE ARTICULAR RHEUMATISM OR RHEUMATIC FEVER.

(See Infectious Diseases.)

#### MUSCULAR RHEUMATISM.

SYNONYMS.—*Rheumatic Myositis; Myalgia.*

**Definition.**—A painful condition of voluntary muscles and their aponeurotic coverings, especially aggravated by motion and pressure. It affects especially large muscles, such as those of the neck, the shoulders, the arms, the back, the thighs, and the calves of the legs, and the intercostal muscles.

**Etiology and Pathology.**—Exposure to cold, damp and wet, and especially to drafts of cool air, as from an open door or window, is the most frequent cause. The acute form, at least, does not move about, but persists in the muscles primarily attacked until relieved. Barometric changes with or without the approach of rain may increase the severity of the pain, more particularly in the chronic variety.

Its true nature is unknown, and whether it is an affection of muscular substance or of the intermuscular connective tissue is also unknown. From the supposed rôle played by the latter, the term “fibrositis” has been suggested as a substitute for muscular rheumatism.<sup>1</sup> Certain forms of muscular rheumatism, especially that of the back, are ascribed to gout. An infectious origin has been suggested. It is sometimes associated with articular rheumatism, but has probably a different etiology, though like exciting causes operate to produce it. Similar pain often succeeds muscular strain, but it is doubtful if this should be called muscular rheumatism.

The division of muscular rheumatism into *acute* and *chronic* is based upon the duration of the pain and upon its disposition to recurrence. The term chronic is justified by those forms which recur with changes

<sup>1</sup>For an excellent paper by Arthur P. Luff, enlarging these views, see “Clinical Journal,” Oct. 11, 1905. “Forms of The Diagnosis and Treatment of Some of the So-called Rheumatism.”

in the weather, and are either excited or relieved by them. It, too, is less localized than the acute. On the other hand, it is not inaptly at times called wandering. It is more common in men than in women, because of their more frequent exposure to its cause.

**Symptoms.**—The only invariable symptom is *pain*, aggravated by motion or pressure. Sometimes there is *swelling*. It is usually rather sudden in its onset, requiring at most but a few hours, and often less, to develop it. It is never accompanied by marked constitutional disturbance. The *pulse* may be somewhat accelerated, and the *temperature* may approach 100° F. (37.8° C.), but more often there is no fever at all.

Muscular rheumatism is especially named according as it involves special muscles. Thus, *lumbago* is a painful affection of the lumbar muscles and their tendinous attachments. The attacks come on under the conditions already named, but sometimes suddenly without discoverable cause. The suddenness of its occurrence under these circumstances—as, for example, subsequent to a simple twist or stooping—has given rise to the term “kink in the back,” or, among the Germans, to the word *Hexenschuss*, or “witches’ shot.” It has seemed to me that this sudden pain was really a “cramp,” being entirely analogous to the cramps which seize the muscles in other localities. The strain in most cases is altogether too insignificant to cause laceration. As a consequence, the body is at times immovable as in a vice, so excruciating is the pain caused by motion.

Rheumatic *stiff neck* or *torticollis* (as contrasted with congenital and spasmodic torticollis, p. 1131) is an affection of the side and back of the neck, forcing the patient to hold his neck to one side as the situation of least discomfort, and when he desires to turn his head he is forced to turn the whole body. The relief given to pain by dropping the head toward the painful side may be ascribed to relaxation and not contraction of the muscle. In a few instances the pain is on the side opposite that toward which the head is drawn, in the muscle which is on the stretch.<sup>1</sup> Sometimes it becomes chronic and is rather difficult to cure. It is more frequently met in children and young adults.

*Omalgia* is a similar condition of the muscles of the shoulder and upper arm, making motion exquisitely painful. Ankylosis of the shoulder joint may be caused by delayed motion. *Pleurodynia* affects the intercostal muscles and makes breathing and coughing very painful, while a deep breath becomes impossible and sneezing an agony. The pectoral and serratus muscles may also be involved when the pain is higher up. It occurs more frequently on the left side.

*Cephalodynia*, or rheumatism of the muscles of the scalp, *scapulodynia*, and *dorsodynia* are all forms of muscular rheumatism which explain themselves. It also affects the *abdominal muscles*, and a most interesting instance of this form simulating peritonitis was published by myself in the “Philadelphia Medical Times,” volume x., 1880.

The duration of the acute form is brief, seldom lasting for more than a few days, though there may be a tendency to relapse. The chronic forms are indefinite in duration.

<sup>1</sup> See a paper on “Rheumatic Torticollis” (with references) by John M. Swan, “Philadelphia Polyclinic,” Sep. 3, 1898.

**Diagnosis.**—This is easy for the coarser acute forms of omalgia, stiff neck, and lumbago. Muscular rheumatism may, however, be confounded with *neuritis* and *neuralgia*. In muscular rheumatism the pain is more diffuse; in neuritis there is pain with tenderness more localized and along the course of large nerve trunks. Muscular rheumatism and neuritis are distinctly worse on motion; neuralgia less so. Rheumatism is commonly relieved by the warmth of the bed; neuritis may be aggravated while neuralgia is uninfluenced by this cause and increased by cold winds. *Pleurodynia* is sometimes difficult to distinguish from intercostal neuralgia, but attention to the points named will prevent mistakes. *Neuritis of the brachial nerve trunks* resembles omalgia, but the former is early followed by atrophy, while muscular rheumatism is not. From *pleurisy*, pleurodynia is easily distinguished by the absence of fever and of physical signs. The lancinating pains of *locomotor ataxia* and the pains of *incipient disease of the vertebræ* resemble at first those of lumbago, but the special symptoms of these diseases are soon superadded.

**Treatment.**—The *acute* form of muscular rheumatism is occasionally amenable to treatment by the *salicylates* and *salicin*. Some phenomenally good results sometimes follow the use of these remedies. They are, however, inconstant, and if, after a fair trial, such results are not promptly attained, the drugs should be omitted. If efficient, the same rules as to their continued use in reduced doses after relief has been obtained apply as in acute articular rheumatism. The group of muscles treated must be placed at *absolute rest*, and in the case of the thorax this is best accomplished by strapping the side with adhesive plaster. Rest may, however, be overdone, in case of muscles like those of the shoulder in which atrophy may result from too prolonged a rest. Another measure of great value is *dry heat*, applied by means of a hot-water bag covered with flannel, or by a warm flat-iron. To use a popular expression, a muscular rheumatism may thus be sometimes “ironed out.” A flannel cloth should be interposed. With these measures may also be associated massage. Sometimes a single efficient treatment by massage is enough to “rub out” such a rheumatism. Of less permanent utility are hot poultices, although they allay pain, at least. The same effect is accomplished by moist hot-air or vapor (steam) baths, which, in special establishments, can be localized.

The chronic form is also treated by massage, passive motion, and electricity, either the induced or direct current. Counterirritation by liniments, such as those made with chloroform, ammonia hydrate, or turpentine, have long enjoyed a reputation, but at the present day it is beginning to be questioned as to whether, after all, it is not the friction, rather than the liniment itself, which produces the good effect. Some efficiency in the liniment itself, I think, must still be admitted, and I would advise its use as determined by circumstances. Acupuncture, consisting in the puncture by needles thrust deeply into the skin, is a measure which has some advocates, especially in the treatment of lumbago. My experience with it is limited. Hydrotherapy is more likely to be useful, and here the warm or cold pack is the better method of application. Dry-cupping is also often of service. Small blisters should not be forgotten.

General treatment should not be neglected: cod-liver oil, iron, strychn-

nin, quinin, and good food are necessary measures when the patient is run down. Among diseases which need nutritious food, chronic muscular rheumatism is preeminent.

### CHRONIC ARTICULAR RHEUMATISM.

**Definition.**—A term, often vaguely applied, which should be restricted to chronic inflammatory swelling involving the soft tissues of the joint, not due to sepsis, traumatism or tuberculosis.

**Etiology.**—Occasionally a sequel of acute rheumatism, it is more frequently of independent origin in those subject to prolonged exposure to cold and dampness or to changes in the weather. It is often a sequel of the subacute form, as the subacute is of the acute. On the other hand, it sometimes precedes the acute and subacute forms. It is a disease usually of middle life, and is more frequent among the poor and the working classes. Evidence, to the effect that many of the cases of so-called chronic articulation rheumatism are due to a pathogenic organism of no settled variety, is growing. Most recent studies in this direction have been by Goldthwait,<sup>1</sup> Schüller<sup>2</sup> and Fayerweather<sup>3</sup>.

**Morbid Anatomy.**—This, superficially, is similar to that of acute rheumatism, but the internal joint changes are more marked. The joint is enlarged chiefly because the capsule and tendons are thickened, as are also the sheaths of the tendons, explaining the difficulty of motion and the stiffness. The cartilages may be involved and eroded in chronic cases. On the other hand, the joint tissues may be unaltered. In protracted cases, especially when there is neuritis, atrophy of the muscles covering the joints takes place, producing marked deformity. In these cases, too, there may be ankylosis. At other times there is distention of the joint with effusion, the pressure of which upon the muscles themselves or on the vessels leading to them may be responsible for the atrophy.

**Symptoms.**—These are chiefly *stiffness and pain in the joints*, including their muscular and fibrous coverings. The latter is characteristically increased on motion, while the stiffness is often diminished by exercise. There may be little swelling, but marked *tenderness* to the touch, though not always. All the symptoms are aggravated by cool and damp weather, and often by other unknown meteorological influences. They are almost invariably improved by warm weather. There is rarely slight fever, nor is the pulse much altered. The stiffness may pass into actual immobility due to ankylosis, and there may be distortions of the joint, as described under morbid anatomy. Cardiac lesions as the direct result of the cause do not occur, but the valves may gradually be sclerosed, and fibroid changes may take place in the muscle.

**Diagnosis.**—This is not usually difficult. The age of the patient, the family history, the varying amount of the pain, the multiple joint affection, and the large size of the joints involved, the effect of motion, and the slight fever are sufficient to distinguish it from *gout* and *surgical monarthritis*.

<sup>3</sup>"Infectious Arthritis: A Bacteriological Contribution to the Differentiation of Rheumatic Affections." "Am. Jour. Med. Sci.," Dec., 1905.

**Prognosis.**—This, as to cure, is unfavorable, unless the patient can be removed to a warm climate. Generally, in spite of treatment, the symptoms gradually grow worse as the patient ages, though his life is rarely shortened. Yet unaccountable improvement sometimes takes place.

**Treatment.**—The remedies useful in acute rheumatism are not usually efficient in the chronic form. Occasionally acute exacerbations are relieved by the salicylates. Of drugs sometimes serviceable, the iodid of potassium and bichlorid of mercury may be named. Cod-liver oil, iron, and tonics are often useful by building up the strength of the patient. Guaiacum is a drug which still maintains some reputation in the treatment of chronic rheumatism. It is usually given in the form of the tincture or ammoniated tincture, 5 to 30 minims (0.3 to 2 c.c.), four times a day, preferably in milk.

*Local treatment* is more important than internal medication. Counter-irritation by iodin or blisters persistently kept up is sometimes useful. Encasing the joints in red-flannel bandages occasionally gives relief and is a convenient adjuvant. Massage is undoubtedly an efficient measure, though its effects are not always permanent. It is especially useful when there is atrophy of muscles, in which condition it may be combined with electricity and passive motion. A local application quite efficient is a mixture of equal part of chloral hydrate, camphor and menthol rubbed together, and applied to the painful area by a brush or cotton, then rubbed in with the fingers. The menthol may be omitted if the cooling sensation is complained of.

Hot baths, which should be taken at night, give temporary relief, but in my experience it is not always permanent. Even the systematic baths at the various hot springs, as those of Virginia, Arkansas, St. Catharine's and Banf, in Canada, and elsewhere, which are undoubtedly serviceable, are apt to be followed by relapses. More satisfactory is permanent residence in a warm climate for those who can afford it.

In some of the obstinate forms of this affection, the Tallerman-Sheffield hot dry-air treatment may reasonably be expected to be of service, and should be tried. In this treatment the affected part is exposed to a temperature of 250° to 300° F. (121° to 148.7° C.).

See also treatment of rheumatoid arthritis.

#### JOINT AFFECTIONS SIMULATING RHEUMATISM.

These include numerous joint inflammations of septic origin, such as occur in septicemia, scarlet fever, diphtheria, and the like. They have all been appropriately referred to when treating of the infectious diseases.

#### ARTHRITIS DEFORMANS.

**SYNONYMS.**—*Chronic Rheumatic Arthritis; Rheumatoid Arthritis; Osteoarthritis; Rheumatic Joint.*

**Definition.**—A deforming disease of the joints, regarded by most authorities as distinct from gout and rheumatism, and characterized by destructive changes in the synovial membranes, cartilages, and bone, and by bony outgrowths restricting the motion of the joint.

**Historical.**—Sydenham (1633), Musgrave (1763), Haller (1764), and de Sauvages (1768) allude to the characteristic changes in the bone due to arthritis deformans, but the first correct description was read by Landre Beauvais before the Paris Academy of Medicine, August 3, 1800, under the name "Goute Asthénique Primitive." William Heberden, Sr. (1710–1801), of England,<sup>1</sup> was, however, the first to recognize its true clinical position as something distinct from gout and rheumatism on the terminal finger-joints, since known as Heberden's nodosities. Haygarth's paper on "Nodosity of the Joints," in 1805, describes the disease clinically, and he remarked upon the peculiar liability of its occurrence in the female sex. Robert Smith (1835), R. Adams, and Charcot (1868) contributed to its morbid anatomy; Trastour (1853), Vidal (1853), and Charcot to its clinical aspects. Charcot and Trastour regarded it as a variety of chronic rheumatism, as do Mitchell Bruce, of England, and Kahler, of Vienna, at the present day. H. W. Fuller (1852) and A. B. Garrod (1859) described the disease accurately as something distinct from gout and rheumatism, basing their views on the absence of the visceral complications of these two diseases. Jonathan Hutchinson and others at the present day still hold that the disease is the product of a blending of gout and rheumatism. J. K. Mitchell suggested a nervous origin for the multiple form, and this idea has been developed by Senator (1877) and R. Wichmann (1890) in Germany, W. M. Ord (1884) and Dyce Duckworth (1884) in England, L. Weber (1884) in America, and others, until at the present day this neurotrophic view seems to be the most popular. Arbutnot Lane (1891) attaches much importance to mechanical wear and tear in the production of the lesions. Archibald E. Garrod contributed an exhaustive paper to volume ii. of the "Twentieth Century Practice of Medicine," 1895, from which the facts of this historical sketch are mainly drawn. In 1897, James Stewart, of Montreal, read before the Section on Medicine of the British Medical Association a paper in which an infectious origin of the disease was supported.

**Etiology.**—Although in the clinical features of its incipency arthritis sometimes closely resembles the mild form of acute rheumatism, its independence of rheumatism and gout and their causes is generally conceded. Heredity, however, plays a likely, if not an important, rôle. Some relation to gout is still claimed. Thus, the late J. M. Da Costa said rheumatoid arthritis is the form assumed by hereditary gout in the female. Females are much more liable to the disease than males, especially sterile women and those who have had uterine or ovarian disease. A. E. Garrod collected 500 cases, of which 411 were females and only 89 males. It is a disease said to be as common in the rich as in the poor, though I have seen many more of the latter, perhaps because of hospital practice. It usually begins between the ages of 20 and 30, but it may occur in children under 12 and as late as 50. The beginning of the menstrual period in women is a favorite time for its incipency.

Traumatism, often assigned by the subjects of the disease as a cause, has commonly no well-sustained relation, but must be allowed as a factor in *monarthritic* cases. Exposure, cold, and dietetic errors are ruled out at the present day as exciting causes, yet sometimes it seems impossible to exclude them. Certainly, insufficient food seems to favor the disease. Shock, worry, care, and grief are alleged causes.

**Nature of the Disease.**—The neurotrophic theory of the disease suggested by the late J. K. Mitchell, and additionally supported by Charcot's studies of the arthropathies, certainly explains the phenomena better than any other. According to this view, there must be allowed a lesion of the spinal cord, either primary or secondary to peripheral irritation, the result of uterine or traumatic disease. The reasons in favor of it are,

<sup>1</sup> "Commentaries on the History and Cure of Diseases" by William Heberden, Sr., a posthumous work, edited by his son, W. Heberden, Jr., was published in English and Latin in London in 1802 by T. Payne. It was arranged in 1782 by the elder Heberden, who was born in 1710 and died in 1801. On page 148 of the English edition appears the short article on "Nodes of the Fingers," in which he says: "They have no connection with the gout, being found in persons who never had it."

briefly, the symmetrical distribution of the articular dystrophies in the multiple form, the primary invasion of peripheral joints, and the centripetal extension of the disease; its etiology, the atrophy of muscles, the contractures, the occasional skin dystrophies manifested by pigmentation and local sweating. All these are, however, offset by the absence of anatomical evidence of spinal cord lesion, without which evidence the theory must still be regarded as not proved. The reflex origin of a cord lesion was especially supported by W. M. Ord.<sup>1</sup>

At the present day the infectious origin of the disease is gaining supporters. In evidence of this may be mentioned the paper of James Stewart read before the British Medical Association at its meeting in Montreal, 1897. Recent studies by C. A. Herter<sup>2</sup> and Wakeman<sup>3</sup> find evidence of perverted metabolism in the presence in the urine of an organic acid, other than that normally present probably due to intestinal putrefaction, which was found constantly excessive in those patients who had active symptoms of the disease. More recently G. A. Bannatyne, F. J. Poynton, Payne, Chaufford and Fayerweather have added further testimony. (See Chronic Rheumatism.)

**Morbid Anatomy.**—All three of the structures which enter into the formation of the joint share in the process, but the changes probably begin in the cartilages. These consist in a proliferation of the cartilage cells, succeeded by fibrillation of the intercellular substance, which subsequently undergoes mucous degeneration, liquefaction, and absorption. Thus, the bone ends are laid bare. These subsequently become atrophied, smooth, and eburnated. The bone ends and joint cavities are alike distorted; concavities may become convexities, and convexities concavities. The edges of the cartilages where overlapped by synovial membranes, thicken and form outgrowths, which subsequently ossify and become the osteophytes which contribute to the deformity of the bone, sometimes also forming rims or lips. The effect of the latter is to impair motion without producing actual ankylosis, except in very rare instances, which may include even vertebre. The synovial membranes also become thickened and the fringes hypertrophied. Effusion is sometimes present in the joints and in the bursæ. Fragments of cartilage may be attached to the tufts, or, becoming detached, they may lie loose in the joint. Muscular atrophy also makes a conspicuous part of the morbid changes.

**Symptoms.**—If the joint lesions be made the criterion of the presence of arthritis deformans, any remaining difference in symptoms depends mainly upon the grouping and extent of these lesions. Hence it is more convenient to subdivide them into clinical varieties. Two such are easily made:

1. Multiple arthritis deformans, including (a) Heberden's nodosities on the small joints and (b) the progressive form, in which large joints are successively invaded in an acute or a chronic manner.
2. The monarthritic or partial form, in which one or two joints are alone attacked.

## I. MULTIPLE ARTHRITIS DEFORMANS.

(a) **HEBERDEN'S NODOSITIES.**—These are prominences or nodules which develop gradually on the sides and ends of the distal phalanges, especially of the fingers and sometimes also of the toes. Women are the most frequent subjects, and the development begins usually between the 30th and 40th years, and gradually increases with age, but varies also at times and seasons independently of this gradual increase. The pain and tenderness also vary, being usually worse when the hands become cold, and especially when accidentally struck. At other times they are insensitve. These same nodosities occur in gout, and are especially attributed by the laity to gout, but this is an error. They may be considered of probable gouty nature when they are aggravated by errors of diet. They are quite independent of the tophaceous deposits of gout, which

FIG. 82.—Heberden's Nodosities.

From a photograph of the hand of a patient of the author.

are altogether absent in arthritis deformans. Persons in whom they are permanently present rarely have the large joints invaded, and, indeed, are said to have promise of long life. Subcutaneous nodules, similar to those characteristic of acute rheumatism, are also found in rheumatoid arthritis.

(b) **THE PROGRESSIVE FORM.**—This may be acute or chronic. The *acute* form simulates in its beginning a mild form of rheumatic fever in young women of from 20 to 30 years, but it may occur also in children. There are swelling of the joints, tenderness, and fever. These may continue without material change for weeks, or may abate to recur with increased severity; on the whole, however, growing worse, until the permanently enlarged and distorted state to be described is established.

In the *chronic* form the same changes develop more slowly and without fever, maintaining with remarkable constancy a symmetrical order of development, the order of frequency being the hands, knees, feet, ankles, wrists, elbows, shoulders, jaws, cervical spine, hips, and dorsal spine.

The most striking changes are seen in the knees, which become enlarged and so fixed that the legs are constantly flexed on the thighs, and the thighs on the trunk. These *flexions* may be contributed to by *contractures*, which may, however, arise secondarily, subsequent to the flexion, or form *pari passu* with it. They are seen in the upper extremity as well as in the lower, producing the "seal-fin" deflection at the wrist and a rectangular bend at the elbow. The actual *enlargement* is exaggerated in appearance because of wasting of the adjacent muscles and thickening of the capsular ligament. Its surface becomes hard and shining. There may also be some *effusion* in the joint, though the condition has been called by the French *arthrite sèche*. Motion grows more and more difficult, until the joint is almost locked, and grating and crackling attend attempt at motion. *Pain* varies greatly: at times it is very severe, at others it is quiescent, but it is always excited by attempt at motion. *Tingling*, *numbness* of the hands and feet, and *local sweating* and *skin pigmentations* are not uncommon among the early symptoms, and are regarded as trophic in origin. Day by day the patient becomes more helpless and, in the absence of fresh air, wan, weary, and anemic. Fortunately, in many cases the fingers are unencumbered, and the patient may be able to occupy himself or herself in some handiwork, such occupation serving to make more bearable a life of virtual imprisonment. *Weather* has its influences; diet rarely. The condition is singularly free from complications of all kinds.

## 2. THE PARTIAL OR MONARTHROTIC FORM.

This affects men more frequently than women, and of these, elderly men. The hip-joint is a frequent site, constituting the *morbus coxæ*, or chronic rheumatic arthritis of Adams, whose studies of this subject have added so much to our knowledge of the morbid anatomy. The other joints affected are the knee, the shoulder, and the vertebral articulations. It is often traced, rightly or wrongly, to injury. It is not always unassociated with disease in other joints, as there may be Heberden's nodosities, or the disease may involve in a less degree the corresponding joint on the other side. *Wasting* of the muscles of the buttock and thigh is a conspicuous associated symptom. The *knee-jerk* is commonly increased on the affected side. An interesting, though unusual, symptom, when the hip is affected, is the presence of a large *cyst* at some distance from the joint, ascribed by W. Marrant Baker<sup>1</sup> to an outflow of the serum from an overfilled joint to a point at which it is restrained by the muscular and other tissues of the part.

This form may occur in children, in whom it has been especially described by Still and is characterized by bony thickening and lipping about the joints as in adults.

**Diagnosis.**—This is rarely difficult. Arthritis deformans differs widely from *gout* in the total absence of tophaceous deposits, and from *acute rheumatism* in the absence of fever, though in the incipency of the progressive multi-articular form there is a certain resemblance to *acute*

<sup>1</sup> "St. Bartholomew's Hospital Reports," xiii, 1877; xxi, 1885.

rheumatism, while in the more advanced stage, a stage in which the joint lesions are conspicuous, it resembles also *chronic* articular rheumatism. This will be appreciated when it is remembered that some regard it as only a further development of chronic rheumatism. The lapse of time may be necessary to determine which it is. The atrophied shoulder of *omoneuritis* also somewhat resembles the monarticular form, but the greater tenderness and painfulness, as well as acuteness, of this affection distinguish it. The arthropathies attending *locomotor ataxia* and *syringomyelia* are distinguished by the symptoms peculiar to them and by the absence of osteophytes.

**Treatment.**—This is not generally promising, and the usual remedies for rheumatism are of little avail. Yet treatment is by no means unavailing, especially if instituted early, and we may always hold out to the patient the hope of arrest at some stage. The principle of treatment consists in efforts to *improve nutrition* by means of good food and tonics, of which cod-liver oil, iron, iodine, and arsenic are the most efficient. A systematic course of these remedies, continuous, except so far as judicious intermission may be necessary, will sometimes accomplish surprising results if instituted early and continued perseveringly. The iodid, either in the form of the pill or syrup, is the best preparation of iron. A grain (0.066 gm.) of the former and 15 minims (1 c.c.) of the latter are suitable doses three times a day. Massage is, perhaps, the single measure calculated to be of most use, and if cod-liver oil and iron be used in connection with it, further benefit may be expected. Disappointing as the treatment often is, in a few cases surprising results may be obtained. One of the most serious drawbacks in certain cases is the difficulty in securing outdoor life and the advantage of exercise. One of the objects of massage must be to substitute the latter, while every possible effort should be made to have the patient in the open air as much as possible, and when his means will permit it, to take advantage of residence in warm but dry climates. It is very important to avoid the use of anodynes altogether, if possible. The relief afforded by them is but temporary, they militate against the effort at securing an improved nutrition, and, above all, there is danger of forming the morphin habit. Simple support by splints is sometimes a comfort to patients. The treatment by *hydrotherapy*, as carried out at Aix-les-Bains and Aix-la-Chapelle in Europe undoubtedly affords temporary relief. The same may be said of the treatment at the Hot Springs of Arkansas, Virginia, and North Carolina in this country, and at St. Catharine's in Canada. While general steam baths are contraindicated by reason of their debilitating effect, local vapor baths applied to separate limbs or portions of limbs by a specially constructed apparatus are sometimes useful. Some mention should be made of the electric bath. Like so many remedies, it is often of service at first, but I have yet to see any permanent good results follow its use. It may, however, be tried in cases which have resisted other treatment. The bath should be given under intelligent supervision and the current should be weak at first.

Much was expected first from the hot dry-air or Tallerman-Sheffield treatment of this disease. Temporarily it does produce relief of pain,

but I have been unable to learn that any permanent benefit has been secured.

The bowels should receive close attention, the body should be frequently bathed, preferably in warm water, and all measures desirable to secure the most perfect personal hygiene should be practiced. This is another of the few diseases where an abundance of good, nourishing food is necessary. This is the more important when we remember that many cases originate among the poor and badly fed. The use of wine, porter, stout, and ale should be encouraged.

Having a highly intelligent friend afflicted for many years with rheumatoid arthritis whose circumstances permitted him to seek every available means of relief, I asked him to give me the benefit of his experience. He replied in a letter so sensible, and which appeared to me to contain the truth so well condensed, that I append it with the belief that it will be useful.

"I received no benefit at any of the following places: Aix-les-Bains,\* Bourbonne, Royat, Wiesbaden, Homburg,\* Carlsbad,\* Gastein,\* Wiltbad,\* Acqui,\* Montesumano, Richfield (N. Y.), Green Sulphur (Fla.). In all the places marked with an \* there were people to all appearances affected similarly to myself who did receive benefit, and at the same time there were others also so afflicted who were made worse. In short, I am convinced from my experience that no physician can definitely settle what spring will be of the greatest service to any patient, and that the only chance of finding this out will be for him to select those which he thinks will be of the most service and let the patient try them in turn. In this way the patient will perhaps find one which will either materially alleviate or absolutely cure him. I found that the mud baths of Battaglia, Italy, did me the most good, but they, at the same time, nearly cost me my life. I am also convinced that rheumatoid arthritis cannot be successfully treated by giving the same remedies to different people suffering from it. There must be variations in our general make-up as there are in our features. In my judgment, therefore, each patient must be a law to himself. He must find out for himself by judicious experiments the food and drink that he can best assimilate, and confine himself to them, even if the usual practice would indicate that they ought to injure him. I also think that no patient ought to take any hot baths anywhere without ample nourishment of some kind, for a depleted diet and terrific perspiration have done me great harm, for it was like 'burning my candle at both ends.' My experience has convinced me that careful attention to diet, outdoor exercise, freedom from anxiety, and good digestion are much more serviceable than any springs in the world."

## GOUT.

SYNONYM.—*Podagra*.

**Definition.**—An acute and chronic constitutional affection, due to an abnormal accumulation of uric acid in the blood and tissues, causing various symptoms, of which arthritis is the most distinctive and significant.

**Historical.**—With the exception of the classic work of Thomas Sydenham, "*Tractatus de podagrâ et hydrope*," published in 1683, and based upon his own case, he having been himself a victim for 40 years,—the history of our knowledge of gout is the history of the development of its pathology, which begins with Wollaston's discovery in 1797 that the deposits in the joints and vicinity in this disease are largely composed of uric acid. Previous to this time a humoral view of the nature of gout was accepted, though without tangible foundation. In 1784 Cullen promulgated the nervous theory of gout which was adopted from G. E. Stahl. Cullen's theory did not entirely exclude the humoralistic, since he allowed that a morbid substance appeared in the blood of some gouty persons after a time, but as the effect of the disease rather than as its cause. (See also Pathology.)

**Etiology.**—The tendency to gout is more frequently inherited, but is also acquired. Between 50 and 60 per cent. of all cases of gout can be traced to ancestry, parents or grandparents. More men are gouty than women, and it is the male line through which the tendency is most frequently transmitted. It is not usually manifested until after 40 years of age, sometimes later, but the signs which are almost sure to eventuate in gout may show themselves before the 12th year. While over-eating, especially of meats, and intemperate drinking, associated with the luxurious habits which grow out of the possession of wealth, are the most frequent causes of acquired gout, these last are by no means essential. Sir Dyce Duckworth's studies of gout in what is probably the richest field in the world, London, go to show that many of the peasantry of Ireland, among whom gout is unknown, became gouty after having lived for a time in London. This may be due to free indulgence in malt liquors. Such gout is often spoken of as poor man's gout. Not every person who inherits a tendency to gout becomes gouty, since the fostering causes previously mentioned may be wanting. In others this tendency is so great as not even to require the favoring condition. Negroes are not exempt, and Osler reports three out of 59 cases admitted to Johns Hopkins Hospital, up to April 1, 1905.

While alcohol is an acknowledged cause of gout, it has been observed that something depends on the shape in which it is presented. Malt liquors, especially the "heavy" English ales and beers, strong in alcohol, are more active in the production of gout than the lighter beers consumed in Germany and this country where gout is less common. Strümpell believes, however, that gout is more common in Germany and especially in Bavaria than is commonly supposed. The strong and sweet wines, of which port and sherry are the type, are strongly predisposing, while pure whisky is less harmful. The glycogenic substances in the malts and sweet wines are probably responsible as sources of acid fermentation products in the stomach, which, after absorption, reduce the alkalinity of the blood and impair its solvent power over uric acid.

An interesting cause of gout is lead-poisoning. This is seen particularly in England and especially in London, as pointed out by Sir Alfred Garrod in 1854. It is, however, rare in other parts of Great Britain and Ireland, and is growing more infrequent in London; for in 1870, according to Garrod, 33 per cent. of people who suffered from gout had been poisoned by lead, while Sir Dyce Duckworth, up to 1890, found only 18 per cent. in hospital cases. It is a rare cause also in France and Germany. It may be, as suggested by Alexander Haig, that the effect of plumbism is to diminish the alkalinity of the blood and thus its solvent power

for uric acid which is consequently precipitated. In this country the combination is comparatively rare.

Injuries and blows on susceptible parts, and so slight a cause as pressure by a boot, are often predisposing causes. On the other hand, worry or shock may be exciting causes.

**Pathogeny.**—It is the habit at the present day to speak of gout as a result of faulty metabolism; and that this faulty metabolism results in an accumulation of uric acid in the blood and tissues. The fact that views as to the origin and formation of uric acid have changed does not affect its relation to gout. It may, however, be worth while to state briefly what these modern views are. According to them, uric acid is not, as was formerly supposed, an earlier stage in proteid oxidation of which urea is the end-product, but is derived from the nucleins of the ingested food and of the body cells, especially leukocytes. The production takes place in all organs of the body, but especially in those rich in nuclei, viz., the spleen and lymphatic glands. Alongside of uric acid are formed also the so-called xanthin or purin bases, including xanthin, hypoxanthin or sarcin, episarcin and others; these represent earlier stages of oxidation. The more active the oxidation the larger the proportion of uric acid and the less the xanthins. The xanthins are toxic, uric acid nontoxic but locally irritant. Since uric acid is largely derived from the food ingested, it is therefore influenced, by such foods, whence it is plain the new views affect the treatment of gout rather than its pathology. Whether, however, the uric acid thus responsible is the result of increased formation or diminished excretion, or both, is not well settled. As early as 1797, Wollaston showed that the deposits in the joints and vicinity were a compound of uric acid. About 1838 Sir Henry Holland suggested that the peccant material was uric acid in the blood. This was, indeed, suspected by others, but it was not until 1848 that Sir Alfred Garrod furnished the first demonstrative evidence of such accumulation by his well-known thread test.<sup>1</sup>

Alexander Haig<sup>2</sup> claims that there is "almost never" an excessive formation of uric acid at any time, and that its accumulation in the blood and body is generally due to retention or failure of excretion; that uric acid is, on the whole, continuously formed in the proportion of 1 to 33 of urea. In certain states of the blood, consisting essentially in increased alkalinity, uric acid is held in solution in larger quantity, constituting uricacidemia. At such times, too, it is eliminated in increased quantity in the urine, by which it is also readily held in solution because of the alkalinity of this secretion. In opposite states of the blood the uric acid is driven out of this fluid and deposited in the tissues of the joints. Haig holds, also, that these opposite conditions, which are fluctuations in secretion only, can be artificially produced by drugs, food, temperature, and other conditions influencing the reaction of the blood. Thus, alkalies, alkaline foods, and warm weather favor the former—*i. e.*, solution—while acids and cold weather favor precipitation, and it is under influences

<sup>1</sup> This is done as follows: To two drams (8 gm.) of serum from a blister add five or six minims (0.33 to 0.390 gm.) of acetic acid in a watch-glass. A thread immersed in this will in a few hours show an incrustation of uric acid. This reaction is not confined to gout. It occurs in chlorosis and leukemia.

<sup>2</sup> "Uric Acid as a Factor in the Causation of Disease," by Alexander Haig, London, 1892.

like these that uric acid in the form of urates is stored up in the body. He further says that the blood never becomes loaded with uric acid except as the result of previous imperfect excretion, and such imperfect excretion or retention is sufficient to account for the largest quantities he has ever seen in the human body, and that it is not necessary to suppose excessive formation in explanation. Further, that he does not assert that such formation never occurs, only that he has never met any conclusive proof of its occurrence, while all the phenomena of disease can be explained without presupposing the excessive formation of a single grain.

The ultimate result is, however, the same. Whether it be from diminished excretion or increased formation, or both, there is an accumulation of uric acid in the blood which is responsible, first, for certain premonitory symptoms of gout, and, second, for certain local symptoms. The latter are of an inflammatory nature, and consist essentially of pain, swelling, and redness of the joints, preferably of the smaller ones, and especially of the metatarsophalangeal articulation of the great toe: more frequently, perhaps, of the left great toe.

As to the relation of the uric acid compounds to the local inflammation, it is scarcely necessary to say that uric acid does not exist in the blood in an uncombined state, even in pathological conditions. The normal urates, as originally shown by Bence Jones, and confirmed by Sir William Roberts, are quadriurates. Such is the composition of the urate sediments in urine. In the pathological state these are converted into the less soluble biurates, which make up the local deposits. It has all along been considered that these deposits are the direct cause of the gouty inflammations. Haig, as the result of his recent researches, reasserts this view in the following graphic language:<sup>1</sup>

"Then I also noticed that in curing a headache by giving an acid to diminish the excretion of uric acid, I always produced a certain amount of pricking and shooting pain in my joints (generally in those which had been most used on the day in question), and it naturally occurred to me that the uric acid was held back in these joints and produced the pains. The uric acid which had failed to appear in the urine must have gone somewhere. What more natural than to suppose that it had been retained in the joints (where in gout it is found), and that the pricking pains were the evidence of its presence? Then, on turning to Sir Alfred Garrod, I find that he had described precisely similar joint pains as occurring in gouty subjects immediately after the ingestion of beer or wine, and a very little investigation sufficed to prove that all wines and beers are strongly acid, so that a very simple explanation could be given of the facts."

E. Pfeiffer holds that both gout and gravel arise from the fact that in these conditions uric acid is produced and excreted in a form difficult of solution. He believes, too, that such patients excrete on an average less uric acid, that the blood becomes overcharged with it and the uric acid salts are deposited in different parts of the body unnoticed and without symptoms of irritation. The attacks of gout occur when from any cause the alkalinity of the blood becomes so great as to dissolve the deposited urates, which then give rise to irritation and inflammation. According to this view,

<sup>1</sup> *Op. cit.*, p. 2.

not the precipitated uric acid, but the dissolved uric acid must be regarded as the irritating agent, an acute attack being the result of a re-resolution in the blood of previously deposited uric acid, while a deposit is the result of diminished alkalescence. Pfeiffer, in further support of this view, calls attention to the fact that the most recent chemical analyses by Lecorché, Ebstein, and himself show that the excretion of uric acid *during* an attack of gout is increased and not diminished, as taught by Garrod. Pfeiffer further cites in support of this view the fact that acids, especially salicylic, in large doses promptly relieve the pain in gout, while it is increased by the administration of alkalies.

The studies on this subject—by Sir William Roberts<sup>1</sup>—reaffirm the older view, that the “mechanical theory offers a natural and complete explanation. The crystalline urate precipitated in the cartilaginous and fibrous structures of the joints necessarily act as foreign bodies; they excite irritation, clog the lymph channels, exercise pressure on the tissue elements, and impede their nutritive operations. These effects sufficiently account for the inflammation, pain, and swelling which ensue, and explain the remoter degenerative changes which follow.” While admitting that old tophaceous deposits are not always painful, my experience is that of Sir William Roberts, and, I believe, of most clinicians, that coincident with a fresh deposit of sodium biurates there is always pain, while the salicylates or alkalies are, in my experience, the promptest means to relieve the pain of gout.

Of modern authorities Ebstein<sup>2</sup> is the most eminent, who ascribes the excess of uric acid in the blood to an abnormal *formation* of this substance in the body, in parts also which do not normally produce it, as bone-marrow and cartilage. The lymph and blood becoming surcharged, a balance is commonly restored by increased excretion or perhaps by decomposition of the uric acid. When, however, from any cause the lymph moves slowly, the so-called premonitory *symptoms of gout occur—viz., a “tired feeling,” vague pains, etc.* If an actual stasis occurs, the acute attack appears. This concentrated solution of uric acid acts like a chemical poison on certain tissues, giving rise to necrobiotic changes, and when these reach a certain stage, characterized by an acid reaction, the uric acid is deposited in them as sodium biurate. If this stage is not reached, the local symptoms disappear and the joints return to their natural state. So much of Ebstein’s view as makes a previously degenerated state of the tissues a necessary condition of the deposit of uric acid is commonly admitted by modern authorities, as represented by Ord, Sir Dyce Duckworth, and Van Noorden. The latter holds that the tissue change is due to a special ferment.

The nervous theory of gout promulgated by Cullen in 1873 was to the effect that it is a mixed neurohumoral rather than a purely neural disease. Of modern authors, Sir Dyce Duckworth has taken the most pains to elaborate and establish the theory that gout is a neurohumoral disease. The sum of his conclusions may be stated as follows:

The diseased states recognized as of undoubted gouty nature are

<sup>1</sup> “Uric Acid, Gravel, and Gout,” p. iii, 1892.

<sup>2</sup> “Beiträge zur Lehre von der Harnruhr-Diathese,” 1891.

primarily dependent on a functional disorder of the nervous system, and thus gout is a primary neurosis. This, like others, may be inherited or acquired, modified, or even repressed, and may be associated with other neuroses. A large part of the symptoms known as gouty is due to perverted relations of uric acid and sodium salts *caused by* the neurosis.

**Morbid Anatomy.**—As will be further evident in treating the symptomatology of gout, there is scarcely a tissue which may not be affected by it, but the morbid conditions which are more distinctive are, first, the characteristic inflamed great toe of acute gout—the true *podagra*. The angry, swollen, dark-red or mottled appearance of such a toe once seen is not forgotten. Similar though less striking changes are sometimes seen in the metacarpophalangeal articulation of the thumb.

The superficial changes in chronic gout are less distinctive, and are often not different from those of chronic rheumatism. But wherever uratic deposits are present in the tissues, there, by universal consent, is gout. They are found most often in joints and in the parts around them: first, the cartilages of the movable joints, then the ligaments, tendons, bursæ, and, finally, the connective tissue and skin, this being the order of feebleness in vascularity and nutritive activity. Frequent situations are the digital joints and cartilages of the ear; more rarely the cartilages of the nose, the vocal cords, the cornea, kidneys, marrow of bone, and expectoration. Cartilages impregnated with urates present the appearance of being smeared with whitewash or white paint, and when preserved in pure alcohol, maintain it for a long time. Minutely examined, cartilages are infiltrated on the peripheral surface, more rarely beneath, with acicular crystals of sodium urate. Rarely they are found in the bone under the cartilage. The cartilage cells are for the most part free, and after the urates are dissolved out, the tissue appears natural or slightly granular. The tophaceous deposits are the best known and most characteristic lesion of gout. About the digital joints, especially the knuckles of the hands, they sometimes ulcerate through the skin, making the oft-repeated story of the gouty subject who chalked his games of whist with his knuckles a not unlikely one. The deposits are often associated with deflection of the fingers to the ulnar side—"seal-fin" type of hands—and of the toes outward, a late symptom not confined to gout—in fact, more common in rheumatoid arthritis. It is due to stronger action of the abductor muscles.

The nodular gouty tophi are not to be confounded with Heberden's nodosities, also characteristic of rheumatoid arthritis. Indeed, Heberden himself denied their gouty nature, though they do occur in gout also. Their significance must be determined by other symptoms more essential to gout. They are irritable nodular outgrowths on the distal ends of the phalangeal bones. They vary in prominence and tenderness at different times, being worse in gout, especially after errors of diet, but on the whole they slowly increase with the age of the patient and the persistence of other symptoms.

Of undoubted gouty nature are the little vesicles over the nodosities, called "crab's-eye" cysts. To these are to be added certain exostoses

and ecchondroses, or "lippings," beneath the synovial membrane, at the edges of the cartilages, and round the heads of the phalanges, and even of larger bones like the femur, patella, and tibia.

Changes in the *internal organs* are most often confined to the kidneys and vascular system. Uratic deposits have been referred to. They are not constant, and are found usually in the interlobular tissue toward the apices, but also more rarely in the tubules. Ultimately the gouty subject acquires an interstitial nephritis, the well-known gouty kidney; though the term "gouty kidney" has also been applied to kidneys the straight tubules of which are found filled with uratic sediments, as is the case sometimes at necropsy. Arterio-sclerosis is almost always present, and must now be ascribed to the irritative effect of the purin bodies, which include xanthen bases on the one hand and uric acid on the other. The heart is hypertrophied in its left ventricle. There may be deposits of urate of sodium on its valves. Changes in the lungs are mainly confined to emphysema, which is found in many cases of long standing.

**Symptoms.**—*Of Typical Acute Gout.*—Persons subject to attacks of gout sometimes have *premonitory symptoms* suggesting the approach of an attack. These vary with the individual and are significant only in each case. They may be headache, neuralgia, any one of the numerous manifestations of deranged digestion, irregularity of the heart's action, palpitation, high tension of the pulse, depression of spirits, drowsiness, a disposition to yawn, a tired feeling—in fact, any symptom which the patient learns to associate with the attack. Attacks are apparently also invited or determined by anything which lowers the vitality of the patient. On the other hand, a supper with wine or a single glass of champagne will often produce an attack.

The first actual symptom of the typical attack is *articular pain*, commonly in the great toe, at the metacarpophalangeal joint, and with its appearance the premonitory symptoms usually pass away. The pain is extremely severe, sharp, shooting, and sudden, often arousing in the middle of the night a patient who has gone to bed apparently well and least expecting an attack. With this pain are the *swelling, heat, and discoloration* already described under morbid anatomy. Rarely, the attack begins with a *slight chill*. On the other hand, there may be pain without heat, redness, or swelling, and all the typical local anatomical features of an attack without pain. In some instances the attack develops more slowly. At times the first attack is so little distinctive that it is assumed to be something much more trifling, such as rheumatism or some slight injury, while the personal peculiarities, natural or acquired, always more or less influence the symptoms. After the outburst at night the extreme pain diminishes as morning advances, but it may recur the next night, and this goes on for four, five, or six days, when the attack terminates.

Some *fever* usually accompanies the onset of acute gout. The temperature promptly rises to 100° F. (37.8° C.) and even higher, but does not far exceed it, 102° F. (38.9° C.) being the usual maximum attained. As in other acute diseases, the temperature is higher in the evening. The local temperature, notwithstanding the sensation of heat, is five or six

degrees below that of the axilla at the same time. The attack terminates with *desquamation* of the epidermis over the inflamed joint.

*Changes in the urine* are almost distinctive. It is scanty, acid, highly colored, and of high specific gravity. It deposits uric acid and urates on standing and cooling and often contains a small quantity of albumin. It sometimes contains sugar in small or even decided quantity, but I am certain that at other times the reaction of uric acid on copper oxid is mistaken for that of glucose. During or preceding an attack the uric acid excreted may be diminished; later it may be increased, but, as elsewhere stated, a relative increase in uric acid is often mistaken for an absolute increase in the 24 hours' amount. The probabilities are that these changes are inconstant.

Futcher has made some interesting studies as to the relations of uric acid and phosphoric acid excretion to the acute attacks. Both increased nearly *pari passu* after a low output before the attack and in its early part, but rose to normal limit shortly after the onset.

A recognized symptom of acute gout, and sometimes the only one, is *pharyngitis*, and now the term "gouty sore throat" is one in common use, though it is doubtless also often used carelessly. There seems no way of distinguishing it locally from other forms of sore throat in which there is no decided swelling.

Gout is said to be *retrocedent* or *metastatic* when it disappears suddenly from its external site and there are substituted for the outward symptoms derangements of some internal organ, especially the *heart* or *stomach* or *brain* or *urinary bladder*. In the first there appear cardiac symptoms of varying severity, including pain, shortness of breath, and irregularity in the heart's action; in the second, gastrointestinal pain, a sinking sensation, vomiting or diarrhea, often associated with intense mental excitement or depression; in the third, meningeal symptoms; and in the fourth, cystitis and prostatitis. More rare events are gouty orchitis, parotitis, and urticaria or other fugitive skin affections. Metastasis is more prone to occur in atonic cases. Sudden death has supervened in some instances, but postmortem lesions of a definite kind seem to be wanting, at least lesions which can be held responsible for the symptoms.

*Of Irregular or Atypical Gout.*—This includes a set of symptoms not so distinctive in themselves as peculiar in this, that they occur in persons who have had gout or who have a decided hereditary tendency thereto. These conditions being fulfilled, there is scarcely any superficial or visceral symptom which may not be of gouty origin, but among them may be named cutaneous eruptions, gastrointestinal disorders, various forms of headache and neuralgia, hot and itching palms and soles, especially at night, a similar condition of the eyeballs, lumbago and other muscular pains, cramps in the legs, arterio-capillary fibrosis and its consequences, iritis, bronchitis, pericarditis, cystitis with hemorrhage into the bladder, and others.

Some affections of the *teeth* occurring under the same conditions may be regarded as gouty. Such are the so-called *pyorrhæa alveolaris* and "dental erosion."

All that was said of the general physical and chemical characteristics of urine in acute and chronic gout may be true of it in irregular gout.

Among other organs the *eye* in its blood-vessels, retina and optic nerve falls heir to changes which are ascribable to gout, but the same law as to their necessary relation holds, by which I mean that identical conditions occur which are not due to gout, and the conclusion that they are thus related depends upon a definite knowledge of the previous existence of gout in the patient. An exception to this exists in the rare cases of actual uratic deposits in certain situations, as the cornea, the crystalline lens, vitreous humor, and even the retina.

Many conditions are called gouty on insufficient foundation.

FIG. 83.—Tophaceous Gout.

Both hands were symmetrically affected, man aged sixty (*after Duckworth.*)

*Of Chronic Gout.*—As repeated attacks of gout occur and the patient grows older, there gradually accumulate the morbid changes described under morbid anatomy as more or less characteristic—the joints deformed by tophaceous and other deposits, the lipping, the seal-fin hand, the renal and arteriovascular changes, interstitial nephritis, etc. The urine now is increased, lighter hued, and contains albumin and a few hyaline and granular casts.

Some further allusion should be made to the deformities thus resulting as symptoms of chronic gout. They appear especially in connection with the toes and fingers, causing swellings, deflections, and torsions which produce the most fantastic shapes. Among these are deflected and abducted toes. Heberden's nodosities, the seal-fin hand, and the deformities caused by tophaceous deposits. It is important to remember that any of these except the tophaceous deposits may be due to rheumatoid arthritis as well as gout. Bursal cysts or crabs' eyes on Heberden's nodosities are said to point to their gouty origin. The appended cut from Duckworth illustrates the appearance of enormous tophaceous deposits undoubtedly of gouty origin as contrasted with Heberden's nodosities.

**Diagnosis.**—Only two events point unmistakably to gout in an individual, viz., podagra or tophi in an affected joint. Gout prefers the distal, smaller joints, and one of these rather than many. Frequent recurrence in the same joint is characteristic of gout rather than articular rheumatism. The gastrointestinal symptoms of gout are in no way distinctive. Nor are the skin affections or interstitial nephritis or cardiovascular changes, as the same may arise from other causes. Yet if they occur in a person who has had podagra or tophaceous deposits they are probably due to gout. Gout and cardiovascular changes may result from the same cause. The presence of lead-poisoning, on the other hand, lends support to a diagnosis of gout. The continued presence of uric acid sediments in the urine also lend a support to the diagnosis of gout. On the other hand, after interstitial nephritis has set in the urine may be increased in quantity, of low specific gravity and light colored. Heberden's nodosities occur in gout or in rheumatoid arthritis alike, but the presence of crab's eye vesicles on them points to gout. A certain unexplained relation exists between gout, diabetes and obesity. All of these or any two of them occur rather frequently in the same individual; or they may alternate.

**Treatment.**—The treatment easily divides itself into two parts: *first*, that of the gouty diathesis; *second*, treatment of the paroxysm or of the acute attack.

*Treatment of the Gouty Diathesis.*—It is plain that we may diminish the quantity of uric acid in two ways: first, by confining the gouty person to such food as produces a minimum of uric acid; second, by administering such medicines as will promote its solution and elimination. The first of these constitutes, in the main, the *dietetic* treatment, the second the *medicinal*.

**I. The Dietetic Treatment.**—This is by far the most efficient of the treatment of gout, without which all else is only palliation. It consists essentially in the elimination, from the dietary, as far as possible, of all *nitrogenous or albuminous* principles, whence arises uric acid in the manner described on p. 860. I say as far as possible, for it is practically impossible to eliminate them altogether. The foods which are the type of this class should, however, be altogether omitted. Such are glandular organs like the liver and pancreas, which are rich in nuclein, the meats of the butcher-shops and the cheeses. The first include beef, veal, mutton, lamb, and pork, whether salt or fresh, and for the most part fish. As to cheese, as one-half pound of this contains almost as much nitrogenous matter as a pound of beef—27 per cent. when made of the whole milk, and 28 per cent. when made of skimmed milk—it is plainly contraindicated. If we consider only the edible parts of beef—*i. e.*, meat deprived of the refuse represented by bones, skin, etc.—it contains according to its source, from 17 to 23 per cent. of proteids; mutton, from 15 to 18 per cent. Of fish, flounder contains 13.8 per cent.; mackerel, 18 per cent.; halibut, 15 per cent.; and salmon, 21 per cent., or quite as much as beef and more than mutton. Salt codfish contains 15 per cent.; smoked herring, 20 per cent.; and canned sardines, 24 per cent. Poultry contains from 14 to 15 per cent. of albuminates, and game 22 per cent. The

hen's egg, including albumen and yolk, contains 13.7 per cent. of proteid, whence it is plain that it is a less objectionable food than meat.

On the other hand, milk contains but from 3 per cent. to 4 per cent. of protein; butter, 1 per cent.; and oleomargarine, 0.6 per cent. The fat oyster contains 8 per cent., the lean, 4.2 per cent., and the lobster, 5.5 per cent.; fish other than those previously mentioned, from 5 to 10 per cent.

Of vegetable foods, wheat bread contains 8.9 per cent. of protein; wheat flour, 11 per cent., and Graham flour, 11.7 per cent.; rye bread, 6.7 per cent.; buckwheat flour, the same; corn (maize), 9 per cent.; rice, 7.4 per cent.; sugar, 0.3 per cent.; potatoes, 2 per cent.; sweet potatoes, 1.5 per cent.; turnips and carrots, 1 per cent.; cabbage, 1.9 per cent.; melons, 1 per cent.; apples and pears, 0.4 per cent.; and bananas, 2 per cent. Again, beans contain 23.2 per cent. and oatmeal from 12 to 15 per cent., large proportions of proteids.

Thus, the typical foods permissible from the standpoint of composition are milk, butter, fruits, and succulent vegetables, except beans, and oatmeal. To these eggs, oysters and lobster may be added, moderately; fish, except that containing a large amount of protein, and, when extreme rigidity is not required, poultry in moderate amount; but all butcher's meat should be strictly forbidden.

It is usual, also, to indierdict the use of *carbohydrates*—*i. e.*, starches and sugars—as well as the *hydrocarbons*—fats and oils—but I have never been able to see any reason for this. There is absolutely none from the standpoint of chemical composition, since they are totally without nitrogen, and, so far as my own experience goes, none from the clinical standpoint. Only in the event of their producing indigestion and fermentation, with the generation of acids, can they become a cause of gout, and then only, I should say, an exciting cause. I am in the habit, therefore, of permitting the use of rice, potatoes, and other farinacea, and, to a reasonable extent, sugar. I am glad to be able to say that I am sustained in this view by Sir William Roberts, who, in the brochure quoted on page 860, says also: "The most trustworthy experiments indicate that fat, starch, and sugar have not the least direct influence on the production of uric acid, but as the free consumption of these articles naturally operates to restrict the intake of nitrogenous food, their use has indirectly the effect of diminishing the average production of uric acid." Basing his conclusions upon experiments with solutions of blood-serum impregnated with common salt (0.1 per cent.), in which he found the precipitation of crystalline biurate always appreciably hastened, Sir William Roberts directed the gouty to restrict, as far as possible, the use of common salt at meals. On the other hand, he recommends that the subjects of uric acid gravel should be advised to take habitually with their meals as much common salt as their palates will tolerate.

There are, however, other sorts of ingesta, also entirely or almost free from nitrogen, acknowledged to be both a predisposing and an exciting cause of gout—namely, *malt liquors* and *wines*. These are composed of water, alcohol, carbohydrates, and a trace of mineral matters, but no nitrogen. It is not easy at first to understand why these substances

should be harmful. Experience, however, shows that the stronger wines, such as port, Madeira, and sherry, by their continued use, are very likely to produce gout, while the lighter wines—the clarets, hocks, and Moselle wines—if taken in moderation, rarely produce it. After these, stout, porter, and the strong ales induce gout. Even lager beer, which contains but 3 per cent. of alcohol, is capable of acting similarly, and I know many men who have been forced to give up this beverage because of such effect. Cider and perry least of all beverages predispose to gout. On the other hand, distilled spirits, especially whisky, are almost entirely without effect in producing gout. Why is this? Apparently, the amount of alcohol is not the measure of the effect, for whisky, gin, brandy, and rum all contain more alcohol than any of the wines named. If an examination is made of wines most likely to produce gout, it will be found that they are those which contain a considerable quantity of both sugar and alcohol. Such are port, sherry, and Madeira, all of which contain more than 15 per cent. of alcohol and much sugar; also sweet champagnes containing 11 per cent. of alcohol. On the other hand, some very sweet wines, as Tokay, Malaga, and the higher Sauternes, which contain much sugar, are said to produce gout less rapidly. It would seem that those liquors which contain alcohol in combination with other substances, especially sugar, are potent in producing gout, particularly when they excite indigestion, *probably by restricting elimination* rather than producing more uric acid.

As to the *acidity* of alcoholic drinks, it is easy to understand how it may act as an exciting cause. In this way act beers, in which both alcohol and sugar are present in small amount, but which are highly acid. An explanation of this fact is less easy from the standpoint that the acute attack of gout is due to a reabsorption of the deposited uric acid by alkaline blood, than on the supposition that the attack is due to the irritative effect of uric acid deposited in the joints because of the diminished alkalinity of the blood resulting from absorbed acid. Whatever be the explanation, few facts in the clinical history of gout are better established than that the ingestion of acid may be an exciting cause of attacks.

In the same way act *acid fruits*, such as strawberries, acid oranges, and lemons. On the other hand, to such influence I have known the most divergent response. Thus, a gouty patient of my own could bring on an attack by drinking a single glass of lemonade, while a gouty friend would drink a pitcher of lemonade at dinner without any ill effect whatever. It is to be remembered that the otherwise harmful effects of the strong distilled spirits, such as are well borne in gout, are no less serious in gouty subjects than in others, and are often induced by the careless prescription of whisky because less harmful than wines in gout.

A most valuable adjuvant to the dietetic treatment are the *natural mineral waters*. The waters which have heretofore received almost universal approval are the alkaline and alkaline-saline waters, although those possessing purgative properties also enjoy a good reputation. In America, however, few alkaline waters are native, while those which are, are so far inferior to the foreign waters that they do not serve the purpose. On the other hand the costliness of the foreign waters constitutes a very serious

obstacle to their general use. Most of the native waters which have been employed and highly vaunted by their owners are of the kind known as negative waters—that is, they have no mineral ingredients in any quantity to justify their classification in any of the five principal varieties of mineral waters—viz., the alkaline, the saline, alkaline-saline, the purgative and sulphurous—or on which to base any therapeutic results except by their diluent effect. At the same time it has been noticed that these waters are not without effect in relieving gouty symptoms. Reasoning from these facts, we may prescribe such native negative waters as are accessible to the patient, or distilled water, with this end in view—the simple diluent and solvent effect which comes from an increased proportion of water ingested. The further propriety of such a course is found in the fact that gouty and lithemic patients are often moderate water-drinkers, never drinking water between meals and very little at meals. To such, eight ounces of water ordered on rising, between meals, and at bedtime, will often clear off a dark-hued urine of high specific gravity and substitute a light-hued, clear urine, without any sediment.

The mineral waters which have actually acquired the greatest reputation in the treatment of gout are those of which sodium bicarbonate is the chief ingredient, to which the calcium bicarbonate is regarded a valuable adjuvant. Such are the alkaline waters of Vals and Vichy in France, Evian-les-Bains in Switzerland, Neuenahr and Fachingen in Prussia, Contrexville and Vittel in the Vosges (France), and Dax in France. Other waters possessed of reputation in the treatment of gout, in which the quantity of alkaline bicarbonate is smaller, owe it to their combined alkaline and aperient properties, chiefly due to sodium sulphate and magnesium sulphate, and belong in the second category of remedies for the treatment of gout. Such are the alkaline and saline waters of Carlsbad and Marienbad in Bohemia, Kronthal in Nassau, and Brides-les-Bains in Savoy. Then there are the saline waters represented by Baden Baden, Ems, Homburg, Kissingen, Wiesbaden, and our own Saratoga waters. In saline waters we are much more fortunate in this country, the Saratoga waters furnishing all that can be desired. Finally, there are the bitter acidulated and bitter purgative waters—Hunyadi Janás, Friedrichshalle and Rakoczy in Hungary, Pülna in Bohemia, and Rubinat in Spain—rarely resorted to for gout, but useful as eliminating agents. Among the weaker aperient waters are those of Bedford Springs, Pa., in this country.

The use of these mineral waters is especially indicated in a continuous manner between the attacks, with a view to averting them. Especially useful are the thermal waters in the chronic arthritic complications, in which their internal use is combined with bathing. In this connection may be mentioned Carlsbad and Marienbad (at both of which the mud-baths are employed). Baden Baden, Ems, Wiesbaden, Hammon R'Irha in Algeria, available in winter, Plombières in the Vosges, and Dax in France. Homburg and Kissingen are also resorted to for their baths, although the waters are cold.

Sulphurous waters also have some reputation in gout. Especially is this the case with the waters of Aix-la-Chapelle in Rhenish Prussia and

Aix-les-Bains in Savoy, Harrogate in England, Richfield Springs, Sharon, and St. Catherine's in Canada and Mt. Clemens in Michigan, U. S. A. In all these places the bath treatment is an important adjuvant. America is also more fortunate in sulphur waters.

The remedies in the second category—the aperients—are decidedly useful in gout, both as eliminators of toxic substances, and to prepare the way for the absorption and prompt action of the alkaline bicarbonates. They are not, however, used at the present day so freely as they were a century ago, and they are commonly reserved for the acute attack.

*Hygienic measures* are also of importance in the treatment of gout. The patient should bathe daily, using the cool bath in the morning or the warm in the evening on retiring, as experience may determine to be the best. The skin should be thoroughly groomed, and daily exercise should be practiced, an open-air, outdoor life being desirable whenever possible.

II. *The Medicinal Treatment and the Treatment of the Acute Attack.*—As a rule, the use of medicines is reserved for the acute attack. From the earliest history of the disease practice has recognized two classes of remedies in the treatment of gout—alkalies and purgatives—the object of both being to eliminate the offender, the first by producing soluble combinations which pass off readily by the kidneys, and the second to carry it off by the bowels. It is plain that a combination of the two principles might be expected to be more efficient than either one alone.

First, as to alkalies and alkaline combinations. My experience places the salicylate of sodium easily at the top, and while it is not so rapid in its effect in relieving the pain of an acute attack of gout as it is in rheumatism, it is nevertheless an invaluable remedy, excelling all others. During an attack it should be given in doses as large as can be borne. As a rule, adult men easily bear 15 grains (1 gm.) four times a day, or 10 grains (0.65 gm.) may be administered every two hours. Even larger doses may be given with advantage, if borne by the stomach. With relief to the acute symptoms the dose should be reduced; but, as in rheumatism, the remedy should not be discontinued, and between attacks smaller doses should be kept up for some time. These, however, may be substituted by the natural mineral waters to be presently alluded to. The efficiency of the salicylates is explained by the fact that their prolonged internal use is attended with an increased elimination of uric acid.

After the salicylates, the alkaline carbonates have always held a high position in the treatment of gout. Half an ounce (15 gm.) of potassium bicarbonate a day in divided doses should be the initial treatment, continued, but in smaller doses, when relief comes to the acute symptoms. It may be combined with a little lemon-juice to improve the flavor, or the citrate of potassium may be given in the same doses.

Among the eliminating remedies is the time-honored colchicum, a drug which is of undoubted value in gout, but which, in my experience, must yield the palm to salicylate of sodium. For a long time its action was inexplicable, and it came to be known as a specific in gout as quinin is in chills and mercury in syphilis. Modern studies have, apparently,

solved this problem. Professor Rutherford has shown that it is one of the most powerful cholagogues known. This, taken in connection with what we now know of the office of the liver in urea formation, simplifies very much the solution of the problem. It explains, too, why colchicum produces its sedative and anesthetic effect without necessarily causing purgation. Indeed, some, as Sir Alfred Garrod, consider that its effects are best attained without purgation, and Garrod says that if cathartic action is required, it is better to combine some aperient with the colchicum, as when much purging and vomiting results from colchicum, nervous and vascular depression follows. I confess I like to see a mild action on the bowels by increasing the dose gradually, and it is not necessary to produce either violent purging or vomiting. Whatever its mode of action, it sometimes operates in the most magical manner in relieving pain. The preparation commonly used is the wine. In this country the wine of the seeds is no longer official, so that if the wine is ordered, that of the root is dispensed. This is more powerful than the wine of the seeds. The dose of the latter is from  $\frac{1}{2}$  to  $1\frac{1}{2}$  drams (2 to 6 c.c.) every three hours during the attack, but of the root from 15 to 30 minims (1 to 2 c.c.), reducing the dose when nausea or purgation ensues. The acetic extract of colchicum was a favorite preparation of the older physicians, especially Scudamore, who introduced it, and who considered its action milder than that of any other form. It is still sometimes used, and has the advantage that it may be put into pill form. Its dose is from 1 to 2 grains (0.065 to 0.13 gm.). Scudamore's gout remedy consisted of magnesium sulphate, 4 drams (15 gm.); magnesia, 80 grains (5 gm.); vinegar of colchicum, 4 fluidrams (15 c.c.); syrup of crocus, 4 fluidrams (15 c.c.); mint water, 5 fluidounces (150 c.c.). From one to three tablespoonfuls are given every two hours until from four to six evacuations are produced in 24 hours. The fluid extract of colchicum may be administered in doses of from 2 to 6 minims (0.12 to 0.30 c.c.).

Colchicin, the active principle of colchicum, is also employed. Its dose is  $\frac{1}{50}$  grain (0.0013 gm.). The same dose may be employed hypodermically. A favorite modern remedy is the salicylate of colchicin in doses of 5 minims (0.31 c.c.), given in pearls or capsules. The other aperients commonly used in gout are the sulphates, of which magnesium sulphate is the favorite. Sodium sulphate is also used, and it is the constituent of the most actively purgative mineral waters already mentioned, viz., the Hunyadi János, Rakoczy, and Friedrichshalle, now largely used instead of the pure salt. It is also the largest constituent of the Carlsbad waters. A favorite combination of the older physicians was magnesium sulphate 2 drams, magnesium carbonate a scruple suspended in an ounce of cinnamon water, given two or three times a day until active purgation resulted. These two substances may be combined with colchicum, and with it make one of the forms of Scudamore's mixture, alluded to. Another of the older remedies, also purgative, should not be lost sight of. It is Warner's gout cordial, essentially the tincture of rhubarb and senna of the pharmacopœia of the present day.

Colocynth is also employed as an aperient in gout, and advantage has been taken of this fact in the preparation of the secret remedy known

as Laville's tincture, which is very largely used by the laity, and which undoubtedly has a very prompt effect in many cases of acute gout. The following has been published<sup>1</sup> as the composition of Laville's remedy, as determined by analysis:

Quinin . . . . .	5	parts.
Cinchonin . . . . .	5.	parts.
Colocynthin . . . . .	2.5	parts.
Lime salts . . . . .	5.	parts.
Water . . . . .	82.5	parts.
Alcohol . . . . .	100	parts.
Port wine . . . . .	800	parts.

The lithium compounds—the carbonate and citrate—have not proved so useful as to cause me to prefer them to salicylic acid. Indeed, the early results of Garrod with them cannot be said to have been realized in modern therapeutics. Sir Dyce Duckworth says of lithia that it is a remedy better adapted to the chronic than to the acute phases of gout, and so I have been using it. Five grains (0.3 gm.) four times a day, freely diluted, is the dose usually administered, and with this the potassium salts are sometimes combined.

Another modern remedy asserted to be efficient in the treatment of gout is *piperazin*. I regret to say that I have been disappointed in it. In my early trials I thought it useful, but soon learned that it was less efficient than the salicylates and colchicum. While an acknowledged solvent for uric acid when dissolved in water, it seems to be incapable of dissolving uric acid in the system. It still has some staunch adherents, and may be tried. From 15 to 30 grains (1 to 2 gm.) daily are advised, dissolved in water or in some one of the numerous mineral waters.

*Local Applications.*—For the relief of the acute attack of gout, leeches, blisters, and cold have all been discontinued of late years, not only because they are useless, but also because their use has been followed by fatal attacks of the so-called internal gout. Warmth and moisture do, however, have a mollifying effect, which is increased if the liquid preparations of opium be associated. Cocain, which might be expected to be useful, operates only through surfaces whence the epiderm is removed. Should such be present, a five per cent. solution may be applied on lint.

It often happens that the pain in a paroxysm of gout is so severe that it is impossible to wait until the effect of the foregoing remedies is secured, and a hypodermic injection of morphin is absolutely necessary to relieve the sufferings of the patient. I must remind the reader, however, that as many old subjects of gout have contracted kidneys, the use of morphin under these circumstances is attended with some danger, and the drug should be used with great caution.

All pressure by boots on joints disposed to gout should be carefully avoided, as well as injuries, as such influences undoubtedly act as predisposing causes. Muscular and mental fatigue are exciting causes of acute attacks, and should be avoided by the gouty.

*Treatment of Retrocedent Gout.*—The true nature of a metastatic attack having been determined, it must be relieved symptomatically, while efforts to stimulate a true external attack may be made by the

<sup>1</sup> "Druggist's Circular," October, 1889.

hot mustard foot-baths, sinapisms, and the like. It has even been suggested that a pint of champagne may be advised, this being the wine most frequently responsible for acute attacks.

### LITHEMIA.

SYNONYMS.—*Uricacidemia; Uricemia; American Gout.*

**Definition.**—A condition of imperfectly determined anatomical and chemical nature, but probably the result of an accumulation in the blood of products of defective metabolism or food metamorphosis, of which uric acid is the type. It differs from gout chiefly in the absence of joint deposits and joint inflammation. In England the name of Murchison is inseparably associated with lithemia, and in this country that of J. M. Da Costa. The former ascribed the accumulation to inactivity of the liver. It has been called American gout, because it has been thought to take in this country the place that gout occupies in England.

**Etiology.**—The accumulation referred to is the result of intemperate eating and drinking, especially with the lack of exercise sufficient to oxidize the food ingested. In either event the income is greater than the output, accumulation results, and morbid phenomena follow. Heredity also plays a part at times.

**Symptoms.**—Among symptoms tolerably constant are manifestations of *indigestion*, including fullness and discomfort after meals, an unpleasant taste, at times nausea, and at others acidity; a tendency to constipation and absence of bile from the discharges; also a tendency to aphthous ulcers in the cheeks and lips, with punctiform ulcers on the end and sides of the tongue. Extreme *nervous irritability* is also often associated or may be the most striking symptom, while *vertigo* and *headache* are among the most conspicuous and annoying. While vertigo is often associated with a fullness and throbbing, the vertigo and severe headache are rarely associated. A further characteristic is the *slow pulse*, which may beat at the rate of but 50 or 60 times a minute and even less, and exhibits a correspondingly increased tension, with sharp accentuation of the aortic second sound. On the other hand, if the patient be an alcoholic or addicted to tobacco, the first sound of the heart may be feeble. Curious *paresthesias* are also often present, of which *tingling* and a *sense of numbness* are conspicuous. There may be *anesthesia*. In contrast to this *muscular pain*, shooting or aching may occur anywhere in the body. Last, but by no means least, is *depression of spirits*, most inveterate and unpleasant, the patient imagining he is the subject of every known disease, while suicide is sometimes sought for relief.

There is almost invariably *alteration* in the *quality* and *quantity* of the *urine*. It is *scanty*, *highly colored*, of *high specific gravity*, depositing on standing, especially at a slightly lower temperature, a large bulky sediment composed of mixed urates or uric acid or both. In this sediment also are sometimes included oxalate of lime crystals. Yet, though almost invariably present, this state of the urine cannot be regarded as essential, and cases occur with the *tout ensemble* of symptoms while the

urine is in a natural condition. There may be slight enlargement of the liver and the symptoms enumerated are sometimes regarded as the early signs of cirrhosis of the liver.

**Diagnosis.**—This hinges very largely upon the condition of the urine, as described, and upon the habits of the patient. It has already been stated that lithemia differs from *gout* in the absence of joint symptoms, but it cannot be denied that the two conditions often occur conjointly. Less frequently, if at all, is lithemia the result of heredity, and it demands as an essential condition the overeating and drinking with defective metabolism referred to, which, while exciting causes of gout, are by no means always necessary to its production, especially when there is a decided hereditary tendency to the same. As intimated in the definition, uricæmia is rather a condition inferred than actually demonstrated—inferred from the disproportionate amount of uric acid excreted as compared with urea.

**Prognosis.**—It may be said, too, of lithemia, as distinguished from irregular gout and from gout, that the prognosis is, on the whole, more favorable, and a cure may be generally promised the patient if he comply with the physician's instructions.

**Treatment.**—The indications are evident. The overeating and overdrinking must be reduced, and active outdoor exercise must be practiced in order to burn up the remnant of unoxidized food. The restriction which would be required depends somewhat upon the severity of the case, but in all instances may be covered by the injunction to the patient to become a vegetarian rather than carnivor. The juicy green vegetables, such as peas, beans, spinach, asparagus, cauliflower, celery, onions, cabbage, lettuce, and an abundance of milk, are allowed. The free use of water, preferably the alkaline mineral waters referred to in treating of gout, and the omission of all alcoholic drinks should be enjoined. A quart (a liter) of Vichy or Vals daily, or in their absence any one of the indifferent mineral waters, with the addition of lithium or sodium carbonate, should be drunk. When urgency is required, a diet of diluted milk or of milk and Vichy may be insisted upon until such symptoms pass away.

Of meats which may be permitted in moderate quantity along with vegetable food are oysters, fish, the white meat of chicken, and game. The question of the carbohydrates is a mooted one. I have never seen such food as rice and potatoes do harm, nor bread—if of good quality and not too freshly baked. Sugar is best restricted, because of its tendency to produce acid fermentations and acidity. There is no chemical contra-indication. Hydrocarbons, on the other hand, are not well borne, and all fats should be forbidden, including butter, as well as the fat of meat.

As to medicines, the most important are the alkalies, which may be added to the negative mineral waters if they are used instead of the more truly alkaline waters. Aperients, and of these again the salines, are especially indicated, and above all the natural mineral purgative waters, such as Saratogo waters in this country, Hunyadi, Friedrichshalle, and the like. Phosphate of sodium is a favorite aperient in these conditions on account of its supposed action upon the liver. The usual dose

is 1 dram (4 gm.) in the morning, on rising, dissolved in hot water. The lithium salts may be used, and while I have not been able to trace any very direct results to their action, they serve as an excuse for the administration of liquids, since they are usually given dissolved in water—say 5 grains (0.3 gm.) of the carbonate or citrate in a glass of water before meals. Pleasant effervescing tablets containing these doses are now made by many manufacturing chemists. The stomachics and bitter tonics, of which *nux vomica* and *strychnin* are the types, may form useful adjuvants, and pepsin with hydrochloric acid after meals is often useful. The salicylates, if well borne, are useful remedies, to hold in solution the uric acid and favor its elimination. Extremely painful attacks may require the use of opiates, but the doses should be as small as possible, and their use should be discouraged under all circumstances excepting in extreme urgency.

### DIABETES MELLITUS.

**Definition.**—A condition of deranged metabolism characterized by copious secretion of a urine charged with glucose and due to some as yet imperfectly understood derangement of the glycogenic and glyco-destructive functions of the organism.

**Historical.**—Diabetes is one of the oldest diseases known, being referred to by the Roman Celsus and the Greek Aretæus, both of whom lived in the first century of the Christian era; also by the early East Indian physicians as a condition characterized by copious secretion of urine, extreme thirst, and emaciation. Little, if anything, was, however, added to the subject until the latter part of the seventeenth century, when Thomas Willis (1622–75) in England first inferred from its sweetness the presence of sugar in the urine. Moreover, it was not until a century later, 1775, that Matthew Dobson, also an Englishman, actually obtained sugar from urine. Among other early students of this subject were Cowley (1788), Frank (1794), John Rollo (1797), W. Prout (1825) in England, and Bouchardat and Mialhe in France. Inseparably associated with the subject is Claude Bernard, who first discovered that glycosuria could be produced by puncturing the floor of the fourth ventricle. Since that time there is perhaps no subject in medicine to which has been contributed so much knowledge from an experimental side as this one, and yet no subject as to the true pathology and etiology of which we possess proportionately less accurate information.

Other names associated with the clinical and experimental investigation of diabetes are Brücke, Cantani, Dickinson, Pavy, Ebstein, Frerichs, Külz, Lécorché, von Mehring, Minkowski, Naunyn, Seegen, C. C. von Voiht, Senator, F. Voit, and Carl von Noorden.

**Geographical and Racial Distribution.**—Diabetes is not a common disease anywhere, and it is variously frequent in different countries and races. Thus it is less common in the United States than in Europe, where there are said to be from five to nine cases among 100,000 inhabitants, while according to the United States Census of 1900 there are but 2.8 in 100,000. According to Dickinson, the disease is more widely prevalent in the agricultural countries of England than in the cities. It is common in Sweden, on the one hand, and in southern Italy and India, especially in Ceylon, on the other, while especially rare statistically in Holland, Russia, and Brazil.

It is much more frequent among Hebrews than among Christians in the experience of almost everyone, yet for what reason I have been unable to discover. One of my Hebrew friends suggested that it is due to the

intensification of hereditation by intermarriage. It is rare in the negro race, though I have met several cases. It is a disease especially frequent among the rich and well-to-do, though the poor are not exempt. It is also a disease of adults, yet it has occurred in infants at the breast. In the reports of the Registrar-General of England for the years 1851-60, ten deaths are registered under the age of one year and 32 under the age of three. The youngest patient I ever had was a little girl aged 22 months, who was delivered prematurely because of nephritis in the mother, though the child was healthy up to one year. Albuminuria was associated with the diabetes. The disease is most frequent between the ages of 30 and 60. It is more serious in the young, recovery in very young subjects being almost unknown. It is much more frequent in males than in females, in the proportion of nearly three to one, though Senator's<sup>1</sup> statistics show that under the age of 20 more females are affected than males. This has been my own experience. Little is known of the effect of occupation, though it is thought that occupations taxing the mind favor it. It has happened to me to treat a number of physicians and farmers. Heredity has in my experience been less conspicuous than European writers find it. From ten to 25 per cent. are thus traced by different Continental observers. On the other hand, it may occur in several members of a family. It is not unusual to find diabetes mellitus in some members of a family and gout in others.

**Pathology and Pathogenesis.**—The etiology of diabetes is so intimately united with its pathology that it is scarcely possible to separate their consideration. What is known, therefore, of its immediate causation will be developed in connection with the pathology, while its more remote causes will be briefly considered in the ensuing paragraph. Inseparably connected, also, with the pathology of diabetes are the phenomena of sugar formation in the economy. A brief statement of the latter seems, therefore, justifiable. During life there is constantly being produced and stored in the liver of man and the lower animals an amyloid substance, which was named by its discoverer, Claude Bernard, *glycogen*.<sup>2</sup> Its formula is  $C_6, H_{10}, O_{15}$ , that of starch, and the term *zoamylin*, or animal starch, was at one time suggested for it. The glycogen formation takes place whether animal or vegetable food be taken, but it is much larger upon a vegetable diet. It is commonly held that it does not occur at all with a diet of pure fats, but Salomon<sup>3</sup> claims that it is produced in the livers of rabbits fed on olive oil. C. von Noorden also considers that fat is converted into sugar in the liver.<sup>4</sup> All physiologists agree that this amyloid substance is derived mainly from the starchy and saccharine principles of food, but partly also by a splitting up and rearrangement of the elements of nitrogenous food. This possibly takes place in the liver, resulting in the production of urea and glycogen, the latter being stored in the liver-cells. The muscles are also favorite reservoirs for glycogen storage. The most important property of glycogen is its ready

<sup>1</sup> See Senator's article on "Diabetes Mellitus" in "Ziemssen's Cyclopædia of Medicine," vol. xvi., p. 866, *ad fin*.

<sup>2</sup> Bernard, "Nov. Fonc. du Foie," Paris, 1853.

<sup>3</sup> "Virchow's Archiv," vol. lxi., part 3, 1874, 18.

<sup>4</sup> Article "Diabetes Mellitus," in "Twentieth Century Practice of Medicine," New York, vol. ii, p. 42, 1895.

convertibility at the temperature of the body into glucose, or grape-sugar; for this a glycolytic ferment is probably required. By means of these storage reservoirs the blood is kept supplied with 0.12 to 0.18 per cent. of grape sugar in health, the oxidation of which contributes to the forces of the economy.

In diabetes mellitus some derangement of this balance takes place, as the result of which more or less of the glucose delivered to the blood is not utilized, in a word, is wasted. This may be brought about in several ways: (1) It may be that the glucose arising by a reconversion of the glycogen stored in the liver is contributed to the blood too rapidly to be oxidized; (2) It may be that, although the glucose is delivered in normal quantity, it is still not consumed because of some defect in the oxidizing mechanism, some deficiency in the glycolytic ferment; (3) It may be that the glucose arising from sugar and starch digestion in the intestine is not first converted into glycogen as in health, but passes directly through that organ to the vena cava too rapidly or in too large quantity to be utilized, or lacking some molecular quality which permits its oxidation. One or the other of these alternates will explain all cases of glycosuria when the nonutilized glucose is derived only from the carbohydrates of the food. These are the milder cases and include also those of glycosuria clearly traceable to overingestion of sugars and starches. Those bad cases of diabetes, however, which Dr. Pavy calls "composite diabetes," in which the glucose arising from proteid foods, and finally even from proteid tissues, is not utilized, are less easy of explanation. For it would seem that not only is the glucose normally arising unconsumed, but that there is also an increased formation of glucose from these sources, and it may be even from the "fixed proteids" of the body. Whichever of these it is, the excess of sugar thus resulting in the blood is eliminated by the kidneys, and thus glycosuria becomes an essential symptom of diabetes mellitus.

**Etiology.**—What causes this deranged mechanism? I have already said that there is no disease concerning which so much accurate knowledge has been arrived at and of the true pathology of which we are so thoroughly in the dark. It is not a kidney disease, as was once supposed in its early history, although this impression still prevails among the laity, and naturally so, because the essential evidence of its existence is found in the urine. We know, further, that diabetes occurs under very different circumstances. We can produce diabetes in an animal by irritating the floor of the fourth ventricle, as was originally done by Claude Bernard in his celebrated *piqûre* experiment. There are, however, also other parts of the nervous system, the irritation of which will produce diabetes, from the cerebellum down to the point of emergence of the sympathetic nerves to the viscera. It is commonly admitted that this experimental glycosuria is caused by a centrifugal stimulus from the nervous centers to the liver, through the vasomotor system. We know, also, that tumors impinging on the floor of the fourth ventricle, and lesions of this part of the brain, including abscesses, are attended by diabetes mellitus; also injuries to the spinal cord.

Relatively remote from the nervous centers is an organ, the pancreas, the diseases of which are often associated with diabetes mellitus, and

whose extirpation is followed by glycosuria. On the other hand, we know that in a large number of the gravest forms of diabetes autopsies have failed to disclose any lesion whatever; in fact, the most unmanageable and serious cases are those in which we find no lesion. Therefore, while we must admit that both the nervous system and the pancreas have something to do with the causation of diabetes, we are not able to trace a nervous or pancreatic lesion in every case. It is further likely that the sympathetic nerve is an important channel for nervous influence, regulating as it does the opening and the closing of the blood-vessels.

A word more as to the relation of the pancreas to diabetes. I have said such relation is proved from the experimental as well as from the clinical side, and I myself, in a few cases at autopsies, have found a pancreatic lesion. Hansemann claims pancreatic lesions in 50 per cent. of cases. From the experimental side it is found by von Mehring and Minkowski that extirpation of the pancreas is immediately followed by diabetes; and, although there are some differences in results, it is one of the best determined facts that glycosuria follows such extirpation. Sometimes such a diabetes has been transient, but then it has been found also that a fragment of the pancreas was left behind. I repeat that while we must admit that the pancreas has something to do with a large number of cases of diabetes, we cannot say so of all, as there are some in which no lesion is found.

The rationale of this relation of the pancreas is not settled. It has been alleged that the absence of the pancreatic secretion is responsible, but it has been shown that simply cutting off the secretion from the intestine does not cause diabetes. It has been suggested that extirpation of the pancreas really operates by disturbing the sympathetic nerves in the vicinity; but this has also been experimentally refuted, and, with this, the view of Klebs, accepted by Senator, that the coexistence of diabetes mellitus and disease of the pancreas is primarily or secondarily due to lesions of the celiac plexus. The researches of Lepine, which have been confirmed, ascribe the glycosuria to the absence of a glycolytic ferment furnished in health by the pancreas to the blood. This explanation certainly accounts for the facts. It is evident that it is impossible to explain all cases of diabetes from any one standpoint to the exclusion of another.

An important relation has recently been established between the suprarenal gland and glycosuria, by the studies of Blum,<sup>1</sup> Herter, and Croftan. The first showed that glycosuria ensued upon subcutaneous injection of animals with freshly prepared suprarenal extract, even when the diet was free of carbohydrates. This was confirmed by G. Suelzer<sup>2</sup> and A. C. Croftan.<sup>3</sup> Reasoning thence Croftan announced that the suprarenal capsules contain a substance which either causes the formation of sugar or inhibits the normal destruction of sugar.

Herter<sup>4</sup> does not accept Croftan's conclusion, but concludes rather

<sup>1</sup> "Ueber Nebennieren Diabetes," *Archiv f. klin. Med.*, 1901, Bd. lxxi., Heft 2 u. 3, S. 146.

<sup>2</sup> "Zur Frage der Nebennieren Diabetes," *Berlin. klin. Wochenschrift*, 1901, No. 48, S. 1209.

<sup>3</sup> "Concerning a Sugar-forming Ferment in Suprarenal Extract," *American Medicine*, January 18,

1902.

<sup>4</sup> With A. N. Richards, "Preliminary Communication," *Med. News*, February 1, 1902. Also "Experimental Glycosuria from Adrenalin Chlorid and its Relations to other Forms of Glycosuria, Dependent on the Action of Reducing Substances on the Cells of the Pancreas," *Trans. Assoc. Amer. Physicians*, 1902.

that many and perhaps most forms of glycosuria and diabetes are due to the action of substances or conditions which interfere with normal oxidation in the cells of the pancreas. He adduces in proof, the fact shown by himself that glycosuria results from subcutaneous injection of adrenalin chlorid, and moreover that painting the pancreas with the same solution is followed by a transitory glycosuria with corresponding glycemia, while no such effect follows a similar application to the liver or spleen; while after adrenalin chlorid undergoes oxidation it loses its ability, when thus applied, to cause glycosuria. Thus is laid at the door of the suprarenal capsule interference with the cell activities in the pancreas which are concerned with the production of an oxidizing enzyme whose function it is to oxidize glucose. Closer than this we have been unable to come. Deranged suprarenal function is of course not the only cause which interferes with the normal function of the pancreas.

Any agency, direct or reflected, which is capable of influencing normal cell activity of the pancreas may become a cause of diabetes. Hence a variety of causes, some of which seem but remotely connected with the disease, may operate to cause diabetes. In illustration of traumatic agency by which the pancreas is indirectly affected I may refer to cases of movable kidney causing pancreatic diabetes, cured by nephropexy reported by Sherman Thompson Brown.<sup>1</sup> As instances of such influence may be mentioned the rare instances of diabetes associated with pregnancy. Operating through the nervous system, in addition to nervous lesions already named, may be worry, gastro-intestinal derangements, disorders of the liver, sexual excesses and the like. Among more remote causes recently suggested are toxic agencies introduced from without or originating in the alimentary canal, which may explain cases otherwise unaccountable.

**Morbid Anatomy.**—Diabetes can hardly be said to have an essential morbid anatomy, for, except in the instances mentioned, the morbid lesions which are found at postmortem examination are mostly the consequences of the continued glycemia rather than such as cause the symptoms. Sometimes there are absolutely no alterations discoverable, either by the unaided eye or with the microscope.

To begin with the organ which has so much to do with the glycogenic function of the body—the liver—it frequently presents the appearances of a hyperemic organ—that is, it is darker and harder than the normal organ, while it is also enlarged, sometimes considerably, at other times only slightly. Corresponding to this, the microscope, by very moderate amplification, shows enlarged and distinct acini, with capillaries dilated and distended in various degree with blood. Higher magnifying powers—300 to 400 diameters—show the liver-cells to be enlarged, distinctly nucleated, rounded, and disposed to fuse. If a weak solution of iodine is added, they may strike a wine-red color, which, according to Rindfleisch, is confined to the nucleus; but, according to Senator, may extend to the whole of the cell. Klebs ascribes this reaction to postmortem changes in the glycogenic substance. The minute changes described are said by Rindfleisch to be more striking in the peripheral zone of the lobule than in that of the portal vein, while the intermediate zone, or that of the hepatic

<sup>1</sup> "Philadelphia Medical Journal," April 4, 1902.

artery, is fatty, and the central part, including the rootlets of the hepatic vein, is nearly normal. Incidental morbid states hypertrophic cirrhosis and atrophic cirrhosis. An interesting fact in this connection is that the most serious organic disease of the liver appears never to cause glycosuria.

As to the *pancreas*, about which so much has already been said, it may be well to mention the changes found at different times. They include calculi found in the pancreas of a diabetic as early as 1778 by T. Cowley, cancer by Bright at a comparatively early date and atrophy by Griesinger, who had found the pancreas atrophied in one of the five diabetics whose bodies he examined after death, yet believed that this lesion was of no significance whatever. But the observations which have been published in great numbers (Hartsen, Fles, von Recklinghausen, Frerichs, Klebs, Harnack, Külz, Schaper, Lancereaux, Senator, and others) allow us to assume that diseases of the pancreas are present in about one-half of all the cases of diabetes. The statement of Senator<sup>1</sup> that this organ "is found diseased with surprising frequency, in particular either atrophied or, in addition, degenerated," is in the main correct. Among nine cases Frerichs saw atrophy or fatty degeneration of the gland five times, and in the Vienna dead-house the pancreas was found strikingly small, soft, and anemic in 13 out of 30 diabetics (Seegen). Other coincident diseases of the pancreas already mentioned are cancer and impacted calculus. Reference should not be omitted to the important work of Eugene L. Opie, who has shown minute changes in the island of Langerhans in certain cases of diabetes mellitus.<sup>2</sup>

The kidneys, primarily unaffected, are in many cases sooner or later influenced by the constant hyperemia to which they are subjected in eliminating the sugar. The appearances commonly met are those of hyperemia and overgrowth of epithelium—in a word, those of catarrhal nephritis. Occasionally the changes are more advanced, and the epithelium is fatty. More rarely granular contracted kidney is present, contributing a more serious significance to the albuminuria. These changes are not necessarily attended by albuminuria previous to death. In most other cases I believe nephritis to be an accidental coincidence. There occurs also sometimes a swelling of the epithelium in the straight tubes, hyaline changes in the descending limb of Henle's loop, as well as a hyaline change in the vessels of the Malpighian tubes. As to the proportion of cases in which the kidneys reveal morbid alterations, it is a decided majority.

The *lungs* are often the seat of tubercular deposits and cavities resulting from their softening; also of bronchopneumonia and croupous pneumonia, which may terminate in gangrene. In many cases of diabetes the heart is found normal or corresponds to the general nutritive condition of the patients. Quite often it is enlarged. An average of cases collected by Saundby, Israel, Mayer and Virchow found the heart hypertrophied in 17 per cent. Cardiac hypertrophy is seldom found in rapidly progressing cases, in young spare individuals, the myocardial changes in these cases being usually fatty though neither pronounced or definite. Naturally, cardiac changes are detected after death which may not have

<sup>1</sup> Senator, *loc. cit.*, p. 887.

<sup>2</sup> "On the Relations of Chronic Interstitial Pancreatitis to the Islands of Langerhans and Diabetes Mellitus," *Jour. of Experimental Medicine*, vol. v., p. 396, 1900-1901.

produce recognizable symptoms during life. Acid intoxication as well as the irritant effect of glucose in the blood may be a cause of any of the cardiac conditions found. Acid intoxication especially is responsible for feeble cardiac action and even syncope during life without true diabetic coma.

**Symptoms.**—Almost invariably the earliest symptoms noticed by the diabetic are *thirst* and *polyuria*. One or the other of the two may be noticed first, or the patient's attention may be called to both simultaneously. It occasionally happens that a *dryness of the fauces* and a glutinous *viscid* character of the *saliva* attract attention before any other symptom. Sometimes it is observed that a drop of urine falling upon the boots or clothing and evaporating there, leaves a persistent white or yellowish spot due to sugar. *Dryness and harshness of the skin*, due to absence of perspiration, soon make their appearance and early attract the attention of those who ordinarily perspire freely, and occasion varying amounts of discomfort. *Itching* of the skin is sometimes present. The *temperature* of the body is not increased, at this stage scarcely altered, although later in the disease it may be decidedly lowered. If the further progress of the disease is not arrested, a *voracious appetite* becomes the next symptom, notwithstanding which the patient observes that he slowly *loses in weight* and grows daily *weaker*. Extreme *languor* and *weakness* are characteristic. The rapidity with which these symptoms succeed one another varies. Sometimes the course is very rapid, constituting an acute form; at other times the successive stages are exceedingly slow in developing chronic diabetes.

*Boils* and *carbuncles* in the skin are also of frequent occurrence, favored by the malnutrition growing out of diabetes, and the former are occasionally the first symptoms recognized. The latter never occur early, but, when present, are frequently the immediate cause of death.

*Gangrene* of various parts of the body is another of this class of symptoms. It is sometimes spontaneous, but more frequently is immediately caused by some trifling injury which, under other circumstances, would be without result. It has been known to start from a blister and from the cutting of a corn. Beginning most frequently in those parts of the body most remote from the center of the circulation, as the toes, its progress and appearances are like those of senile gangrene. Sometimes, however, the gangrene is moist.

*Eczema*, with itching and burning of the labia and vicinity, is a frequent and troublesome symptom in women incident to the extremely frequent micturition. In the male the meatus urinarius is sometimes the seat of a similar irritation. Eczema elsewhere, as on the palms of the hands, is also a symptom.

The early loss of *sexual desire* is characteristic.

*Dyspeptic symptoms* may appear at various stages, seldom very early. Acid eructations, flatulence, and epigastric pain, or an indescribable sensation described as "sinking" of the epigastrium, are among them. *Constipation* is sometimes a very troublesome symptom, and adds, in my experience, to the seriousness of the case; on the other hand, diarrhea is occasionally present.

The foregoing category includes all the symptoms which present themselves in the milder form of the disease. But unless averted, all these symptoms become intensified. The patient complains of constant burning thirst, is continually urinating, and as constantly drinking water to quench his thirst, and, while often eating enormously, grows emaciated, although at the onset of the disease he may have been a robust, vigorous man.

As the disease advances there is a peculiar vinous or *acetous* odor of the breath, which has been compared to that of stale beer, and by Sir Thomas Watson to the odor of a place in which apples are kept. This is believed to be due to acetone and diacetic acid, both of which exist in the blood of severe cases of diabetes.

Later, cough often sets in, owing to bronchitis and tuberculous phthisis, and, with the copious expectoration incident to them, adds to the debilitating agencies already at work. Roberts thinks phthisis occurs in one-half the cases. I am sure not so many die of it in this country. C. von Noorden says one-fourth of all diabetic subjects in Germany have the disease, and Lancereaux, that victims of pancreatic diabetes are especially prone to tuberculosis. The consumption thus induced sometimes rapidly hastens the fatal termination, while at other times it appears to have but a trifling influence in this respect. The other symptoms characteristic of pulmonary consumption are also present, not excepting hectic sweats. The perspiration thus arising may contain sugar.

*Diabetic coma*, first described by Kussmaul in 1874, is a form of coma which often comes on in advanced stages of diabetes and almost as often terminates in death. The condition is one of suddenly or gradually supervening unconsciousness, with or without previous irritability or uneasiness, anxiety, vertigo, or symptoms resembling alcoholic intoxication. Sometimes it is preceded by obstinate constipation or intestinal catarrh or severe colicky and muscular pain. Convulsions do not occur, but the eyes are half open, the pupils dilated, and the eyeballs wandering. In addition to coma there are frequent and feeble pulse, deep inspiration, with short expiration, more or less frequent than in health, and gradually invading cyanosis. The temperature, at first slightly elevated, is subsequently subnormal. The condition lasts for from 24 to 48 hours, when death usually supervenes. Over one-half of all deaths in diabetes are ascribed to diabetic coma by Frerichs, but others assign a much smaller number to it. The odor of acetone may issue with the breath. The coma has been variously ascribed to acetone and diacetic acid, to oxybutyric acid, and many years ago by Professor Saunders and D. J. Hamilton<sup>1</sup> to slow carbonic poisoning due to fat embolism of the pulmonary vessels. All views are speculative. Acetone and diacetic acid are very often present for a long time, and yet no coma supervenes. There would seem to be better reason for ascribing the condition to "acid intoxication" or "acidosis," due to oxybutyric acid as held by Stadelmann and Minkowski, since the continued presence of this acid is always followed, sooner or later, by coma unless the patient die from other cause. Diabetic coma must not be confounded with other forms of coma which may occur in diabetes, as true apoplexy and uremia.

<sup>1</sup> "Edin. Med. Jour.," July, 1879.

Severe *neuritis* in the brachial and crural nerves is not infrequent. In grave cases the *tendon reflexes* are diminished or absent. *Unilateral sweating* has been observed. Senator refers to three cases—two of the left half of the face and one of the right. *Edema* sometimes appears late in the disease, and is not necessarily the result of renal complication.

Among the rarer symptoms is *cataract*, the association of which with diabetes was long ago noticed by Prout. It develops rapidly and is nearly always symmetrical, involving both eyes simultaneously, but not to the same degree. It is sometimes a very nice point to determine whether cataract is due to diabetes or to the usual causes. The earlier the age at which it occurs, the more probably is it due to diabetes.

Other visual defects may occur. Among these are myopia, amblyopia, presbyopia, and loss of accommodating power from defect of the ciliary muscle. George E. de Schweinitz informs me that a sudden development of myopia between the 40th and 60th years without apparent lesion is characteristic of diabetes. It may be due to a fine edema of the choroid, or a choroiditis which in turn determines an elongation of the axis of the eyeball and thus produces myopia.

The ophthalmoscope may reveal dilatation of the *retinal* vessels. Many years ago Albert G. Heyl<sup>1</sup> described a condition which he called *intra-ocular lipemia*, in which the light salmon color of the blood contained in the branches of the retinal vein and artery contrasted with the cinnabar-red of the vein and yellow-red of the artery, also by the greater width of these vessels and the lighter yellow of the fundus. Finally, *atrophy of the retina* and hemorrhagic and inflammatory affections of the eye have been described, and total blindness has been ascribed to the first named.<sup>2</sup> *Derangements* of other *special senses* said to attend diabetes are impairment of hearing, roaring in the ears, and derangement of smell and taste.

A *spongy* state of the *gums*, with recession and excavation, is an occasional symptom, resulting in extreme cases in absorption of the alveolar processes and falling out of the teeth.

*Blood-pressure in Diabetes.*—The results of different observers as to blood-pressure in diabetes are not uniform. My own experience would go to show that blood-pressure is certainly not increased in this disease *per se*. Eliminating complications, the tendency is to be normal or below the normal, say 115–130. Where complicated with arterio-sclerosis, a very frequent complication, of diabetes or by nephritis, blood-pressure is higher, reaching sometimes 160 or more. These results are in accord with those of Vaquez, Hensen, Theodore C. Janeway and Arthur R. Elliott,<sup>3</sup> of Chicago, as contrasted with Potain, Jaques Mayer, Tiessier Schott, Ebstein and others.

*Alterations in the Blood.*—It has already been mentioned that in diabetes the blood becomes highly charged with glucose, which increases from a normal of 0.05 to 0.15 per cent. to 0.2 per cent., and in extreme cases to 0.57 per cent., and from this hyperglycemia comes glycosuria. From the presence of the first we should naturally expect a higher specific

gravity of the blood-serum, which has been found as high as 1033, as contrasted with the normal 1028. On the other hand, the serum has been found thinner than normal, containing, according to different analyses, from 80.2 to 84.8 of water instead of the normal 78 to 79 per cent. The red blood-disks are often diminished. The alkalinity of the blood is also lowered, and as such diminution is at a maximum when oxybutyric acid is being excreted, it has been ascribed to the presence of this substance.

An abnormal amount of fat in the blood, producing the technical lipemia, was observed by the earliest students of diabetes, and is attested by many analyses, as well as by the milky appearance of the serum and the intraocular appearances described by Albert G. Heyl. The analyses of Simon shown from 2 to 2.4 per cent. instead of the normal 1.6 to 1.9 per cent.

*Changes in the Urine.*—The peculiarity of diabetic urine most noticeable to the patient is its enormous quantity, which has been known to exceed 70 pounds (31.78 kilos) in 24 hours, while apocryphal accounts of larger amounts are extant. Frank records 52 pounds (23.6 kilos); Bardsley<sup>1</sup> 36 pints (20.4 liters) and 32 pints (18.6 liters); Bence Jones found 56 pints (31.78 liters); Sir Thomas Watson and Dickinson 26 pints (14.77 liters), and Pavy 32 pints (18.16 liters). From 70 to 100 ounces (2100 to 3000 c.c.) are frequent quantities. The quantity of urine passed is limited by the amount of fluid ingested, for while it is possible that the amount of the former secreted may exceed for a very short period the quantity of the latter ingested, it is evident that this cannot continue for any length of time, and, in point of fact, it is found to be almost invariably a little less, the remainder being removed by the lungs, skin, and bowels. It is said that in health the lungs exhale fully one-fourth as much water as the kidneys secrete. Should it be proven that cases do occur in which the amount of water secreted exceeds that ingested by the mouth for any considerable period, it must then be admitted that absorption of water from the air by the skin is possible. On the other hand, it was early observed by Th. Cowley<sup>2</sup> (1788) that the quantity of water occasionally is not at all or but slightly increased. To this condition Frank,<sup>3</sup> another old author, gave the name of *diabetes decipiens*. It is well known, also, that intercurrent diseases, especially febrile affections, sometimes diminish the quantity of urine as well as the amount of sugar excreted; while the same diminution of urine and sugar also occasionally occurs toward the fatal termination of the disease.

But the most important change is, of course, the presence of *glucose*. Of this, the quantity varies greatly in different cases and at different times in the same case. Every case of trifling and temporary glycosuria should not, however, be considered a case of diabetes. The sugar should be easily recognizable by the ordinary tests and should be constant. From what may be indicated as "evident traces" the proportion of sugar may reach, it is said, as much as 15 per cent. I have never found more than 12 per cent., though I often hear reports of the finding of larger quantities which I can scarcely credit. The 24 hours' quantity varies similarly. The maximum quantity secreted in this time appears to be that reported

<sup>2</sup> Th. Cowley, "London Medical Journal," 1788.

<sup>3</sup> J. P. Frank, "De Curandis Hom. Morbis Epitome," lib. v., "De Profluviis," Pars 1, Manheimii, 1794.

by Dickinson, wherein a man 25 years of age voided 50 ounces (1500 gm.) of glucose in 24 hours. But the more usual quantity is from 10 to 80 milligrams to the cubic centimeter, or from 20 to 25 gm. in 24 hours; equivalent to 5 to 30 grains in the fluidounce, English measure, or from 300 to 3800 grains in the 24 hours.

The effect of muscular exercise in diminishing the quantity of sugar in the urine of diabetics was early confirmed by Külz and others, while it is scarcely necessary to say that accidental as well as intentional changes in diet are followed by consequent variations. So, too, urine passed after fasting, as on rising in the morning, contains generally less sugar than that passed after a meal, and in the clinical study of cases of diabetes, where a part of the 24 hours' urine is not obtainable, it is important to bear this in mind. As the difficulties in obtaining a part of the 24 hours' urine regularly are very great, it is often preferable, in my experience, to take for examination two samples, one passed in the morning on rising, and representing the fasting urine, and another on going to bed, representing the day urine.

Consistently with the increased solid matter thus added, the *specific gravity* of diabetic urine is, as a rule, high, 1040 being very common, while Bouchardat found it as high as 1074 in one instance. The well-known disposition of diabetic urine to become *frothy* on shaking, and to maintain this frothy condition, is a natural physical result of its increased density. Urine may, however, have a low specific gravity and yet contain sugar. I have found it as low as 1010 and lower. Such low specific gravities of glucose, if present in any decided degree, must depend on the low proportion of other normal ingredients. Sugar sometimes disappears very rapidly from urine by fermentation, thus reducing also the specific gravity.

Concurrent with the increase in quantity of urine is an *absence of color*, which in extreme degrees is almost total, so that the urine may be as clear as spring water. Almost all diabetic urine, sooner or later after exposure at a moderate temperature, becomes *cloudy* from the development of fungi coincident with fermentation. The *odor* of the urine is usually normal when first passed, but sooner or later, in consequence of fermentation setting up, it may acquire an acetous odor. The latter change also increases the normal acid reaction and maintains it much longer after exposure to the air than is the case with normal urine. This acetous odor is ascribed to acetone and diacetic acid. The urine may have a sweetish odor when passed, which has been compared to "sweet brier." Diabetic urine is sometimes quite free from *sediment*. At other times there is a copious sediment of uric acid. In the sediment may also be included the *penicilium* fungus, common to acid urine, as well as the more characteristic yeast or sugar fungus, or the *torula cerivisiæ*. This also sometimes appears as a *mold* on the surface of the urine.

Of the normal chemical constituents of the urine, *urea* is almost invariably increased. This is contributed to by two causes. The first is the ingestion of large amounts of nitrogenous food, whether to appease the appetite or by the physician's advice. The second cause is the destruction of the tissues themselves which characterizes the severest cases

in the last stages in spite of the enormous food consumption. In such event the nitrogenous tissues are split up into urea and sugar.

As regards *uric acid*, it is either normal or slightly increased. Of the other constituents of the urine, creatinin is increased; sulphuric acid is subject to its normal variations; chlorin, phosphoric acid, lime, and magnesia are said to be increased; phosphoric acid and lime especially so. Ammonia is sometimes largely increased, indeed enormously so in certain conditions, as in diabetic coma and threatened coma, when it is drawn out of the tissues to neutralize oxybutyric acid.

Of *abnormal* constituents, albumin is often present—perhaps in one-third of all cases; some make it a larger proportion, some less. The albuminuria is not generally large and, in my experience, is not often a serious symptom. Albuminuria does not necessarily imply renal change. The urine may become albuminous from any of the causes of albuminuria independent of diabetes, as pus from pyelitis, cystitis, etc.

*Inosit*, or muscle-sugar, occasionally replaces the grape-sugar in diabetes, but more frequently accompanies it. Gallois<sup>1</sup> found it in five out of 35 diabetics.

Finally, *acetone*, *diacetic acid*, and *beta-oxybutyric acid* are all frequently met in diabetic urine. Knoop's studies<sup>1</sup> have shown that the source of these substances may be either protein or fat, the fatty acids probably constituting the chief source, diacetic or aceto-acetic acid being probably first formed and rapidly transformed into acetone. When but little diacetic acid is produced, it is all converted into acetone; when much is formed, both substances appear in the urine. The conversion takes place mainly in the urine, but doubtless also in the tissues or the blood, since acetone may be present in the expired air. To acetone is ascribed the vinous odor sometimes present in the urine. Acetone is produced in health in a slight amount in the normal decomposition of albumin, freely in certain diseases other than diabetes. According to von Noorden, these substances are formed in the disintegration of the albumin of the body and not of the food—in a word, when the patient is "consuming his own proteids."

Beta-oxybutyric acid is believed by many to be the first stage in the formation of diacetic acid. Von Noorden also thinks this possible, but he claims for it a certain "clinical independence," and considers it probable that oxybutyric acid, on the one hand, and aceto-acetic acid, on the other, arise from qualitatively different disintegration processes. While acetone in the urine does not add to the seriousness of diabetes, the presence of oxybutyric acid is of the gravest prognostic significance. It is said never to disappear permanently after being once present, and to be almost always followed in a few days or weeks by diabetic coma and death. Diacetic acid has an intermediate significance between acetone and beta-oxybutyric acid.

Of the other secretions, the *perspiration*, when present, frequently contains sugar, at times a notable amount, as much as 6 1/2 grains (0.42 gm.) having been extracted by Fletcher from a piece of flannel, three inches square, which had lain upon the skin of a diabetic patient for 48

<sup>1</sup> Gallois, "Comptes Rendues," 1, p. 533; also "De l'Inosurie," Paris, 1864.

hours. The *saliva* has rarely been found to contain sugar independently of that which it acquires from the food. That the *gastric juice* ever contains it under similar conditions is disputed, but it has been found in effusions and exudations, as might be expected.

**Duration.**—Though the course of a few cases of diabetes is so rapid as to justify the name acute, the number of these cases is not sufficient to justify a classification into acute and chronic. In such rapid cases death has taken place at periods ranging from two days to six weeks, yet in no instance can it be averred that the disease was of as short duration as it seemed, since it may have existed some time before it was discovered, while in several it was evidently of longer duration. It is true, therefore, that diabetes mellitus is a disease almost invariably of long duration. Cases of 15, 18, and 20 years' duration are reported. I have had a number of cases under my care for more than ten years. The younger the subject, the shorter the duration and the more promptly fatal the result, while after middle age, under treatment, the duration may be indefinite.

Diabetes mellitus is sometimes distinctly intermittent for a time, regardless of treatment. I was for a long time incredulous on this subject, but experience has taught me that such a form of diabetes occurs, in which both polyuria and glycosuria may disappear without treatment, to recur again. Such cases are, however, easily controlled by treatment when discovered, while they are as certain to pass over into the permanent form if neglected.

**Complications.**—The diabetic is characteristically subject to complications, which may be accounted for in a word by his diminished power of resistance to all disease-causing agencies and to the toxic influences incident to the disease itself. Most of these have already been considered among symptoms. Such are the numerous skin affections, gastro-intestinal disturbances, pancreatic and renal affections, functional cardiac and nervous symptoms, including neuritis and diabetic coma. *Tuberculosis* has also been mentioned. It is especially apt to attack young subjects and to cause their death. *Arterio-sclerosis* is prone to occur in diabetics, with its full train of consequences, and to appear earlier in life among them. *Jaundice* sometimes occurs, and having presented itself twice in the history of a case under my observation, can hardly be considered accidental. Senator says that, when not an accidental complication due to a catarrh of the duodenum, it may result from compression of the biliary capillaries by the overloaded blood-vessels or enlarged gland-cells of the liver.<sup>1</sup>

Gout and diabetes are sometimes associated, and an interesting and important fact has been learned from this association, viz.: that cases of diabetes complicated with gout are always mild cases and easily controlled. Sometimes the symptoms of gout and diabetes alternate. That is, when the glycosuria appears the gouty symptoms subside and *vice versa*. These cases are apt to be associated with arterio-sclerosis and death from apoplexy may ensue.

**Diagnosis.**—The diagnosis of diabetes mellitus is very easy, yet I

<sup>1</sup> Senator, *loc. cit.*, p. 912.

have known it to be long overlooked by the practitioner. Unnatural thirst and copious diuresis should always suggest a chemical examination of the urine, and although there are sources of error in testing for small quantities of sugar, the quantities thus overlooked are not usually of clinical significance. In fact, in my observation, glucose is more frequently declared present by inexperienced examiners when absent than the reverse. Almost any one of the tests, therefore, which are found in the various manuals for the examination of urine, applied with ordinary care, will respond readily to quantities which are of clinical significance.

*Tests for Sugar.*—For provisional purposes Trommer's method of using the copper test answers very well. Its ingredients are easily attainable, and there is no risk of error from changes during keeping, to which Fehling's and Pavy's solutions are subject.

(1) Trommer's test is used as follows:

To a small quantity of urine, say five c.c. (50 minims), add half as much liquor potassæ or sodæ, then drop by drop a 5 or 10 per cent. solution of cupric sulphate. On first adding the copper, a blue precipitate of hydrated cupric protoxid takes place, *which, if sugar is present, is redissolved on shaking*, producing a clear blue liquid. The copper solution should be thus added until the precipitate is no longer dissolved on shaking. Then heat the mixture to boiling, and if sugar is present, a copious yellow precipitate of hydrated cuprous oxid or of red cuprous oxid occurs. Either is conclusive evidence. Occasionally the precipitate of earthy phosphates is so copious as decidedly to obscure the reaction, and by beginners is sometimes mistaken for the suboxid. In this event the earthy phosphates may be removed by filtration after *slightly* warming the mixture. The reaction should take place as soon as the boiling-point is reached—indeed, it sometimes occurs before this point is reached. Prolonged boiling should be avoided.

(2) In Fehling's solution<sup>1</sup> the constituents of Trommer's test are united in definite proportions in order that a quantitative estimation may be made. It is also used for qualitative testing, while a rough quantitative estimation may be made at the same time by what is known as the *clinical method* at the University of Pennsylvania Clinic.

A given quantity, say one c.c., of Fehling's solution is placed in a test-tube, diluted with about four times its bulk of water, and boiled for a few seconds. If the solution remains clear, add immediately the suspected urine, drop by drop. If sugar is abundant, the first few drops will usually cause the red or yellow precipitate, but if the reaction does not occur, the dropping may be continued, followed each time by heating until an equal volume has been added. If no red or yellow precipitate occurs, sugar is absent. Now, Fehling's solution is so composed that if an equal volume is exactly reduced by an equal volume of urine, that

<sup>1</sup> *Fehling's Solution.*—Dissolve 34.652 gm. of pure crystallized sulphate of copper in 200 gm. of distilled water; 175 gm. of chemically pure crystallized neutral sodic tartrate in 480 gm. solution of caustic soda of specific gravity 1.14, and into this basic solution the copper solution is poured, a little at a time. The clear mixed fluid is diluted to one liter, or 1000 c.c.

Ten c.c. of this solution will be reduced by 0.05 gm., or 50 milligrams, of diabetic sugar. If Fehling's solution is to be kept some time, it is absolutely essential that it should be placed in smaller bottles holding from 40 to 80 gm., sealed, and kept in a cellar.

Still greater security may be obtained by dissolving the cupric sulphate in 500 c.c. and the tartrate salt and potash in 500 c.c., keeping the two solutions separate in rubber-stoppered bottles. Equal volumes of the two solutions are united when needed for use.

urine contains one-half of one per cent. of glucose; if by half bulk, one per cent.; if twice the bulk, one-fourth per cent., and so on, whence one can easily estimate roughly the percentage. Should the urine contain more than one per cent. of sugar, it should be diluted one to ten and the result multiplied by ten.

If a reduction takes place on boiling the test fluid alone, a new supply may be obtained, or a little more soda or potash may be added, the fluid filtered, and it is again ready for use. Such spontaneous reduction of the cuprous oxid often occurs when Fehling's solution is kept for some time.

In judging the progress of a case of diabetes under treatment it is not sufficient to test the urine qualitatively, but a quantitative determination of sugar must be made. This may be done by the clinical method just described or by volumetric processes described in the manuals for the examination of urine, but the simplest process is the (3) *fermentation method* of Roberts. In this the specific gravity of the urine is taken before and after fermentation, and the difference in the two results indicates the number of grains of sugar in each fluidounce of urine. Suppose, then, the specific gravity before fermentation to be 1045, and after fermentation 1035: the quantity of sugar is ten grains to the fluidounce, or 0.65 gm. in 30 c.c. These figures can be reduced to percentage by multiplying by 0.23.

Mention should be made of those rare instances in which the sugar does not reduce cupric oxid. I have had a case under my care. The urine had a specific gravity of 1050 when the patient came under observation, but there was no response whatever to the copper or bismuth test; yet by the fermentation test a large amount of sugar was shown to be present.

(4) Polarimetry is a very convenient method of analysis if an instrument is at hand, though the costliness of a good instrument will probably always be in the way of its general use.

*Tests for Acetone, Diacetic Acid, and Oxybutyric Acid.*—Of the numerous tests for acetone, most of which require the distillate for their successful application, Legal's nitroprussid of sodium test is the most satisfactory for the practitioner, because it does not require the distillate.

*Legal's Test for Acetone.*—A fresh, rather strong solution of sodium nitroprussid is made by dissolving a few fragments in a little water in a test-tube. To three or four c.c. of the suspected urine add enough liquor sodæ or potassæ to secure a distinct alkaline reaction. To the mixture then add a *few drops* of the nitroprussid solution, when the whole quickly assumes a red color, whether acetone is present or not, said to be produced by creatinin even more rapidly than by acetone. In any event the red color disappears; but if acetone is present, the addition, of a few drops of concentrated acetic acid causes a purple or violet-red color. If there is no acetone, this final change does not occur, while the purple color also fades in a little while, even if caused by acetone.

To test for *diacetic acid* add a few drops of a solution of ferric chlorid to a small quantity of the urine, when a beautiful Burgundy-red reaction occurs. A precipitate of phosphates succeeds the adding of the first few drops, but this is redissolved by a further addition of the chlorid.

The test is confirmed if, after heating the original fluid, there is no response on application of the chlorid of iron—the effect of heat being to dissipate the diacetic acid. A more brilliant reaction is obtained if the urine be first treated with a solution of acetate of lead, filtering out the white precipitate and testing the filtrate. Urine passed after the administration of salicylic acid, antipyrin, carbolio acid, salol, phenocol, kairin and other drugs furnishes a similar reaction.

The reaction for diacetic acid being obtained, it is scarcely necessary to test for *beta-oxybutyric acid*, as the significance is the same. The test is a complicated one, but *beta-oxybutyric acid* is presumably present when a quantitative estimation indicates a larger quantity of glucose than does polarization, since *beta-oxybutyric acid* rotates polarized light to the left, as contrasted with the dextrorotatory power of grape-sugar. Again, if after complete fermentation with yeast or precipitation with basic acetate of lead and ammonia the urine is found levorotatory, *beta-oxybutyric acid* is presumably present.

**Prognosis.**—The prognosis of diabetes varies with the age at which the disease makes its appearance, the time which has been allowed to elapse before treatment is instituted, and the treatment itself. Once thoroughly established early in life, or before 25 years of age, recovery is rarely possible, but even at this age, if treatment is instituted sufficiently early, much may often be done to avert the end. Diabetes is a disease in which the expectant plan of treatment is disastrous. It is a disease which never gets well of itself, and always gets worse if not properly treated. At the same time the mild cases amenable to treatment are in a decided majority. When the disease appears after middle life in fat persons or those disposed to gout, and is early recognized and promptly treated, it is usually easily controlled; and although it is almost never safe to declare a case of diabetes absolutely cured, it does occasionally happen that recovery is so complete that the patient may be left to his own mode of living. As a rule, however, even those who have apparently recovered must keep a watch upon their diet, and should at intervals have their urine examined with a view to sounding, as it were, their condition. We are entirely justified in saying to a diabetic patient, "As long as your urine remains free of sugar you are practically as well as if you had no tendency to diabetes." On the other hand, for spare, nervous, and hard-worked persons, especially mentally overworked, under 40, there is a much more unfavorable outlook. Even here, if the co-operation of the patient can be secured, much may be done. Every intermediate degree of seriousness may occur. When diabetes depends upon recognized nervous lesions, the prognosis is altogether that of the lesion itself. The cause of death is very frequently some intercurrent or consequent disease, as phthisis or diabetic coma. The syphilitic origin of the disease and obesity are favorable prognostic factors; a spare habit and habitual constipation are unfavorable.

**Treatment.**—This resolves itself easily into the dietetic, the hygienic, and the medical.

1. *Dietetic Treatment.*—This is by far the most efficient, and no permanent results have ever been obtained without it. It consists essentially

in the elimination from the diet of such articles as are readily convertible into glucose—viz., the carbohydrates. It is acknowledged that in the early stages of the disease only the saccharine and amylaceous foods fail to be consumed in the economy in the usual way and appear in the urine as glucose. Hence, if these be excluded from the diet and their place supplied by other assimilable articles, the symptom disappears, and the disappearance of this symptom seems to be, for the time being at least, the cure of the disease.

If it were necessary to select a diet absolutely free from sugar and starch, it would indeed be restricted, as there are comparatively few articles of food thus constituted. Such are, however, meats of every kind, fresh or salted, including tripe, tongue, ham, bacon, and sausage; soups made from meat and without flour; game, poultry, fish, oysters, lobsters, crabs, eggs in every form; butter and new cheese, oils and fats. Happily, however, it is not necessary to use articles absolutely free from the two baneful principles, and in this manner quite a variety of palatable articles may be added to the dietary. Among these are cream, curds, milk and butter milk, and all green vegetables, including spinach, endive, lettuce, dandelion, cabbage in various forms including coleslaw, Brussels sprouts, cauliflower, broccoli, string-beans, tomato, watercress, celery tops, asparagus tops, turnip tops, young onions, cucumbers, pickles, and olives. To these may be added unsweetened jellies (preparations of gelatin) and especially a variety of nuts, including almonds, walnuts, butternuts, filberts, pecan nuts, Brazil nuts, but not chestnuts; also, all acid fruits, as apples, lemons, strawberries, etc. Tea and coffee, with cream and without sugar, cocoa nibs, cocoa, but not chocolate, are permitted; also all wines which contain little or no sugar, including claret, Burgundy, Rhine, and still Moselle wines, together with very dry sherry, unsweetened brandy, whisky, and gin when required. The carbonated waters, natural or artificial (the so-called soda-water of the shops), are pre-eminently suitable. Water is to be allowed *ad libitum*, for water is the medium by which the sugar is carried out of the blood and tissues. Its supply should therefore be liberal, and with the diminished sugar formation comes diminished thirst. Better still are the alkaline mineral waters, especially those of Vals, Vichy, Carlsbad, and the Saratoga Vichy.

Beer, ale, porter, cider, and the fermented liquors generally are not allowable because of the sugar and carbohydrates they contain. They are less objectionable when fermentation is carried to a high degree, resulting in a more complete destruction of the sugar. This is the case with certain bottled lager beers and English ales.

It is not simply the small quantity of sugar and starch contained in them which renders the vegetable substances named admissible, for many of them contain a great deal of sugar; but these sugars, unlike grape-sugar and cane sugar, are more easily assimilable. Such are pre-eminently mannite, the sugar of manna; lactin, or sugar of milk; levulose, or fruit-sugar, and probably, also, inosit, or the sugar of muscle. Such is also inulin, a hydrocarbon and starchy principle found in the *inula helenium*, or elecampane, but especially in Iceland moss. Hence, too, the impunity with which milk can often be taken by diabetics, although it contains from

three to six per cent. of lactic acid. On this account, too, levulose may be cautiously used for sweetening tea and coffee in mild cases. Glycerin is also sometimes substituted for sugar, but though less objectionable, both theory and experience go to show that it is not a safe substitute. Levulose and even mannite are much to be preferred to glycerine, both for sweetening and as a substitute for sugar in force production. But none of these sugars can be used with safety for sweetening purposes, and if sweetening is indispensable for the patient, it should be done with saccharin.

It will be noticed that not only all saccharine substances of animal or vegetable origin and all vegetables largely composed of starch, as potatoes, rice, and corn, are omitted from the category of admissible articles, but that *bread*, and all preparations made of wheat, rye, rice, or corn-flour, are conspicuous by their absence. This is found to be a very important omission from the dietary of most persons, and numerous, indeed, have been the attempts to devise substitutes for it, with varying success. The best known and most popular of these is gluten bread, made of the so-called gluten flour, whence the starch is partially removed by washing. Unfortunately, the so-called gluten flour usually obtained in this country contains nearly as much starch as the white flours. The Battle Creek Sanitarium Co., of Battle Creek, Mich., furnishes a nearly pure gluten meal and a nearly pure gluten biscuit. The latter can be used only for thickening soups and dressings. The "Casoid foods" of Callard & Co., of London, which contain a minimum of carbohydrate, may be obtained of Thomas Leeming & Co., 73 Warren St., New York City. The Battle Creek foods may be obtained of Gimble Bros., in Philadelphia. In England and France diabetic patients are much more fortunate, gluten flours of sufficient purity being there obtainable. Flour of the soya bean (*soya hispida*), containing only four per cent. of starch and a large amount of nitrogenous matter and oil, is also used for making griddle-cakes and biscuit. These, if freshly made, are very palatable; but biscuits made for some time become rapidly rancid from decomposition of the oil.

Another substitute is bran flour or unbolted wheat flour, which contains relatively less starch. The pure bran itself is not wholly innutritious. Prout very early recommended, as a substitute for bread, a compound of bran, milk, and eggs, which he declared not unpalatable.<sup>1</sup>

Still another substitute for wheaten bread is the almond food suggested by Pavy. The almond is composed of 54 per cent. of oil, 24 per cent. of nitrogenized matter known as emulsin, six per cent. of sugar, three per cent. of gum, and *no starch*. Chemically speaking, it is therefore admirably adapted for diabetic food, and when the sugar and gum have been extracted, it leaves nothing to be desired. The sugar and gum are removed by treating the powdered almonds with boiling water slightly acidulated with tartaric acid, or by soaking the almonds in a boiling acidulated liquid, which may form part of the process for blanching. The boiling and the

<sup>1</sup> The following are Camplin's directions for making biscuit of the bran flour: To one-quarter of a pound of flour add three or four fresh eggs, one and a half ounces of butter, and half a pint of milk; mix the eggs with a little of the milk, and warm the butter with the other portion; then stir the whole well together; add a little nutmeg or ginger or other agreeable flavoring, and bake in small forms or patty-pans. The cake, when baked, should be about the thickness of an ordinary captain's biscuit. The pans must be well buttered. Bake in rather a quick oven for half an hour.

These cakes or biscuits may be eaten by the diabetic with meat or cheese for breakfast, dinner or supper; at tea they require rather a free allowance of butter, or they may be eaten with curd or any of the soft cheeses.

acid fluid are necessary in order to precipitate the *emulsin*, which would otherwise emulsify the oil of the almond. Biscuits made of almond-flour<sup>1</sup> and eggs are palatable, and may be eaten with a little dry sherry or whisky and water.

Biscuits made of *inulin*, the starchy principle already referred to on page 892, were suggested by Külz.<sup>2</sup> Lichenin, or moss-starch, abundant in Iceland moss, is a variety of inulin, and would be the material used for the purpose. Being very cheap, it is suitable on this account. Though a starch, it is, according to Külz, one of the assimilable starches already mentioned, of which small quantities, at least, do not increase the excretion of sugar. The biscuits are made with the addition of milk, eggs, and salt.

The best of these substitutes is unsatisfactory, as patients soon tire of them and want the real bread. Aleuronat<sup>3</sup> bread is regarded by von Noorden as the only one at all satisfactory, since it retains the bread taste. Although containing some carbohydrate, I have used it for my patients, but have not found it entirely satisfactory as a substitute for wheat bread.

The following classified summary of articles of food admissible for diabetics will be found convenient for reference:

*Shell-fish*.—Oysters, mussels, and clams, raw or cooked in any way, without the addition of flour.

*Fish* of all kinds, fresh or salted, including lobsters, crabs, sardines, and other fish in oil; fish roe, caviare.

*Meats* of every variety except livers, including beef, mutton, chipped dried beef, tripe, ham, tongue, bacon, and sausages. Also poultry and game of all kinds, with which, however, sweetened jellies and sauces should not be used.

*Soups*.—Clear bouillon and other soups, beef-tea and broth made without flour, rice, vermicelli, or other starchy substances; and without the vegetables named below as inadmissible.

*Vegetables*.—Cabbage, cauliflower, Brussels sprouts, broccoli, green string-beans, the green ends of asparagus, spinach, dandelion, mushrooms, tomatoes, lettuce, endive, coleslaw, olives, cucumber (fresh or pickled), radishes, sorrel, young onions, watercresses, mustard and cress, turnip tops, celery tops, artichokes, gherkins, okra, parsley, or any other green vegetables.

*Bread and cakes* made of pure gluten, bran, aleuronat, soya, peanut- or almond flour, inulin, with or without eggs and butter. Griddle-cakes, pan-cakes, biscuit, porridges, etc., made of these flours. Oatmeal porridge with cream. Where especial stringency is required, the last should be altogether omitted.

<sup>1</sup> Seegen recommends an almond food made as follows: Beat a quarter of a pound of blanched sweet almonds in a stone mortar for about three-quarters of an hour, as fine as possible; put the flour thus produced into a linen bag, which is then immersed for an hour and a quarter in boiling water acidulated with a few drops of vinegar. The mass is then thoroughly mixed with three ounces of butter and two eggs; the yolks of three eggs and a little salt are added, and the whole is to be stirred briskly for a long time. A fine broth made by beating the whites of the three eggs is then added. The whole paste is now put into a form, smeared with melted butter, and baked by a gentle fire.

<sup>2</sup> Külz, "Beitrag zur Path. und Therapie des Diabetes Mellitus," Marburg. Bd. 1, p. 145, 1874.

<sup>3</sup> Aleuronat bread is made by R. Williamson as follows: Mix two ounces (62 gm.) of desiccated cocoanut powder with a little water containing a small quantity of German yeast. Make the mass into a sort of paste, and put in a warm place for half an hour or longer. The small amount of sugar contained in the cocoanut is almost entirely decomposed by the fermentation produced by the yeast, and the cocoanut paste becomes spongy. Add two ounces (62 gm.) of aleuronat, one beaten egg, and a small quantity of water in which a little saccharin has been dissolved, and mix well until a dough is formed. Divide into cakes and bake in a moderate oven for 20 or 30 minutes.

Aleuronat is a yellowish powder containing from 80 to 90 per cent. of vegetable albumin and only seven per cent. of carbohydrates. I have found much difficulty in securing properly desiccated cocoanut powder.

*Eggs* in any quantity and prepared in all possible ways, without sugar or ordinary flours.

*Butter and Cheese.*

*Nuts.*—All except chestnuts, including almonds, walnuts, Brazil nuts, hazelnuts, filberts, pecan nuts, butternuts, cocoanuts.

*Condiments.*—Salt, vinegar, and pepper in moderate quantities.

*Fruits.*—Cranberries, plums, cherries, gooseberries, red currants, strawberries, acid apples, lemons, oranges sparingly—all without sugar. Acid fruits may be stewed, with the addition of bicarbonate of sodium instead of sugar.

*Jellies.*—None except those not sweetened with sugar. Saccharin may be used for sweetening instead of sugar. Jellies may be made of calf's foot or gelatin and flavored with wine.

*Drinks.*—Coffee, tea, and cocoa-nibs, with milk or cream, but without sugar. Also, milk, cream, soda- (carbonated) water, and all mineral waters freely; lemonade without sugar, acid wines, including clarets, Bordeaux, Rhine, and still Moselle wines, and very dry sherry. Unsweetened brandy, whisky, and gin. No malt liquors except those ales and beers which have been long bottled and in which the sugar has all been converted into carbonic acid and alcohol. Saccharin may be used for sweetening tea and coffee.

*To be Especially Avoided.*—Cantaloupes, watermelons, peaches, grapes, and all other sweet melons and fruits; potatoes (white and sweet), rice, beets, carrots, turnips, parsnips, peas, and beans; all vegetables containing starch or sugar in any quantity; sweet wines, including sherry, Madeira, port, and champagne:

In mild cases the dietetic measures previously indicated are usually followed by the most prompt and decided results, in some instances by the permanent removal of all symptoms, in others by a continued absence of them so long as a watchfulness over diet is maintained. In a more advanced stage of the disease, in which more rapid emaciation and loss of strength show themselves, such a regimen is followed by a decided diminution in the amount of sugar excreted, but it fails to disappear altogether, and a more rigid elimination of saccharin and amylaceous articles must be attempted. Sooner or later, however, a stage is reached when not only albuminous food breaks up into urea and sugar and urea and water, but the albumin of the tissues undergoes the same metabolism and excretion, while emaciation, starting first with the disappearance of fats, invades even the muscular tissue. Fatty foods longest resist this breaking up, but, ultimately, in progressive cases, even they increase the elimination of sugar.

Each case should be thoroughly studied as to its own peculiarities and demands. I do not pursue the same plan in every case. Sometimes I place the patient at the onset on a strict nitrogenous diet of broths, meat, and eggs, with a view to determining what can be accomplished. This done, successive articles of food are added and their effect upon the urine is watched. In other cases, especially when the quantity of sugar is not large, I first take away from the diet all sweets, and the purest starch foods, including bread. Too great stringency must not be insisted upon, and

the presence of one per cent. or a maximum of two per cent. of glucose in urine may be permitted for a time; but semi-occasionally, say once a month, a return should be made to the strict diet, with a view to taking soundings, and if it is found that all the glucose disappears, we may be encouraged to permit for a time a more liberal diet.

In many cases of diabetes of long standing there comes a time when it becomes necessary for the welfare of the patient that a rigid diet must be suspended for a time. So settled is this truth that some physicians erred on the other side and have been led to decry altogether the dietetic treatment. A question of great practical importance asks what shall guide us to such a change of diet? Modern studies go to show that the indication for such a change is the flooding of the tissues and circulation with organic acids, especially oxybutyric, to which Naunyn has given the name "acidosis." It is under these circumstances that the "oat cure" of von Noorden and the "potato cure" of Mosse are recommended. Von Noorden makes the striking statement that "many diabetics," particularly severe cases with marked acetonuria, secrete much less sugar when they eat large quantities of oatmeal than when they are put upon the strictest diet which is as free from carbohydrates as is technically possible.

Von Noorden's *oatmeal* food consists of:

Eight and one-third ounces (250 gm.) of oatmeal are cooked for about two hours on a moderate fire, with 3 or 4 quarts of water and a little salt; 100 gm. roborat, gliden, rice albumin, etc., may be added.<sup>1</sup> When the gruel is done add 10 ounces (300 gm.) of butter and pass through a sieve. Divide the whole into eight equal parts and take a part every two hours. The whole amount must be eaten in the 24 hours. American and Scotch oats are most suitable.

Tea or black coffee without cream or sugar may be taken on the same day with the above, also red wine and brandy, bouillon and lemon juice. The oatmeal may be taken hot or cold, and, if desired, fried in its own liquid.

When the gruel is ordered for one meal only, as at the second breakfast or supper, a larger proportion of butter (two and one-half to three parts to one of oats) may be used. Such a porridge is the following:

To 1 ounce (30 gm.) of oatmeal are added in the evening 2 fluid-ounces (60 c.c.) of water and soaked overnight. The next day add 3 to 5 ounces (100 to 150 c.c.) of water, and cook two hours in a water boiler. One-half hour before it is finished add 2  $\frac{2}{3}$  ounces (80 gm.) of butter. For porridge take only Scotch or American oats. Buckwheat may be substituted for oatmeal.

My experience with such large proportions of butter has been unsatisfactory. I have found, too, that as an exclusive diet for a day or more the oatmeal is prone to nauseate and disgust the patient. Much more bearable is the "portion" taken at one meal, as at breakfast, and if it is made an exclusive diet the proportion of butter must be reduced and the interval made every three hours instead of every two.

2. *Hygienic Treatment.*—Next in importance to the dietetic is the

<sup>1</sup> These may be omitted as they are not easily obtainable in the United States. The student is referred to the diet tables of V. Noorden for further arrangement of foods and meals for diet.

hygienic treatment of diabetes. This consists in bathing, and attention to the skin, together with outdoor muscular exercise and perfect ventilation within doors.

The diabetic should breathe the freshest and purest air. While the cases are not numerous in which embarrassed respiration results in glycosuria, there are undoubted instances in which this has occurred, as in croup and whooping-cough; and it is well known that asphyxiated lower animals are likely to have glycosuria. Although the glycosuria thus resulting is probably reflex, it can hardly be expected that the diabetic should improve under unfavorable respiratory conditions. He should not, therefore, live, work, or sleep in a confined atmosphere, but secure the most perfect ventilation, spending much of his time out of doors, and sleeping in large, well ventilated chambers, with windows open, etc. Especially should he avoid inhalation of irrespirable gases. Attention to the skin, or skin culture, is most important to the diabetic. He should bathe at least twice a week in tepid or hot water on going to bed in winter, and on rising take a cool sponge-bath daily. In summer he may take a cool bath on rising and on retiring. He should groom his skin thoroughly daily, either after the bath or independent of it on the days on which he does not bathe. Two tablespoonfuls of sodium carbonate to an ordinary bath is a suitable addition to the latter, softening the skin and facilitating its action by removing the effete epithelium.

Muscular exercise should be taken daily by the diabetic, both by walking and gymnastics. Glycogen is undoubtedly consumed in the muscles during their action, and it is quite certain that in diabetes there is an undue accumulation of sugar in the muscles. Exercise should be sustained regularly day by day, even in wet weather, care being taken to keep the feet dry, while it should never be carried to the point of fatigue.

Attention to other secretions, particularly to that of the bowels, is of the greatest importance. Diabetics who are constipated are always more difficult to relieve. It is probably partly on account of their action in this respect that the alkaline and alkaline-saline aperient waters, as those of Vichy, Vals, and Carlsbad, are so useful. To those who visit these springs, a part of the benefit is ascribable to the other favorable hygienic influences, such as rest, fresh air, and exercise, by which they are surrounded. Independently of these influences, however, there is reason to believe that the alkaline waters are of service to diabetics, and when their cost is not a consideration, a quart of Vichy or Vals and half as much Carlsbad may be taken during the day, beginning before breakfast. The Vichy is a more alkaline water, containing 35 grains (2.3 gm.) of carbonates to a pint (0.5 liter), while Carlsbad contains but 11 grains (0.51 gm.), but twice the proportion of chlorids, eight grains (0.7 gm.) to a pint (0.5 liter), and nearly ten times as much sodium sulphate, or 19 grains (1.25 gm.); hence its more purgative quality to which some of the good effect may be due.

The waters of the celebrated Saratoga Springs in this country have an undoubted action on the liver, probably through the chlorids they contain, which are in very large proportion, reaching in the Geyser Spring 70 grains (4.6 gm.) to the pint (0.5 liter), and in the Empire and Hathorn, 63 grains (4.19 gm.) to the pint (0.5 liter). They contain no sulphates, but the

carbonates are present in considerable proportion, though much less than in the Vichy waters. Saratoga Vichy, which, of the Saratoga waters, contains most sodium carbonate, has ten grains (0.6 gm.) to the pint; the Geyser, 9 grains (0.58 gm.). In the absence of the Carlsbad and Vichy waters I would use the purgative Saratoga waters, especially the Vichy and Geyser.

3. *The Medicinal Treatment.*—Like all diseases in which treatment by drugs is relatively inefficient, diabetes has its full share of reputed remedies, most of which are useless. This dare not, however, be said of all.

The only drug that can be relied upon to produce an effect in diminishing glycosuria is opium. It seems that it was used for diabetes as early as the second century by Archigenes. It was also used by Ætius the physician, in the fourth century, and in the latter part of the 18th century and beginning of the 19th by Rollo, Frank, Tommasson, and especially the English physician, Pelham Warren, in 1812. It is certainly a useful agent in diabetes, but its use is united with disadvantages in the locking-up of the secretions. On account of its comparative freedom from these effects, codein has come to be the favorite alkaloid of opium in diabetes. It may be given in  $\frac{1}{4}$  grain (0.016 gm.) doses three times a day, or  $\frac{1}{2}$  grain (0.032 gm.) twice a day, increasing  $\frac{1}{4}$  grain (0.016 gm.) daily until the desired effect is produced or it proves useless. If the sugar disappears, the drugs should be gradually withdrawn. If constipation is caused by it, aperient remedies should be associated, and very suitable are the natural aperient waters, including the bitter waters, Friedrichshalle, Hunyadi János, Racokzy, Püllna, etc. I have seen a patient entirely relieved under its use, and it alone, with no return of the sugar after its omission. I rarely give as much as ten grains (0.65 gm.) a day, and usually defer its use until I find other measures insufficient.

After opium, arsenic has longest maintained its reputation as a remedy in diabetes, and I use it in all mild cases, preferring Fowler's solution. It seems to me there is something more than a simple tonic action in it. Possibly it acts partly on the gastro-intestinal tract and partly on the red blood-disks, increasing their oxidizing power over glucose. The plan I have adopted, after many years' experience, is to give small doses long continued rather than to attempt to bring about its physiological action. Hence three drops twice or thrice a day, continued indefinitely, is now my favorite dose.

The bromid of potassium is sometimes efficient in diabetes accompanying functional nervous disorders due to mental overwork or psychic disturbance. Bromin and arsenic are combined in the shape of Clemens' solution of bromid of arsenic, of which the dose is from 3 to 5 minims (0.184 to 0.3 c.c.).

Substances which possess the power of oxidizing sugar in the blood have long been sought. The alkalies, and especially the alkaline carbonates, acquired considerable reputation in the treatment of diabetes, after Mialhe claimed for them the power of destroying the sugar in the blood, and of neutralizing the volatile acids retained within the organism in consequence of the defective action of the skin. Whatever their mode of action, the carbonates continue to be used with results which justify the practice, and my almost invariable practice is to place my diabetic patients on sodium

bicarbonate in doses of a drachm (4 gm.) or more three times daily. It is probable that it neutralizes the acedosis which we have ascertained to be a dangerous condition. The efficiency of the alkaline mineral waters is thus explained.

Much was hoped of pancreas preparations, especially since the brilliant results that followed the use of thyroid extract in myxedema. They have proved disappointing, at least when given by the stomach. More hopeful is, however, the hypodermic use of these substances. Of these I have used amylopsin in 10 minim doses, increased to 20 minims, with results sufficiently good to encourage me to continue their use, although they have been temporary. The glycolytic ferment isolated by Lepine from the pancreas and from malt diastase has not been any more satisfactory. Suprarenal extract has also been employed, without effect. Secretin, a hormone derived from the mucous membrane of the duodenum, should be tried hypodermically or its production stimulated by the administration of hydrochloric acid.

The coal-tar derivatives, antipyrin, antifebrin, and phenacetin have been highly recommended by the French physicians, and I have found them of service in mild cases, giving from 10 to 15 grains (0.6 to 1 gm.) three times a day on an empty stomach, beginning with the smaller dose in the case of the first two. Their efficacy is said to be increased when combined with an equal bulk of sodium bicarbonate. Salicylate of sodium has warm advocates, and in gouty cases it may be useful. According to von Noorden, it is especially in neurogenous diabetes that the sodium salicylate is useful, quieting the irritability of the central nervous system.

Jambul is a remedy with some reputation. I have been so much disappointed in its effects that I rarely use it. It is given in the shape of powder or fluid extract, in doses of 5 to 30 grains (0.3 to 2 gm.) of the former and a half to 2 drams (1.8 to 7 c.c.) of the latter.

Iodid of potassium has produced some striking results in the case of diabetes due to syphilitic lesions of the brain.

Lactic acid was strongly advocated by the Italian physicians. Cantani recommends that from 75 to 150 grains (5 to 10 gm.) of the acid should be taken daily in from eight to ten fluidounces (240 to 300 c.c.) of water. Whence buttermilk or Zoolak (a fermented milk in which the sugar of milk is converted into lactic acid by a ferment) becomes a suitable food at least.

Cod-liver oil becomes a useful remedy in cases in which the proteins are largely and the carbohydrates totally converted into sugar and excreted, while the body albumin is being encroached upon as a source of energy. Especially useful does it become when associated with alcohol in the shape of whisky or brandy, which always helps the assimilation of fat. In the same category as cod-liver oil must be placed butter, cream, bacon, and the like as foods.

### Treatment of Complications.

*Eczema and Pruritus.*—These sometimes intensely annoying symptoms commonly abate with the reduction of the glycosuria, but require also other measures. In the first place scrupulous cleanliness is necessary, accomplished by warm, tepid bathing. In addition, we may use solutions of

boric acid 2 drams (8 gm.) to the quart (1 liter) or sodium hyposulphite, 1 ounce (30 gm.) to a quart (1 liter) of water; also zinc ointment, ointment of acetate of lead; solutions of corrosive sublimate, very weak—1 to 3000—and tumenol-sulphonic acid in 10 per cent. alcohol solutions. Carbolic acid 5 to 10 minims (.3 to .6 gm.) glycerine ʒij (8 c.c.) and water an ounce (30 c.c.) make a soothing preparation. As a last resort in pruritis nitrate of silver may be used in the strength of 20 grains (1.3 gm.) to the ounce (30 c.c.), making daily applications, which though sometimes painful, are ultimately effectual.

*Diabetic Coma.*—Treatment is usually futile here. The alkalies and alkaline mineral waters should be pushed. Intravenous injections of alkaline solutions have been disappointing. More hopeful is the intravenous injection of a 0.8 per cent. salt solution, as recommended by von Noorden, using a liter in four doses at intervals of four hours. A teaspoonful of common salt to a gallon of sterilized water affords a strength sufficiently near the percentage named. Hypodermoclysis, which is much easier, will accomplish the same result, as I can attest from personal experience. Copious diuresis follows, and may be expected to carry out noxious substances.

More hopeful is a *prophylactic* treatment of diabetic coma, called for when diacetic acid or oxybutyric acid and large amounts of acetone are found in the urine. Under these circumstances it seems certain that whatever be the form of diet in use at the time, it must be changed, and if it be remembered that these substances are now conceded to arise from the disintegration of body albumin and not from food, as formerly supposed, diet would at least seem a matter of indifference under the circumstances, while a change alone seems desirable. The patient should be immediately placed upon alkaline treatment, associated with the free use of alkaline mineral waters. Thus, 30 grains (1.3 gm.) or more of sodium bicarbonate may be given every three hours, dissolved in 8 ounces (250 c.c.) of Vals or Vichy water. The bowels should be kept open, and alcohol in the shape of whisky or brandy freely given.

## DIABETES INSIPIDUS.

**Definition.**—Any excessive secretion of non-saccharine and non-albuminous urine which has continued for a long time.

**Etiology.**—The condition, unlike diabetes mellitus, affects more frequently younger persons, being rare in those over 50 years of age, relatively frequent in infancy, and most common between the ages of twenty and thirty.

As to sex, it is said to be much more frequent in males than in females, affecting two or three times as many of the former as of the latter. In my own experience I have found the disease nearly equally frequent in both sexes.

As to causes, the same uncertainty prevails as with diabetes mellitus. An examination of cases shows an association with a certain number of conditions, such as cerebral disease, including tumor of the brain, menin-

gitis, paralysis of the sixth nerve, sunstroke, cerebrospinal fever, falls and blows on the head; exposure to cold and the drinking of cold fluids, drunkenness, pregnancy, hysteria, emotion, especially fright, hereditary influence, syphilis, and previous disease, etc., but this does not show causation. The proportion, however, of cases in which the condition is associated with brain disease and injuries to the head, taken in connection with the fact of Bernard's discovery that puncture of the floor of the fourth ventricle above the diabetic center produces polyuria without glycosuria, makes it very likely that central nervous irritation, however induced, is at the bottom of the symptom. It is reasonable to suppose, too, that diabetes insipidus may be the result of some irritation, direct or reflex, of this center in the medulla oblongata, or of the sympathetic ganglia in the abdomen. The latter explanation also applies to cases of polyuria attending the presence of abdominal diseases, such as tumor, aneurysm, or peritonitis, though it is doubtful whether these should be regarded as cases of true diabetes insipidus.

**Morbid Anatomy.**—The essential morbid anatomy of diabetes insipidus would be the lesions of the nerve centers or sympathetic ganglia which may underlie the symptoms. But as these are often undiscoverable, or at least indefinite, it is impossible to describe them. Notably is the case with lesions of the third and sixth nerves. Associated central nervous lesions, when present, are found more frequently in the vicinity of the base of the brain.

**Symptoms.**—The *enormous secretion of urine* of almost spring-water-like clearness, and of specific gravity often as low as 1003, is the most conspicuous symptom, but more annoying, probably, is the *extreme thirst* which always attends it. These may be said to be the essential symptoms, others which may or may not be present being rather their consequence. Very constant among the latter are *dryness of the skin* and *absence of perspiration*. The health may be otherwise perfect, though *emaciation* and *weakness* are often present. The debility is sometimes extreme. Occasionally there are derangements of digestion, and sometimes also the appetite is ravenous, as in diabetes mellitus, though less frequently so.

These symptoms may occur suddenly in the midst of apparent health, or they may supervene upon others or be substituted for them, chiefly those of a nervous character, which may be the result of the nervous lesion causing the polyuria. Such symptoms are headache, restlessness, irritability, sleeplessness, what is commonly called *nervousness*, more rarely convulsions, delirium, paralyses—indeed, any one or more of the great variety of symptoms which result from organic or functional nervous disease. Sometimes these symptoms succeed upon the polyuria or are increased by it. It is certain that the milder nervous symptoms are sometimes the result simply of the inconvenience and annoyance caused by the two cardinal symptoms, polyuria and thirst. The patient is kept busy, as it were, night and day, in passing water. It is not surprising that such a patient should be fretful and irritable, and that sooner or later his health should be broken if the symptoms are not relieved.

In addition to the symptoms detailed, there are said to occur at times dryness of the tongue, epigastric and lumbar pains, diarrhea and impair-

ment of mental faculties and of the sexual function. In some instances there is the most extraordinary tolerance of alcoholic drinks, while in others there is an exaggerated susceptibility to their influence. A very slight lowering of the body *temperature* has been observed, amounting, however, to but a few tenths of a degree, and it is never below 97° F. (36.1° C.). In advanced stages of the disease *edema* of the lower extremities sometimes occurs.

*Physical and Chemical Characters of the Urine.*—As to the quantity of urine passed, it is enormous, exceeding often the amount passed in saccharine diabetes. As many as 43 liters (90 pints) are recorded by Trousseau, and one-fourth this quantity is common. It has been said, even, that the quantity secreted sometimes exceeds the amount of fluid ingested, but this is impossible for any length of time, unless water is absorbed from the atmosphere, which is not impossible. In point of fact, the water excreted is always a little less than that ingested, either as drink or in the solid food. As the quantity of urine excreted increases or its normal acidity diminishes, its color disappears and its specific gravity declines. In one case under my care the specific gravity was scarcely 1001, while the urine in moderate bulk was absolutely colorless. Again, a faint greenish tinge is exhibited by the urine in bulk.

As to the other constituents of the urine, it may be said in general that they are all increased, except possibly uric acid. Thus, the *urca* is increased to three and even four times its normal amount. In a case reported by J. M. Da Costa<sup>1</sup> the urea was diminished.

*Sulphuric* and *phosphoric* acids are both increased, and especially, according to Dickinson, the combination of phosphoric acid with the earths, lime, and magnesia. The same is true of the *chlorids*.

Of abnormal constituents, *inosit* has been found, and *albumin* very rarely, but care should be taken not to confound the polyuria with the slight albuminuria of a contracted kidney or with an albuminous polyuria in which there is no organic disease of the kidney.

Some of the accounts published as to the quantity of water consumed and excreted are almost incredible, yet they seem well authenticated. In illustration may be mentioned the following instances from Willis' work on "Urinary Diseases":<sup>2</sup> An artisan, 55 years old, had had constant thirst with commensurate diuresis since he was five years of age. From the age of 16 he had drunk, on an average, no less than two pailfuls daily. While in the Hôtel Dieu, to which he was admitted for an injury of the knee, he drank on an average 33 pints of water every day, often swallowing two liters, or about two quarts at a draught. He passed daily about 34 pounds of urine and one pound of feces. He otherwise enjoyed good health, and was the father of several children. The long duration of this case and the otherwise excellent health enjoyed by him are by no means exceptionable. Very little serious disturbance seems to result so long as water is supplied to quench the resulting thirst. In extreme cases patients have been known to drink their own urine.

An extraordinary flow of *saliva* was observed in one instance by Külz,<sup>3</sup>

<sup>1</sup> "Transactions of the College of Physicians of Philadelphia," third series, vol. i., p. 139, 1875.

<sup>2</sup> American edition, Philadelphia, p. 23, 1839.

<sup>3</sup> "Diabetes Mellitus and Insipidus," Marburg, 1875.

along with polyuria, in a hysterical girl of 18 years, from whom as much as 18.72 ounces (525 c.c.) were collected in 24 hours, while the quantity ranged during four months from 360 c.c. to the former amount. The quantity of urine passed during this time ranged from 200 to 260 ounces (6000 to 7800 c.c.). The increased flow of saliva may be explained by the fact that in some of the experiments of Eckhard,<sup>1</sup> Loebe,<sup>2</sup> and Gruetzner<sup>3</sup> puncture of the medulla oblongata was followed by ptyalism.

The *duration* of the condition varies greatly. Sometimes it continues through life with no inconvenience except that from the constant diuresis and thirst. Willis records a case lasting 50 years. On the other hand, it is seldom of brief duration; indeed, there is needed a certain chronicity in order to admit it in the category of diseases. One case is reported as terminating fatally in seven weeks. Under prognosis will be found some further information as to duration, but it may be said, in general, that most cases which terminate unfavorably and most which recover completely do so within a year. I had under my care for 11 years a lad of 17, who was able to work quite hard much of the time.

*No complications* arise except such as cause the disease or result from it. Among the latter is occasionally dilatation of the pelvis of the kidney, and atrophy of this organ is mentioned, due to pressure of the accumulated urine and resulting in a sacculated condition. The symptoms of the malady are almost always influenced, and sometimes even cut short, by intercurrent disease, especially of a febrile character, or even by a profound physical impression, as long-continued suppuration after a blister. The boy referred to was an aggravated choreic before he became diabetic.

**Diagnosis.**—The diagnosis of diabetes insipidus is very easy. The persistent thirst, polyuria, and absence of sugar from the urine are pathognomonic. The only possible error is mistaking the polyuria of chronically contracted kidney of *interstitial nephritis* for that of diabetes insipidus. In addition, however, to the fact that a careful examination for albumin will disclose it in the urine of contracted kidney, the quantity is never so large, nor is the thirst so extreme; so that it would seem only necessary to mention the possibility of such an error in order to avoid it.

**Prognosis.**—It is extremely unusual for a case of diabetes insipidus to terminate unfavorably unless there have been also present symptoms pointing to serious nervous lesion. Recovery is not infrequent. According to Roberts, of 67 cases collected, 16 are reported as complete recoveries and 14 ended fatally, nearly an equal proportion. The remaining 37 were still in progress. In cases of recovery or death the duration is comparatively short. Of the 16 recoveries, in nine the duration was less than a year; in one, four years; in two, 18 and 19 years, and in the remainder, some years. Of the 14 fatal cases, nine terminated in less than a year, one *in seven weeks*, and two in two months; the other two survived 18 months and 20 years, respectively. Of the 37 cases in progress, only five continued for a year or less. The remainder lasted for periods ranging from something over a year to 59 years.

These results seem to be tolerably independent of treatment. It may be said, therefore, that, as a rule, cases that last more than a year are likely

<sup>1</sup> Eckhard, "Beiträge zur Anat. und Physiol.," iv., p. 191.

<sup>3</sup> Gruetzner, "Pflüger's Archiv," vii., p. 552.

to continue, but ordinarily only require to be furnished with an abundance of water to keep them tolerably comfortable. According to Dickinson, cases due to drunkenness are more likely to run a severe and rapid course, usually terminating fatally within a few months, and one terminated thus in two months.

The disease appears to me altogether less serious than diabetes mellitus, and I quite concur with Senator, who says "it is rather a troublesome than a dangerous complaint." But Trousseau and Da Costa were inclined to consider it more serious than diabetes mellitus.

**Treatment.**—The treatment of diabetes insipidus would naturally resolve itself into the treatment for the disease of which it is the symptom rather than of the symptom itself; but as the former is very frequently undiscoverable, it must consist mainly of efforts to diminish the secretion of urine, and with it the thirst.

First, it is generally conceded that there should be no restriction in the drinking of water or other harmless fluids, for the diuresis is not so much caused by the great ingestion of water as the thirst is caused by the diuresis. It should be mentioned, however, that one or two instances are reported wherein improvement seems to have resulted from such restriction; and if, as in some cases, a habit of drinking has been the initial event, moderate restriction may be reasonable. Caution should be used in the administration of drugs, though my experience is not that of Dickinson, who says that "remedies designed to restrain the urinary secretion seldom fail to do harm." The older remedies are ergot, opium, gallic acid, and valerian; of all, the doses ultimately used are usually large. In one of my patients the symptoms subsided under the use of gallic acid after I had failed with full doses of ergot. In another, probably due to syphilis, the effect of the iodid of potassium was shown in an aggravation of the symptoms whenever it was discontinued and an amelioration when it was resumed. Of all drugs, I have found the iodid of potassium most frequently followed by improvement.

Trousseau and Rayer claimed extraordinary results from the use of valerian, the former using the fluid extract in large doses—2 1/2 drams (6 c.c.) a day, which was increased to 1 ounce (30 c.c.) daily in one instance. Rayer used the powdered valerian and the valerianate of zinc, giving the latter in pills in gradually increasing doses until 20 grains (1.25 gm.) a day were given. At the present day the more palatable elixir of valerianate of ammonia, combined with bromid of potassium, is to be preferred.

Reasoning from the effect of intercurrent disease and powerful physical and nervous impressions, Roberts suggests a large *blister* at the nape of the neck or epigastrium, according as the associated symptoms and the anamnesis point to the nervous or the digestive system, a suggestion which may be acted upon with advantage.

The constant galvanic current has been recommended, and in cases of spinal lesion may be expected to be of advantage. Both Seidel and Külz have used it with good results. The former applied one pole of a "strong battery" over the loins near the spine, and the other as deeply as possible over the hypochondrium, upon each side daily for five minutes. In eight

days the urine fell from 195.9 ounces (5957 c.c.) to 153.3 ounces (4600 c.c.) per diem, in three weeks to 76.6 ounces (2300 c.c.), and the next month 63.5 ounces (1904 c.c.), while the weight of the body increased nine pounds. Külz applied one pole of a battery of from 30 to 40 cells as high as possible in the nape of the neck, and the other to the loins or epigastrium, the best results being apparently obtained with the positive pole to the nape of the neck, and the negative first to the loins for four minutes and then to the pit of the stomach for four minutes.

Tonics and nervines, such as strychnin, iron, arsenic, salts of quinin, cod-liver oil, etc., are appropriately added to the treatment with a view to sustaining the strength of the patient, which is apt to fail. To these are to be added fresh air, sea air, exercise, and all possible favorable hygienic influences.

Hygiene is even more important than in diabetes mellitus, and should include a careful attention to the skin, warm clothing, warm baths, frictions, etc., in order to divert a portion of the circulation from the kidneys to the skin. The thirst should also be quenched when possible by bits of ice and acidulous fluids.

## OBESITY.

SYNONYMS.—*Adipositas universalis; Polysarcia adiposa; Corpulence.*

**Definition.**—Obesity may be defined as an inconvenient accumulation of adipose tissue in the body.

**Etiology.**—The most usual cause of an excessive accumulation of fat doubtless is overeating associated with an inactive life; and though it may be true of some fat persons that they are really moderate eaters, careful examination will generally prove that they are not. Heredity exerts an undoubted influence, and we find corpulence running in families. Commonly it does not make its appearance until after 35 years of age, but in this country particularly it is often seen earlier, in boys and girls of ten years and upward. Gouty and rheumatic persons are often fat, probably from the causes which produce these diseases.

Of foods, each one of the representative varieties, albuminoids, carbohydrates, and fats, is capable of contributing fat, deposited in fat vesicles in the body, and it has even been said that albuminoids furnish more of the fatty tissues of the body than the carbohydrates. Certain it is that a person may become corpulent who eats very little fat. In most cases, however, corpulent persons are found to be liberal consumers of all three of the food elements. While the carbohydrates are direct sources of fat production, it is generally conceded that they act largely by sparing the fats derived from other sources. They decompose and oxidize so rapidly, and thus give themselves up so readily to force production, that the stored fats are not called upon. Thus it is that sugars and starches indirectly favor corpulence. To this class belong also alcohol, and especially beer, which contains over five per cent. of carbohydrates, in addition to from three to four per cent. of alcohol, and it is well known that liberal beer

drinking furnishes a large quota of fat men. A second method in which large quantities of alcohol contribute to adiposis is by hastening albuminous metamorphosis, setting free non-nitrogenous substances readily converted into fat, which are deposited, among other situations, in the liver, giving rise to the fatty liver so constantly found in drunkards.

Another cause of corpulency is muscular inactivity. Fat is consumed by muscular contraction, and its absence must contribute to fat accumulation, and one need not go far to see its evidence in many who lead lives of idleness. Oertel has especially called attention to the fact that a simple diminished ingestion of fluids, without other changes in the diet, will reduce the amount of fat. The effect may be brought about in two ways; first, by diminishing the work of the heart and thereby favoring oxidation; second, by an effect which is not so much the diminution of fat as a withdrawal of water—a sort of “desiccation,” it is called by Strümpell.

The subjects of anemia and chlorosis often become fat, probably because of defective oxidation, growing out of a diminished supply of oxygen, which the crippled corpuscles are unable to carry in sufficient quantity.

Sexual continence probably contributes to corpulence, since eunuchs are well known to grow fat, and both women and men are disposed to grow fat when the sexual function begins to abate. Finally, corpulence itself favors the further accumulation of fat, first by interfering with the muscular activity of its subject, and therefore with the oxidation of fat, and, again, diminishing combustion by reason of a reduced demand for heat, the fat itself conserving heat by preventing its radiation.

**Morbid Anatomy.**—There is no essential morbid anatomy of corpulence. Incidentally the liver may become infiltrated with fat and enlarged, as may also the heart; later there may be dilatation of the latter. The lungs, too, may become infiltrated with fat. Even the blood-vessels may contain fat drops in the media and intima.

**Symptoms.**—A description is scarcely needed of the anatomical condition which constitutes obesity. The round, plump face, the double chin and hanging cheeks, the enormous girth of the body, the pendulous belly and elephantine arms, legs, and thighs need no further description. The labored, waddling gait is often conspicuous. The first evident indication of harmfulness due to corpulence is an increased frequency in the breathing-rate, at first on slight exertion and later independently of it. This is in part a true cardiac asthma—due, first, to the fact that the heart cannot push the blood through the lungs rapidly enough to permit its aeration at the ordinary breathing-rate; and, second, to the fact that the motion of the lungs is also restricted. The latter is due to the accumulation of fat over the thorax and in the mediastinum, and to the accumulated intra-abdominal fat and probably enlarged liver, which interfere with the proper descent of the diaphragm. This leads at first to cardiac hypertrophy, further stimulated by the extra work demanded of the heart in propelling the increased bulk of the blood; further augmented by resulting arteriosclerosis, and impeded venous circulation. Later the fatty infiltration of the muscular walls of the heart leads to further embarrassment in its action and to impairment of its nutrition, whence come cardiac weakness

and ultimate failure, with edema, pericardial and pleuritic effusion, and sometimes sudden death.

The pulse, hard to find, is usually frequent, but may be slow and irregular. The heart can be examined only with difficulty, on account of the large accumulation of fat, and the normal sounds are feeble and distant. The situation of the apex can be found only by the aid of the stethoscope. Intertrigo is often an annoying symptom, and great care is required to avert it. Interstitial nephritis may be superadded. By no means all corpulent persons run this course. Many lead lives of considerable comfort.

**Treatment.**—This consists in acting upon two principles: first, furnishing less food to oxidize, and, second, increasing the oxidation of the fat in the body.

The first is accomplished by cutting down the quantity of all kinds of food, but especially carbohydrates. Sugar should be prohibited altogether, and saccharin substituted, if sweetening is desired. Bread may be taken in small amounts, say two ounces, well toasted and with it a thin layer of butter; or hard biscuit may be substituted. A cup of tea or coffee with a little milk may be allowed; also a single egg at breakfast or luncheon; meat once a day. The latter may be of any kind, and with it may be taken green vegetables, such as peas, string-beans, tomatoes, cabbage, spinach, Brussels sprouts, lettuce, celery, and the like, omitting altogether rice, potatoes, and the farinacea in general. A little cheese may be allowed.

Only small quantities of fluid should be permitted at meals—just enough to aid in the solution and digestion of food. This may be tea, coffee, water, or skimmed milk, the first two without sugar or cream. Beer, porter, and sweet wines should be prohibited, but a glass or two of hock or claret with an alkaline mineral water may be allowed.

A diet of skimmed milk only is a sure way of reducing fat, and a start may be made with it, commencing with 2 ounces (60 c.c.) every two hours and increasing until from 6 to 8 ounces (180 to 240 c.c.) are attained. Unfortunately, very few persons will bear this treatment for any length of time, but, as stated, a beginning may be made with it, and when the patient tires, the other treatment just described may be instituted.

The second indication to promote oxidation is accomplished by exercise, gymnastics, walking, mountain-climbing, or cycling. The last has been effective in reducing the weight of the corpulent, and if combined with a proper diet, may be expected to do more. Massage is also useful, especially in co-operation with the Turkish bath and steam bath. These last help in the "desiccation" of the body, which in turn facilitates oxidation. Great difficulty is experienced in getting the patient to carry out the dietary and to exercise assiduously. Greatly in the way of exercise with a view to reducing adiposity is the unwieldy and cumbersome body and early fatigue which ensues on effort.

Certain health resorts have much reputation for their efficiency in reducing corpulence. Homburg, Marienbad, and Carlsbad are among the most celebrated of these, and I have seen many patients return thence after a cure of four to six weeks markedly improved in all the symptoms which come from obesity. The effect is probably altogether due to the strict diet, the systematic exercise, and the bathing, the massage, and the

laxative effect of the waters, although the physicians at the various spas which have a reputation for reducing obesity claim also that the effect of the sulphate of soda, which is a constituent of most of these waters, is to stimulate oxidation in the direction of the fatty structures, while limiting the metamorphosis of the nitrogenous substances. This intermittent method of treating obesity, by recourse to baths and springs once a year while the intervening period is spent in free eating, is not to be recommended. It is much better to adopt a continuous method which may not be as rapid, but is persistent.

*Medicinal Treatment.*—This is unsatisfactory. Thyroid extract has been administered with claimed advantage in doses of 1 grain (0.066 gm.) three times daily, and may be gradually increased to 3 and even 5 (0.35 gm.), with the same precautions as advised in the treatment of myxedema. Under this treatment the loss of weight is sometimes quite rapid, going to show that defective thyroid secretion may be a factor in causing obesity. The juice of the phytolacca berry has been recommended, but is not considered a safe remedy.

*Systems of Diet.*—Mention should perhaps be made of the so-called systems of diet for reducing corpulency, a number of which have been suggested. Those especially deserving of notice are the Banting system, Ebstein's method, the method of Dancel-Oertel, in addition to the mineral water cures. It is, of course, impossible in the limited space of a text-book to give these methods in full. The principles of their application will alone be considered and the student is referred to special sources for their description.<sup>1</sup>

(1) The Banting system consists in the administration of a large amount of albuminous food, especially lean meat to the exclusion of fats and carbohydrates; green vegetables being allowed *ad libitum*; (2) Ebstein's method demands moderation and restriction in the quantity of foods generally, and for the fat-forming carbohydrates substitutes fat itself, which does not increase stored fat and by diminishing appetite favors loss of weight. Sugar and potatoes are excluded; (3) the Dancel-Oertel method reduces especially the quantity of water and other liquids, only a maximum of 800 grams (about 1 1/2 pints) of water mixed with wine, and twice a day a cup of coffee or tea; of solid foods, nitrogenous alimentary substances and vegetables, especially such as contain little water, with fat only in such quantity as to render the dishes palatable. Oertel emphasizes the mechanical advantages of restriction in the use of water upon derangements of the vascular system; (4) the mineral water cures, as might be expected, are based chiefly upon the use of such waters, especially those containing sulphate of sodium and chlorid of sodium, the cold springs being preferred. The springs are thus classified: (a) cold waters containing sulphate of soda—Marienbad, Tarasp, Schulz-Tarasp, Frazensbad, Elster, Cudowa, and Rolitsch—carbonic acid waters; (b) hot springs containing sulphate of sodium—Carlsbad, Bertrich; (c) cold waters containing chlorid of sodium—Homburg, Kissengen, Nauheim, Neuhaus and Oeynhausien; in America the Saratoga springs; (d) springs containing iodine—Hall, Krankenheil, Salzschlirf, Kreuznach, Münster am

<sup>1</sup> "Dietetic and Therapeutic Hints to the Visitors of Bad Homburg." By Heinrich Will, 1893.

Stein. The drinking of waters at these places is combined with the use of saline, carbonated, mud, and steam baths.

*Prophylaxis* should not be overlooked especially in the case of hereditary tendency on the principle of the old claim of an "ounce of prevention" as contrasted with a pound of cure, and much may be accomplished in families in which there is tendency to corpulence.

For *Adiposis Dolorosa* see Nervous Diseases, subheading Neuritis.

## RICKETS.

SYNONYM.—*Rachitis*.

**Definition.**—"There is a disease of infants called the rickets, wherein the head waxeth too great, while the legs and lower parts wane too little" (Thomas Fuller, 1608-61). This quaint description of the celebrated English chaplain, written over 250 years ago, remains so nearly correct at the present day that I cannot forbear adopting it. It is further defined as a constitutional disease characterized by deformity in bones, due to cell overgrowth and deficiency in lime salts.

The term rickets is derived from the old English word *wrickken*, to twist. "The rickets" was evidently known for some time by the laity before it received its description by F. Glisson, in 1650, who suggested the change of name to rachitis from the Greek *ῥαχίς*, the spine.

**Etiology.**—Rickets rarely begins before the child is six months old or later than the age of 18 months, though a form was described by Sir William Jenner coming on as late as the ninth or even the 12th year; on the other hand, it may begin earlier, and the child may even be rickety in the womb. Yet it cannot be admitted that rickets is hereditary, in the usual sense of the term. The child may become rickety in the womb if the mother is feeble, underfed, and overworked, and if the father is weak at its conception, but not because the father and mother were rickety when children. Again, certain races tend to be rickety, especially the negro and the Italian. Foul air and bad food, absence of sunlight and exposure to dampness and cold, are more potent factors, and it is likely that a defective composition of the breast-milk, including a deficiency in the phosphates, is the strongest. Prolonged lactation may contribute to such deficiency. It is a disease of the city rather than of the country, and of the Continent of Europe rather than of America. Vienna, London, and Paris are prolific fields. In the first-named cities from 50 to 70 per cent. of all children brought to the clinics are said to be rickety. Parrot held that congenital rickets was a form of syphilis, basing this view on studies in the French capital. On the other hand, there is reason to believe that the changes in prenatal rickets are not identical with those of the postnatal form. The subjects of the former are usually still-born, are short of limb, and though the curves of the bones are exaggerated, there is no proliferating zone of cartilage between the epiphysis and apophysis, whence the term *achondroplasy*, suggested by Parrot, and *chondrodystrophia fetalis*, by Kaufmann. These terms are now used for a different variety of arrest of development to be considered later. Boys and girls are equally

liable to rickets. The syphilitic origin of congenital rickets is not, however, conceded by others.

Minute examination recognizes numerous cells in the spongy spaces in the bone. The studies of Kassowitz lead him to believe that a hyperemia of the periosteum, the marrow, the cartilage, and the bone itself is the fundamental condition responsible for the abnormal development. His views may be regarded as a refinement and development of those originally

FIG. 84.—Deformed Skeleton from a Case of Rachitis—(from *Atlas du Musée Dupuytren*).

suggested in 1650 by F. Glisson, who held that an excessive vascularity was at the bottom of the changes.

**Morbid Anatomy.**—This shades somewhat into symptomatology, and the two can scarcely be separated. The changes are mainly in the bones of the skull, the long bones, and the ribs. The first may escape if the disease sets in after the middle or end of the second year. The frontal and parietal eminences are exaggerated, while the top of the head and the occiput are flattened, the whole effect being toward making the head square or “box-

shaped." The fontanels remain open some time—until the second or third year of life—while the edges of the bones where they come together to form the sutures are thickened, though soft and yielding. In addition to these changes, or instead of them, there may be large areas of delayed ossification in the parieto-occipital regions, producing yielding spots, constituting the so-called *craniotabes* of Elsässer; but as *craniotabes* occurs in connection with syphilis and other wasting diseases of young infants exhibiting no other sign of rickets, and even in new-born infants, it cannot be regarded as pathognomonic.

In the *long bones*, such as the radius and ulna, swelling of the cartilage between the epiphysis and shaft is apparent. Owing to the rapid proliferation of the cartilage cells, resulting in a broad band of jelly-like material between the cartilage and the bone, a spongy structure is rapidly built up, deficient in strength and stiffness. Beneath the periosteum the same gelatinous material is deposited, and a spongy tissue is formed instead of

FIG. 85.—Ricky Chest—(after Gee).

Dotted line indicates the shape of the chest of a healthy infant about the same age.

normal bone. The process of bone formation does not proceed further. There is no deposit of lime salts. The periosteum is loosely attached. The long bones bend easily, especially the tibia, producing the characteristic bow leg, which may occur even before the child walks, when it is caused by sitting cross-legged. The thighs may also become bowed, the inner ends of the condyles prolonged downward and the tibia set outward, producing the "knock-knee." This does not, however, appear until the child begins to walk. In extreme cases the long bones may fracture. Sometimes both the femora and tibiae are bowed forward.

Quite as characteristic are the changes in the chondral ends of the *ribs* and in the shape of the chest. The former are enlarged and nodular at the junction with the bone, producing the well-known beaded appearance, which may often be recognized at a glance. The altered shape of the chest-walls, most marked in children who have had much cough, is due to the yielding of the soft costal ends of the cartilages and to a falling-in of the ribs at these points, while the sternum and cartilages are pushed forward, as seen in Fig. 85.

This is especially the case in the region between the fourth and eighth ribs, which may be so bent in as to form a vertical groove, increased during inspiration. Associated with this is sometimes a transverse groove, known as Harrison's groove, starting at the ensiform cartilage and passing transversely outward toward the axilla. At the same time the arch of the ribs

below may be widened and the belly thrown forward by the arching inward of the vertebræ. Extreme degrees of this chest deformity produce the prominent sternum constituting the "chicken breast" or "keel-shaped" thorax. Other changes in the bones are an exaggeration of the normal double curve in the clavicle; a bending of the humerus, usually at the insertion of the deltoid, sometimes produced by lifting the child by the arms; the radius and ulna may be curved and twisted, the articulations knotted and bulbous, loose and mobile, because of relaxed ligaments. The spine is also often altered, the change being for the most part an increase in the normal curve outward in the cervico-thoracic portion and inward at the lumbo-sacral. In other cases there is a lateral curvature. The scapula is often thickened. The pelvis is distorted and twisted, and the antero-posterior diameter is markedly lessened. The rickety pelvis is one of the well-recognized causes of dystocia. These changes are all the result of mechanical causes, such as the weight of the body or muscular traction.

*Chemical analysis* of rickety bones approximately reverses the normal proportion of organic and mineral constituents (calcium salts), reducing the latter to 35 per cent., while the gelatinous or organic matters amount to 65 per cent.

An *enlarged liver* and *spleen* are usually present, and sometimes also the mesenteric glands are enlarged.

**Symptoms.**—(See also Morbid Anatomy.) The earliest symptoms noticed are not invariably the same. There is usually *profuse sweating*, especially about the head and neck, and a mild degree of fever, as the result of which the child is inclined to throw off the bed-clothing. There is evident discomfort in being handled. The last symptom is apparently due to a *tenderness* of the skeleton, causing pain when the child is raised or danced up and down after the manner of amusing children. Along with these are the less distinctive symptoms of indigestion, indicated by nausea and vomiting, offensive stools containing partly digested milk, and flatulent distention, causing the belly to be prominent. Among other less essential symptoms may be mentioned *nervousness*, *restlessness*, *peevishness*, and *infantile convulsions*, the relationship of which to rickets is not accidental, and was pointed out by Jenner. *Tetany* and *laryngismus stridulus* are also often symptoms.

Concurrently it is noticed that teething is delayed, and we have the authority of Sir William Jenner that if there are no teeth at nine months there is something rickety about the child. But I am confident that I have seen dentition delayed after this time in children who were not rickety and who did not become so. In rickety children the teeth which are cut soon decay. *Muscular weakness* is characteristic, so that the child cannot sit up and makes but a feeble or no effort to walk. Such muscular weakness has been mistaken for paralysis, whence it has been called the *pseudoparesis* of rickets. Close upon these symptoms, or at least within two or three weeks of the first symptom, follow the *skeletal changes* described under morbid anatomy, page 910. The head is large in comparison with the face, and the skin is pale and thin, and the child has often an old and a wise look quite beyond its years. The appearance of the beaded ribs, the bowed

legs or "knock-knees," prominent belly, and curved spine often serve to make the diagnosis easy at a glance. The prominent belly requires some further description, as it varies somewhat at different periods. Before the child walks the normal cervical anterior curve may be increased and a posterior curve present from the first dorsal to the last lumbar vertebra, which may be recognized by holding the child up. After it begins to walk, however, the dorsal spine continues curved backward while the lumbar projects forward. The latter, therefore, contributes also to the prominent belly produced in part by the flatulent distention, and partly at times by an enlarged liver and spleen.

**Complications.**—These include especially bronchial catarrh and bronchopneumonia, the effects of which are aggravated by the conformity of the chest, the weakness of the ribs, and the feebleness of the respiratory muscles. Collapse of the lung is often a consequence of lung affections. Chronic hydrocephalus is a complication, while many of the conditions mentioned under symptomatology—viz., diarrhea, convulsions, laryngismus stridulus, and the like—may also be so regarded. The rickety child is weak and is vulnerable to all the illnesses of childhood.

**Diagnosis.**—This is usually easy, although, of course, all the symptoms detailed are not always present in their typical expression. The various spinal curvatures may be somewhat confusing. Thus, the question of *caries* may arise. But the rickety spine differs from that of *caries* by the wide curve, the absence of angularity, the flexibility of the spine, and the fact that by laying the child flat on its face the curve disappears. The other symptoms of rickets are also present. The lordosis of rickets produces a deformity resembling that of *congenital dislocation of the hip* and of *hip disease*, but here again other signs of rickets are present, while the distinctive signs of the disease in question are absent.

**Prognosis.**—Rickets is never in itself fatal, and the course is toward recovery. But the child is always in danger from the complications. Such are bronchitis, bronchopneumonia, laryngeal spasm, and convulsions. Walking is always delayed, and the child may be still unable to walk at the end of the second or third year. Mention has been made of the fact that the rickety pelvis in women is one of the most frequent causes of difficult labor.

**Treatment.**—We should seek to avert rickets by a judicious prophylaxis which consists in keeping the health of the mother at the highest point at all times; this, not by organic food only, but by a judicious admixture of salts such as are contained in the whole cereal grain, especially in wheat and barley. Frequent pregnancies and prolonged nursing, being acknowledged causes, should be interdicted.

The treatment of the child should be *dietetic, medicinal, hygienic, and operative or mechanical*. As the condition depends often upon the lack of ordinary good food, the simple addition of such food in lieu of the mother's milk, if this be found defective, may be all that is required, especially if it be possible to secure that rarely attainable article, a healthy wet-nurse. In the absence of this, beef-juice, the yolk of eggs, peptonized milk, and beef peptonoids may be substituted. Due consideration must, however, be paid to digestion in the selection of food, the stools should be examined

daily, and if undigested residue is found, the food should be changed. Pepsin and hydrochloric acid in doses adapted to the age of the child should be given, while the predigested foods are often highly useful. Cod-liver oil inunctions are invaluable, and though in some respects unpleasant, I have seen so many children seemingly wrested from death by their use that I value nothing more highly. Saccharine and starchy foods should not be allowed, except in very moderate quantities. The flours of the whole cereals, well baked and cooked as thin gruels and strained, make a suitable addition to the food, while the fruit-juices of orange and lemon may be given in small quantities. Medicines should be cautiously given. Among them are lime salts, as the hypophosphite of calcium or lactophosphate of calcium, 10 grains (0.65 gm.) of either three times a day, or lime-water, or the official syrups containing the salts mentioned. Doses should be carefully regulated, as digestion is feeble. Minute doses of iron, preferably the citrate or malate, may be given. Phosphorus was recommended by Kassowitz, and is indorsed by Wegener, Jacobi, and Strümpell, in doses of from 1/200 to 1/100 grain (0.00033 to 0.00066 gm.) two or three times a day dissolved in olive oil or cod-liver oil. The principle of the administration of these two drugs is different. The salts previously mentioned are convenient modes of administering calcium, while phosphorus is supposed to stimulate *bone growth*.

The hygienic treatment is more important than the medicinal. Fresh air and outdoor life are indispensable. If the child is warmly clothed and well protected, it may be taken out even in cold weather. *It should not be allowed to walk or even to sit up unless properly supported*—in fact, should be handled as little as possible.

Mechanical appliances may be employed with advantage, especially in lateral bowing, before the bone is hardened. Forcible manual straightening may also be employed in moderate grades of deformity, but should be relegated to the experienced orthopedic surgeon. After ossification is complete, deformities may be corrected by the orthopedic surgeon, by osteotomy, chiefly of the bones of the lower extremities, though the radius and ulna are sometimes operated on. Osteotomy of the pelvis has been suggested by Macewen in parturient women in whom delivery is impossible, but a recently revived operation, symphysiotomy, has made it unnecessary.

## ACHONDROPLASIA.

SYNONYMS.—*Chondrodystrophia fetalis; Epiphyscal dystrophy.*

A condition of arrested development, in which the shafts of the long bones cease to grow, while the flat bones, such as the cranial and scapulæ, developed from membrane obtain a normal growth. As a consequence the legs and arms are very much shortened, while the cranium and trunk are nearly normally developed. The bridge of the nose is depressed and the fingers are shortened and trident. The joints are enlarged from hyperplasia of the cartilaginous ends. Hence the subject, whether child or an adult, shows the effects of the disease more especially when sitting, the feet being high above the floor, while the trunk appears of normal length. The shortening is

increased by some tendency to bowing of the bones of the legs. The arrest of development begins usually in fetal life, although it is said to start at times after birth. Most children die before birth.

The cause is unknown, but the joints are enlarged from hyperplasia of the end cartilages, while the arrest in the growth of the diaphysis seems to be due to fibrous outgrowth from the periosteum of the shaft over into the epiphysis, restricting development of the former and producing premature union between the epiphysis and diaphysis.

Achondroplasia is to be distinguished from true dwarfism, rickets, and cretinism. The arrest of development in the true *dwarf*, is symmetrical and universal. In *rickets* the disease does not begin until the period of dentition. It is due to a primary hyperemia of the cartilages and bone, as the result of which all the bones are defective in lime salts. Hence the bones are soft, easily bent and twisted, producing especially deformity of the pelvis and legs. The chondro-osseous articulations of the ribs are enlarged, producing the rickety rosary. The head is enlarged and the forehead broad, resembling that of hydrocephalus, and above all there is a universal tenderness, causing the child to cry out when taken up. There is a tendency to profuse sweating about the head and neck and a slight elevation of temperature.

Cretinism is also a much later development, generally appearing when the child is six months old and is characterized by the idiotic, expressionless face, large open mouth, broad thick nostrils, and thick lips. The skin is dry and rough, swollen and edematous in appearance, but does not pit on pressure. The mind is sluggish and motion slow.

## OSTEOMALACIA.

**Definition.**—A softening which takes place in the bones by a solution of lime salts subsequent to their complete development.

**Etiology.**—The precise cause is unknown. A geographical distribution, however, exists, in accordance with which it is common on the Rhine, in Westphalia, in Eastern Belgium, and in Northern Italy. In this respect it is similar to goiter, which prevails in special localities, and it has been suggested on this account that it may be due to some local cause. It is for the most part a disease of adults between 30 and 40 years old, and of women more than of men. It is favored by unhygienic surroundings, such as damp and badly ventilated dwellings. Frequent pregnancy is supposed to be an exciting cause.

**Pathogeny.**—There is, primarily, *increased vascularity*. To this succeed a solution and disappearance of the *lime salts* of the bone. These take place from within outward, from the marrow cavity, dissolving out first the lime salts and then melting away the matrix, enlarging the central cavity until the cortical portion acquires a paper-like thinness. The whole bone has been compared to an "inflated and dried intestine." The product of the solution at first is a mucoid matter that mixes with the marrow. The latter soon loses its vascularity and gradually acquires a thinner but still viscid character and a yellow color. The periosteum is likewise

hyperemic and at first thickened. The process is compared to the artificial solution of the earthy salts from bone by hydrochloric acid, and it is supposed that the solvent agent exerts its effect from the medullary spaces and Haversian canals. It has been suggested that lactic acid is the solvent, as it has been found in the medullary canal and in the urine of subjects of osteomalacia. The process extends unevenly. *It differs from rickets in being a degeneration of fully formed bone, while the latter is a degeneration of developing bone.*

**Morbid Anatomy.**—The favorite seats of the process are the vertebræ and the bones of the pelvis and thorax; also of the thighs. The result in the former is an S-like curve of the spinal column, due to a kyphoscoliosis or backward curvature of the dorsal and a lordoscoliosis or forward curvature of the lumbar part, while the cervical portion in connection with the upper dorsal portion protrudes anteriorly. The thorax is distorted and compressed laterally, while the sternum is prominent and bent. The pelvis is also compressed laterally, the symphysis projects like the prow of a ship, and the sacrum projects forward producing a deformity of the pelvis often discoverable only by internal examination.

**Symptoms.**—The first symptom is usually *pain*, deep seated and severe, oftenest in the sacral region, nape of the neck, back, and thighs, and this pain is persistent and increased by motion, giving rise to a hobbling gait. There is also *tenderness*. *Walking*, therefore, becomes more and more *difficult* and finally impossible, and the patient takes to bed. But this affords no relief, the pain being kept up by the pressure of the bed-clothing and the weight of the body. In the meantime the deformities described under morbid anatomy take place, though those of the pelvis are less obvious externally. *Difficult labor* is an inevitable consequence should the patient conceive, just as it is in rickets. *Dyspnea* is a frequent consequence of compression of the lung by the distorted thorax. *Fractures*, complete and incomplete, are frequent events, even of the ribs as well as of the extremities. In this respect osteomalacia differs from rickets, in which the bones bend but do not break. Such fractures repair imperfectly. Sometimes, on the other hand, the limbs are soft and yielding, and may be bent like a lead pipe. The bones of the head and face are for the most part exempt, though the head is much bent toward the chest, making the stature lower.

The *general condition* of the patient often remains for a long time unaltered. There is little or no fever. The organic functions are normally maintained. The presence of lactic acid in the urine has been mentioned. It is said that phosphoric acid is diminished. Albumin is also sometimes present. Calcareous concretions have been found in the kidneys and bladder.

**Diagnosis.**—At first there may be doubt as to the nature of the disease, but as the characteristic symptoms present themselves, its real nature becomes evident. *Disease of the vertebræ and cord* has been confounded with it, but the hobbling gait peculiar to it does not usually resemble any of the gaits of spinal disease. Being a disease of adults, it is not likely to be mistaken for *rickets*. Moreover, it is a disease which affects the shafts of bones rather than the epiphyses.

**Prognosis.**—The disease is usually ultimately fatal, although death is often long deferred and the course is chronic—from two to ten years. Arrest sometimes occurs, but is only temporary. The disease again starts, and its course is generally irresistible. Death commonly takes place from exhaustion or from some complication like pneumonia. Recovery is not impossible. The so-called cystic degeneration of bone is said to be a consequence.

**Treatment.**—Theoretically, the indications are the same as for rickets—viz., to supply the blood with lime salts. Practically, they have not proved of much value. They may, however, be prescribed in the shape of the syrup of the lactophosphate of lime in the dose of from 1 to 2 fluidrams (4 to 8 c.c.) or the syrup of the hypophosphates in the same dose or the latter in combination with iron or with cod-liver oil. Proper hygiene and good food are of the utmost importance. Phosphorus itself is a drug highly commended. (See Rickets.) Strümpell gives the following prescription for it:

℞ Phosphori,	0.01 gm. (3/20 grain)
Olei amyg. express,	10.00 gm. (150 grains)
Misce, deinde adde	
Pulv. acacie,	} āā 5.00 gm. (75 grains)
Syrupi, simplicis,	
Aquæ dest.,	
M. et Sig.—Two to four teaspoonfuls a day.	80.00 gm. (1200 grains)

Women who are subjects to osteomalacia should be warned against marriage.

## MULTIPLE MYELOMA.

**SYNONYMS.**—*Myelopathic Albumosuria; Kahler's Disease.*

**Definition.**—A disease characterized by pain in the bones, especially those of the trunk, the presence of Bence Jones' albumose in the urine and a more or less rapidly fatal course. It differs from osteomalacia in that the urine contains albumose while that of osteomalacia does not. Up to June, 1904, 35 reliable cases were published.

**Morbid Anatomy.**—The cases which have come to autopsy have revealed a more or less diffuse neoplasm, sarcomatous in structure, invading simultaneously several bones of the trunk, without the occurrence of metastases. It consists of round cells resembling those of the normal cells of the bone-marrow. This neoplasm replaces the bony structure in the cavity of the bone sometimes causing swelling of the bone and spontaneous fracture.

**Etiology.**—The condition has as yet been traced to no cause.

**Symptoms.**—Along with albumose in the urine, severe intermittent pain in the affected bones is the most constant symptom. The pain may be in the thigh, in a part or all of it; in the bones of the arm, the sternum or the ribs, or the spinal column. The pain is described as dull and continuous. The pain disappears at times regardless of treatment. There is at first no tenderness, but as the disease continues points of tenderness develop when moderate pressure or even the physician's percussion may cause intense

pain. When the disease is established, motion of the body, even that of breathing, aggravates the pain. As it continues, extreme weakness develops with anemia. There may be also attacks of nausea and vomiting with intermittent diarrhea, although the viscera, including liver, spleen, and lymphatic glands are normal. There is no fever, the temperature not exceeding 99; the pulse is moderately frequent, rising to 120. There is no edema of the extremities, though death may be preceded by edema of the lungs. Pleurisy has been found antecedent as in Meltzer's case.<sup>1</sup>

*Urine.*—As stated, the urine contains large quantities of albumose, one of the intermediate products of albumin digestion between albumin and the ultimate product peptone.

Albumose is thus recognized: It is precipitated from urine by nitric acid, more abundantly than albumin, as a rule, but is redissolved by heating to the boiling temperature. When urine containing Bence Jones' albumose is gradually heated, it becomes turbid at a comparatively low temperature, not more than 130° F., and coagulates when heated a little more. When the temperature reaches the boiling-point the coagulum redissolves leaving only a slight turbidity. As the urine cools the albumose precipitates again, and again dissolves on boiling. The quantity of urine is not materially altered being from 1200 to 2500 c.c. with a specific gravity of from 1015 to 1025. A peculiar feature is the absence of tendency to decomposition, although in the course of time the albumose disappears. If, however, thymol be added, the albumose is retained many months after the urine is passed, as shown by Meltzer.

The course of the disease is usually rapid, although one case described by Kahler, that of a physician, lasted over eight years.

**Diagnosis.**—The presence of albumose is pathognomonic of myeloma, and cases probably escape detection because of deficient examination of the urine, since routine examinations for albumin does not disclose albumose, hence the urine of all cases of pain in the bones of the kind described, should be tested for albumose by suitable tests.

**Prognosis.**—The termination is invariably fatal usually after a rapid course, but sometimes the disease is more prolonged as in the case of Kahler's physician referred to.

**Treatment.**—No remedy has been found which can be regarded in any sense as curative. A local application of ice in Meltzer's case relieved the pain.

## PURPURA.

SYNONYMS.—*Morbus maculosus; Peliosis.*

**Definition.**—A name given to several dyscrasic states, all attended by subcutaneous or submucous extravasations of blood. Such extravasations do not disappear on pressure, and vary in size from that of a pin-point to areas a centimeter or more in extent. When minute or punctiform, they are called petechiæ; when larger than this, ecchymoses. An indisposition on the part of the blood to coagulate is commensurate with the tendency to

<sup>1</sup> Meltzer, S. J., "Myelopathic Albumosuria." Reprint from "New York Medical Record," June 18, 1904.

extravasation. Purpura is always a symptom rather than a disease, but in certain conditions it forms the most conspicuous symptom of a group which scarcely admits of any other classification. In this event an adjective term derived from some more conspicuous one of these symptoms, or from the name of some investigator who has described the condition, is added to give precision. In other instances it is so purely a symptom and plays so minor a rôle in the disease that it is called symptomatic. Under any circumstances it is not always easy to keep the varieties distinct.

#### SYMPTOMATIC PURPURA.

This includes the forms of purpura in which the petechiæ and ecchymoses are usually of minor importance. In a few instances in which the dyscrasia is very great they become by their number and extent indices of the degree of such dyscrasia. Such are:

1. The purpura which often invades the extremities of the old (senile purpura).

2. The purpura of the infectious diseases (infectious symptomatic purpura), especially typhus fever, smallpox, scarlet fever, measles, pyemia, mycotic endocarditis.

3. The purpura of poisons (toxic symptomatic purpura)—as, for example, that which occurs in connection with venomous snake-bites, or with overdoses of certain medicines, such as ergot, mercury, copaiba, quinin, iodid of potassium, and others. Certain persons possessed of idiosyncrasies acquire purpura on the administration of much smaller doses. In these the extravasations may occur anywhere on the body.

4. The purpura attending certain diseases which, though *not infectious*, induce cachectic states—viz. (cachectic symptomatic purpura), cancer, tuberculosis, Bright's disease.

5. Certain nervous diseases (neurotic symptomatic purpura), including locomotor ataxia, myelitis, rarely neuralgia, and hysterical states associated with the bleeding points known as *stigmata*.

6. Mechanical symptomatic purpura, when induced by some cause resisting the onward movement of the blood, as a paroxysm of whooping-cough, croup, or an epileptoid fit.

The diagnosis of these conditions is a purely etiological one, and the prognosis and treatment are those of the diseases causing them.

#### SCURVY.

SYNONYM.—*Scorbutic Purpura*.

**Definition.**—A disease characterized by a dyscrasic state of the blood, associated with subcutaneous or submucous hemorrhages, by a peculiar spongy state of the gums, and extreme general weakness.

**Etiology.**—Less than half a century ago the idea of scurvy was always associated with the seafaring life, since sailors were its chief victims, though almshouses and prisons also held their complement. In the food of these persons fresh vegetables and vegetable juices and organic salts were want-

ing. So it came to be acknowledged that such privation was responsible for scurvy, and proof of this belief was thought to exist in the fact that with the quicker voyages of ships and a supply of suitable food, scurvy had almost vanished from the nosology. It appears, however, that, after all, the effect of such causes is predisposing and the disease may be really infectious, being due to some as yet undetected organism. Especially firm in this belief are those who have, by reason of its distribution, had the best opportunities for its studies—as, for example, in Russia, where the disease is endemic, sometimes epidemic. Finally, it turns out that not only sporadic cases, but even epidemics, occur quite independently of the dietetic causes named.

At the present day scurvy has become a rare disease, but is still met in camps, prisons, almshouses, and situations where the food causes named exist along with dampness, foul air, and depressing influences generally, among which nostalgia is supposed to be especially potent. The effect of the food causes has been held by Garrod and by Ralfe to be the deficiency of the potassium salts, more especially of the alkaline carbonates derived from the conversion of the organic salts of the vegetable and fruit-juices—viz., the malates, tartrates, citrates, and lactates. Experimental proof of the latter is adduced by feeding animals upon acid salts, the effect of which is to impair their nutrition and to produce dyscrasic states of the blood similar to those of scurvy and followed by like extravasations.

The disease attacks the old and young of either sex, though the old are more susceptible, and it happens, probably from accidental circumstances, that more males are affected than females.

Reference should be made to the observations of my colleague J. P. C. Griffith,<sup>1</sup> who has shown that scurvy has appeared in children who have been too long fed on certain artificial infant foods.

**Morbid Anatomy.**—This consists in (1) alterations of the blood; (2) the extravasations of blood, which may be anywhere—subcutaneous, sub-mucous, intermuscular, and interstitial. The blood changes are not distinctive. The blood is dark and thin, the blood-corpuscles and hemoglobin are concurrently reduced in number, and there is no leukocytosis. Rarely there is even sloughing of the skin and mucous membrane, leaving ulcerated patches in the skin and bowels. The spleen is soft and enlarged, and there may be degenerative changes as well as hemorrhages in the kidneys, liver, and muscles.

**Symptoms.**—The more evident symptoms are the *changes in the gums*, and the *deep-seated and superficial hemorrhages*.

The *gums* are swollen, soft, and spongy, with disposition to bleed easily. In the more severe cases there is ulceration, with loosening and falling out of the teeth, the tongue is swollen, and the breath excessively foul. The gums of young children and of the aged are more often uninvaded. In rare cases only is there *necrosis* of the jaw.

The *hemorrhages*, always petechial, appear usually first in the lower extremities, then on the arms and trunk, but they occur anywhere as roundish, dark-red spots which may assume larger size. They are rare in

<sup>1</sup> "The Relation of Scurvy to Recent Methods of Artificial Feeding," "N. Y. Med. Jour.," Feb. 23, 1901; "Scurvy, Not Rheumatism," "Phila. Med. Jour.," Feb. 2, 1901; "American Pediatric Society's Collective Investigation on Infantile Scurvy," "Arch. of Ped.," July, 1898.

the face and scalp, and are less common under the mucous membranes and in deep-seated tissues. Subperiosteal hemorrhages may occur. Nasal hemorrhages may be frequent, melena and hematuria rare, hematemesis and hemoptysis still rarer. The extravasations are slow to disappear, even when recovery takes place. The occasional sloughing has been referred to. A residual, slowly healing ulcer results.

Other symptoms are *debility*, extreme in severe cases, and *anemia*. The *pulse* is small, feeble, and frequent, and corresponds to the heart's action, which is sometimes irregular; more rarely is it slower than in health. The *temperature* is normal, rarely somewhat elevated. *Sore throat* is mentioned as a premonitory symptom. In bad cases *nephritis* and *endocarditis* occur. Articular swelling is an occasional symptom; it is one of the results of the dyscrasia; so are *wheals* and *vesicles*.

**Diagnosis.**—This depends, as stated, on the etiology, the gingival changes, and the hemorrhages. It is these which chiefly distinguish it from the other forms of purpura.

**Prognosis.**—Sporadic cases always get well, and epidemic cases usually, unless too far advanced before coming under treatment.

**Treatment.**—This is usually most satisfactory when the necessary conditions are fulfilled—a restored wholesome hygiene and suitable food. Good ventilation and outdoor life in healthy localities, with plenty of fresh vegetables, fruits, and fresh meats, ordinarily suffice to accomplish a prompt cure. It is usual to give lemon and orange-juice as the types of the fruit-juices. Tonics and roborants, of which iron, quinin, and strychnin are the type, are the medicines needed. Calcium chlorid may be used in doses of from 5 to 15 grains (0.3 to 1 gm.). Antiseptic and astringent mouth-washes should be used, and ulcers should be stimulated by local applications, of which nitrate of silver in solution is the best.

#### INFANTILE SCURVY.

**SYNONYMS.**—*Barlow's Disease; Periosteal Cachexia.*

**Definition.**—A cachectic condition of infants, associated with subperiosteal hemorrhagic extravasations.

**Historical.**—In 1878 and again in 1882 Cheadle published in the "Lancet," and about the same time Gee published as occurring in England, cases of a cachexia in very young children, associated with hemorrhage, and due to imperfect food-supply. About the same time Barlow made an exhaustive study of the subject and gave his results in the "Medico-Chirurgical Transactions," volume xlvi., 1883, and in the Bradshaw Lecture for 1894. W. P. Northrup published a paper on "Scorbutus in Infants," describing cases in this country, in the "New York Medical Journal," December 12, 1891, and another with Crandall in the same journal, volume i., 1894.

**Symptoms.**—Barlow's account is graphic, almost sensational, but I gather that the condition exists essentially in a *hemorrhagic subperiosteal extravasation*, causing thickening and tenderness in the shafts of the bones beginning in the lower extremities, but invading also the forearm and arm, more rarely the scapula, vault of the cranium, and face. Rarely there is intermuscular extravasation. The resulting *tenderness* and *pain on motion* cause the child to keep quiet, with the legs drawn up, and to cry out when

handled. The lesions are symmetrical. The *joints* remain *free*. The sternum and adjacent cartilages and a small portion of the contiguous ribs may be sunk bodily back as though subjected to violence. There may be a sudden *prolapse of an eyeball*. Along with these symptoms are profound *anemia* and *erratic temperature*, which may be subnormal, normal, or as high as 102° F. (38.9° C.).

The disease occurs at any period after four months, but it is most common from the ninth to the 18th month, and is of rapid development.

**Treatment.**—It has been ascribed to the use of the proprietary forms of condensed milk and preserved foods for infants. These should therefore be omitted, and fresh cow's milk substituted, with beef-juice and strained gruel made from whole-grain cereals only. Orange-juice or lemon-juice in water may also be given in moderate doses. Under this treatment the prognosis is favorable and recovery prompt.

### ARTHRITIC PURPURA.

SYNONYM.—*Rheumatic Purpura*.

**Definition.**—The characteristic feature of arthritic purpura is a joint involvement. Hence it is also called rheumatic purpura, though its rheumatic nature cannot be said to be absolutely settled. Rheumatoid purpura would be more accurate.

**Symptoms.**—Three varieties are distinguished:

1. *Simple Arthritic Purpura*.—This is a mild form, most frequent in children. The *articular pain* is very mild and attended with but slight fever. The *spots* are found for the most part on the *legs*, more rarely on the trunk and arms. There may be *digestive derangement*, manifested by loss of appetite and diarrhea. The condition terminates favorably in a week or ten days. It may be associated with a mild degree of anemia.

2. *Peliosis Rheumatica*.—Schönlein's disease. This is a much more serious affection from every standpoint, occurring usually in young persons from 14 to 30. The *joint* symptoms are pronounced and multiple, and there are decided *swelling*, *pain*, and *fever*, with a temperature of 101° to 103° F. (38.3° to 39.4° C.). The *eruption* first appears on the legs near the affected joint, but I have seen it present extensively on the arm, distant from the joint, followed by sloughing; in the same case were retinal hemorrhages. *Sloughing* and *necrosis* of the skin even have occurred. It may be simply purpuric, or may be associated with urticarial wheals—exudative—or vesicles (pemphigoid purpura). When severe, it is often associated with hematuria and hemorrhagic nephritis with edema. I saw, with Agnew and Osler, a remarkable case in which the latter condition hastened a fatal termination by uremia. Endocarditis is also a complication.

3. *Henoch's Purpura*.—This is a variety occurring most often in children, but also in adults, characterized by *severe gastro-intestinal* disturbance *in addition to the previously named symptoms*. There are pain, vomiting, and diarrhea, rarely intestinal ulceration and perforation with fatal peritonitis. Acute enlargement of the spleen has been observed.

Here, also, recovery is the rule.

**Diagnosis of Arthritic Purpura.**—The diagnosis is easy by reason of the associated joint symptoms, but the same doubt exists as to a true rheumatic nature in all forms.

**Prognosis.**—This is regarded as favorable, but fatal terminations do occur, especially in peliosis rheumatica in which there is nephritis. Relapses in this form may occur at the same time of year for several years in succession.

#### PURPURA HEMORRHAGICA.

SYNONYM.—*Morbus maculosus Werlhofii*.

**Symptoms.**—This form of purpura is characterized by *hemorrhage* from the mucous membranes, including nose, mouth, palate, stomach, and intestinal canal, in *addition to extensive subcutaneous ecchymosis*. The brain and kidneys and serous membranes may also be seats of hemorrhage—apoplectic symptoms indicating the first. A *prodrome* of languor and weakness may precede for a couple of days, to be succeeded by a rapid succession of ecchymoses and hemorrhages. More decided constitutional disturbances follow, including typhoid symptoms and fever, though the latter is mild and may be altogether absent, even in severe cases.

In the *purpura fulminans* the hemorrhages are mainly confined to the skin, producing confluent ecchymoses and dense infiltrations covering large areas, with sanguineous blisters. The internal organs, on the other hand, remain free, while the urine and the bowel evacuations are natural. At times there is fever; at others, not. Hemorrhagic purpura has occurred after pneumonia and scarlet fever, and again in children apparently healthy.

**Diagnosis.**—As to diagnosis, *scurvy* is almost the only condition liable to be mistaken for purpura hemorrhagica. In the latter the gums are intact, and there is an absence of the conditions favoring scurvy.

**Prognosis.**—The termination is usually favorable in from ten days to two weeks, although there may be fulminating cases, usually in children, terminating fatally in 24 hours. Severe cases recover more slowly.

**Treatment of Arthritic Purpura and Purpura Hemorrhagica.**—Treatment is best directed to improving the quality of the blood and to building up the general tone rather than to the control of the hemorrhage, though the latter must not be entirely ignored. Almost all that has been said of the treatment of scurvy is applicable to these forms of purpura. Iron and arsenic are the typical roborants and blood-builders, to which nutritious food, including vegetable-juices, is to be added. Arsenic should be given in full doses, beginning with small ones and ascending rapidly.

In the articular forms the salicylates and salicin should be used in such doses as the stomach will tolerate.

Of the astringent remedies found serviceable may be mentioned ergot, in doses of from 5 to 30 minims (0.3 to 2 c.c.) of the fluid extract; per-sulphate of iron, in doses of from  $\frac{1}{4}$  to  $\frac{1}{2}$  grain (0.016 to 0.032 gm.); acetate of lead, 1 to 3 grains (0.0648 to 0.2 gm.); dilute or aromatic sulphuric acid, 5 to 15 minims (0.33 to 1 c.c.).

## HEMORRHAGIC DISEASES OF THE NEW-BORN.

*Hemorrhagic Syphilis of the New-born.*—Usually about from the *third* to the *fifth* day after birth hemorrhage is observed at the navel of the child, or it may occur earlier. Blood also flows from the mucous membranes of the mouth, the bowels, and the kidneys. The skin becomes jaundiced. The stomach rejects food, and though it may appear well nourished at birth, the child rapidly wastes, and dies at the end of a *week* or *ten* days. The autopsy discloses *syphilitic lesions* in the liver, lungs, nasal passages, and elsewhere.

*Epidemic Hemoglobinuria of Infants, or Winckel's Disease.*—As described by Winckel in 1879, in an epidemic at the Foundlings' Hospital, at Dresden, the first symptoms, noticed usually on the *fourth day after birth*, are a bluish tinge on the skin of the face, trunk, and limbs, with a more or less icteroid hue. There are *fever*, *rapid breathing*, and sometimes *cyanosis*. Occasionally there are *vomiting* and *diarrhea*. The *urine* is light brown, albuminous, contains methemoglobin, and deposits a sediment consisting of epithelium and tube-casts. The *blood* contains an excess of leukocytes and numerous granular bodies. The child *lives*, on an average, *two days*, though in one case death supervened in nine hours. The autopsy in this case disclosed yellow staining of the skin and internal organs; the spleen was large, hard, and darkened; the kidneys were dark brown in color, their tubules being filled with granular pigment; the liver and heart were fatty. There may be punctiform hemorrhages on the surface of the internal organs. There is no septic condition of the umbilical vessels. An infectious origin is not unlikely.

*Acute Degeneration of the Internal Organs of the New-born, or Buhl's Disease.*—How far this disease, described by Buhl in 1861, differs from Winckel's disease, or the latter from the former, remain to be settled, for, in the first place, fatty degeneration of the heart and liver is found in many cases of Winckel's disease, while in others there is found the general fatty degeneration of kidneys, liver, heart, etc., described by Buhl. In the second place, infants surviving the first few hours after birth in Buhl's disease have the same symptoms as those described under Winckel's disease, while the other symptoms, such as minute hemorrhages and bile staining of various internal organs, are not essentially different.

*Morbus Maculosus Neonatorum.*—Still another form of hemorrhage from one or more of the surfaces, and especially of the alimentary canal, in the new-born is described under this title. The bleeding generally begins within the *first week*, but may be as late as the second or third week. *Hemorrhage from the bowels* (*mekena neonatorum*) is the most frequent form, but it may be from the stomach, mouth, nose and navel, or from the navel alone. It may be accompanied by hematogenous jaundice—indeed, by any or all the symptoms described under Winckel's disease—but differs in the occasional presence of *fever* and apparent *absence of postmortem* lesions, though ulcers of the esophagus, stomach, and duodenum have been found. It is generally fatal in from one to seven days. All these conditions can be appropriately considered as forms of purpura.

**Treatment.**—The treatment of hemorrhagic affections of the new-born

often avails little, though recoveries sometimes take place, especially in the last-described form, in which C. W. Townsend reports 19 recoveries out of 50 cases collected.

The treatment demands *absolute rest* with the head low. Even the exertion necessary in nursing at the breast should be interdicted, and the infant should be fed, while recumbent, with a teaspoon, using also the mother's milk if this be not condemned as worthless. The utmost care in providing *uniform warmth* should be taken. This can be best accomplished by means of an incubator. One may be improvised, as suggested by F. A. Hoffman, out of a box in the bottom of which hot bricks are placed. Over them is swung the infant's bed. A thermometer is so inserted as to be readily observable, and the temperature is kept at 90° F. (32° C.). To control the hemorrhage ergotin may be used hypodermically, one grain or minim (0.06 gm.) every six hours. Gallic acid may be given by the mouth in 1 grain (0.06 gm.) doses, but extreme care should be taken in using remedies by the mouth.

## HEMOPHILIA.

**Definition.**—A hereditary vice of constitution, manifested by a tendency to uncontrollable hemorrhage, occurring either spontaneously or as the result of trifling injury.

**Etiology.**—No explanation has as yet been offered of hemophilia. Some agency, be it a bacterium, a toxin or chemical solvent, so destroys the integrity of the vessel-walls as to permit the transudation of blood. While the disease is usually hereditary, it is sometimes though rarely acquired. While individual instances of fatal hemorrhage were observed centuries ago, the first mention of it seems to have been by an Arabian physician who died in 1107. "Families of bleeders" were first described in this country. Of great importance because of its bearing on the marriage of these hemophilic subjects is the fact that the tendency is transmitted through the female line rather than through the male. Thus, if a man belonging to a bleeding family who is himself not a bleeder marries a woman who is healthy and not a bleeder, his offspring are usually exempt from the affliction. On the other hand, a woman a member of a bleeding family marries, and even if she be exempt herself, she may have offspring who are bleeders. These facts were pointed out by Grandidier. Not all the children of such persons are afflicted, while the male members are more frequently subject than females. The families of bleeders are apt to be large, and their appearance is that of health, as a rule. It is said that blondes predominate, with delicate, soft skin and distinct, distended veins.

**Morbid Anatomy.**—Two facts of importance have been recognized—viz., that in some instances the walls of the blood-vessels have been found thin with a fatty degeneration of the intima, and in many there is deficient coagulability of the blood. A third fact, which adds nothing in explanation of the hemorrhagic tendency, is a superficial situation of the arteries. A striking case of this kind in a blonde woman, formerly a

bleeder, was for a time under my observation. Beyond this we know nothing, notwithstanding the exhaustive studies of Wickham Legg, Grandidier, and Hössli.

**Symptoms.**—Attention is commonly called to a bleeder by the occurrence of a hemorrhage difficult to control, though induced by some trifling cause. The extraction of a tooth is one of the most frequent of these events. It may be the prick of a pin, or a scratch, or a slight cut, as in vaccination, or no cause may be discoverable. The tendency may manifest itself at the cutting of the umbilical cord at birth, or in Jewish children at the circumcision. On the other hand, the same accidents which are without result early in life may induce the hemorrhage later. Uncontrollable epistaxis is one of the most frequent manifestations, occurring in 169 out of 334 cases collected by Grandidier. It may be induced by simply blowing the nose. Other situations are the mouth, stomach, ear, and eyelids. On the other hand, hemorrhages rarely occur in the interstices of organs, and though interstitial hemorrhages do occur, they are usually the result of trifling blows, when the well-known "black-and-blue" appearance is produced. The absence of interstitial hemorrhages, except as the result of some cause, however trifling, may be said to distinguish hemophilia from the acquired hemorrhagic tendency.

Menstruation may be very copious in women, but not fatal, while the natural loss of blood in child-bearing is rarely augmented. In a case which came to my notice the hemophilia disappeared with the appearance of the menopause, soon after which it was substituted by a chronic nephritis.

The external hemorrhages, including those of the mouth and nose, may be profuse and even fatal. They often last 24 hours or longer. When checked, reaction from them is rapid, and the victims quickly resume their natural appearance, though repeated hemorrhages may engender a permanent anemia.

Joint affections may be associated with this as with the acquired hemorrhagic tendency. They involve usually the larger joints, and may include swelling and pain, with fever, producing a close resemblance to rheumatism, or there may only be pain.

**Diagnosis.**—This is apparent if the family tendency is known, and any alarming hemorrhage without sufficient cause should excite inquiry.

**Prognosis.**—Sooner or later hemophilia is apt to be fatal, though there may be many severe hemorrhages before the last one comes. *The younger the subject, the more serious the outlook.* It does, however, happen that the tendency is outgrown, subsequent attacks becoming milder and milder. In the majority of cases death takes place between the first and the eighth year, and adolescence once survived, the chances of outgrowing it are greatly increased.

**Treatment.**—This may be prophylactic. The children of bleeding families should be carefully guarded against traumatic causes, however slight, while they should be carefully looked after from the hygienic and nutritive standpoints. Fresh air, daily bathing, outdoor exercise, and judicious measures intended to harden the threatened subject should be practiced. Plain, wholesome, and nourishing food should be given, and due attention should be paid to digestion. As a part of the prophylactic treat-

ment, too, is discouragement from marriage especially in the case of women.

During an attack absolute quiet must be enjoined. Styptics are to be employed locally, rather than internal medicines. Of styptics, the solution of the perchlorid or persulphate of iron is the best, beginning at first with dilute solutions and increasing to the full strength of the official solution if necessary. Tannic acid is another good styptic, and if at hand, may be dusted well upon the part or applied on cotton to cavities. In epitaxis the nose must be plugged if the ordinary methods of applying these agents fail.

Though little is to be expected from internal remedies, they may be tried. Wickham Legg recommends the tincture of the perchlorid of iron in  $1/2$  dram (2 c.c.) doses every two hours. Ergotin and acetate of lead may also be used. Suprarenal extract and its active principle, adrenalin chlorid, have also been employed for hemophilia, the former in doses of 5 grains every three hours. Adrenalin chlorid is used in the shape of a 1 to 2000 solution applied directly to the bleeding point; or a fluidram (4 c.c.) of a 1/1000 solution may be added to a  $1/2$  pint or 1 pint (250 to 500 c.c.) of normal salt solution and administered by hypoder-moclysis, or intravenous injection. If urgent 15 minims (1 c.c.) may be used undiluted and the remainder in the diluted form.

The serum treatment of hemophilia is promising. P. Emile Weil has found the injection of fresh serum to prevent hemorrhages in two cases of the acquired form. In the hereditary form the injections of serum had also an excellent effect, though an incomplete one both as a preventive and curative.<sup>1</sup>

The usual treatment for consequent anemia should be employed.

## SECTION IX.

### DISEASES OF THE NERVOUS SYSTEM.

#### GENERAL INTRODUCTION.

#### HISTOLOGY OF THE NERVOUS SYSTEM.

The difficulties in the diagnosis of diseases of the nervous system are gradually diminishing as the thread of its histology is being unraveled. The studies of Golgi, His, Forel, Waldeyer, Ramón y Cajal, Dejerine, Lenhossék, van Gehuchten, and others have considerably altered previously accepted views. A brief statement of the fundamental features of histology seems, therefore, necessary.

The studies of these and other observers resolve the nervous system into an immense number of units, to which Waldeyer has given the name *neurons*—whence the name neuron theory. It is necessary to state that the neuron theory is vigorously attacked, but as it is of service in explaining nervous diseases, it may be employed until the evidence against it becomes so convincing that we are forced to abandon it. Each *neuron* is made up of:

1. A nerve cell body.
2. Protoplasmic processes, or dendrites.
3. An axis-cylinder or axon continuous with the nerve-fiber.
4. Terminal ramifications of the axis-cylinder.

The *axis-cylinder* of a *motor* spinal cell gives off at different intervals lateral branches known as *collaterals*. These *collaterals* or *paraxons*, and finally the axis-cylinder itself, break up into many fine fibers, known as *terminal ramifications*, or *end brushes*, or *branch tufts*. Each neuron has been believed to be independent of every other—that is, no protoplasmic process of one neuron is continuous with that of another, nervous communication being through simple contact or proximity. More recent investigations, however, throw some doubt on this. The protoplasmic processes conduct impulses to the cell, are *cellulipetal*, as named by Cajal; the axis-cylinders conduct impulses away from it and are *cellulifugal*. The nutrition of the neuron depends largely on the cell body. If the latter is intact, the processes are preserved. If it is injured they waste, or if they are cut off they degenerate; on the other hand, the cell body suffers when its processes become diseased.

The motor neurons having their cell bodies in the gray matter of the brain, are called central neurons; those neurons having their cell bodies in the spinal cord and in the ganglia on the posterior roots, are called peripheral neurons. The end brushes or terminal ramifications of a central motor neuron surround the body and protoplasmic processes of a peripheral motor neuron, while those of the peripheral neuron are in connection with a motor plate. The axis-cylinders of the central and peripheral neurons traverse chiefly the white tracts of the brain and spinal cord and the per-

ipheral nerves. The cells of the anterior roots of the spinal nerves lie in the anterior cornua of the gray matter, and have the protoplasmic processes short and the axis-cylinders long. (See Fig. 86.)

The cells of the posterior roots are situated in the ganglia on those roots; the axis-cylinders of these cell bodies divide soon after leaving the cell body, one process passing to the periphery, the other to the spinal cord. Communication between different parts of the nervous system and with the rest of the body is thus rendered possible. The processes extending to the periphery receive impressions from the exterior and carry them cellulipetal to the ganglion cells on the posterior roots of the spinal nerves, whence they

FIG. 86.—Diagram of an Element of the Motor Path —(after Strumpell, modified).

C. Motor ganglion cell in the cerebral cortex. Py S. Lateral pyramidal tract, central or upper motor neuron. V. Ganglion cell of anterior horn. m. Motor nerve, peripheral neuron. M. Muscular fiber.

are conveyed by the axis-cylinders cellulifugal to the cord. This impression may result in a reflex act, or it may proceed to the brain and give rise to a volitional act through the motor tract.

A motor impulse starting from the brain cortex must pass through at least two sets of neurons before it can reach the muscles. In this course it is cellulifugal from the cell in the cortex, cellulipetal to the cells in the gray matter at different levels in the anterior cornua, and thence cellulifugal from the latter cells to the various muscles of the body, ending in the end-plates. Hence we speak of the motor tract as being composed of two segments, an upper and a lower. The neurons of the upper motor segment have their cell bodies and protoplasmic processes in the cortex in front of the fissure of Rolando. The axis-cylinder processes run through the

internal capsule and the cerebral peduncles, through the pons, medulla oblongata, and cord, ending in terminal ramifications around the protoplasmic processes and cell bodies of the lower segment. The neurons of the lower segment are those having their cell bodies and protoplasmic processes in the anterior cornua of the gray matter, while their axis-cylinders leave the spinal cord by the anterior roots of the spinal nerves, to be distributed as described. The *upper segment*, in large extent at least, is a *crossed tract*—that is, the neurons composing it have their cell bodies and protoplasmic processes in the cortex, while their axis-cylinders cross the middle line to end about the cell bodies in the opposite half of the spinal cord; so that motor impulses starting in the left half of the brain produce contraction in the muscles of the right half of the body, and vice versa, although both sides of the brain probably innervate unequally each side of the body. (Fig. 86.) The *lower motor segment* is a *direct tract*—that is, its neurons, and the muscles to which they are distributed, are all on the same side of the body.

The path for sensory conduction is also composed of segments, but the direct route of sensory conduction is more complicated and our knowledge is much less exact. The cell bodies of the lower neurons are in the ganglia on the posterior roots of the spinal nerves and in the ganglia of the sensory cranial nerves. These ganglion cells have a single process, which, after leaving the cell, divides in a T-shaped manner, one branch running into the central nervous system and the other toward the periphery. (Fig. 86.) The process which connects with the periphery is regarded by some as a protoplasmic process, while that which passes to the center is known as the axis-cylinder. The former runs in the sensory nerves, starting from the various specialized sensory apparatus of the periphery. The axis-cylinder enters the cord by the posterior roots. After entering the cord it divides into an ascending and a descending limb, which traverse the posterior columns. The descending branch runs a short distance and ends in the gray matter of the same side of the cord, giving off a number of collaterals, which also end in the gray matter. The ascending branch may end in the gray matter soon after entering the cord, or it may run in the posterior columns as high as the medulla oblongata, ending in the nuclei of the posterior columns. Thus the *lower segment* is also a *direct tract* terminating in the gray matter of the posterior cornua at different levels, and in the gray matter of the medulla oblongata. (See also section on Spinal Cord.) The *upper segment* starting from these is a *crossed tract*, crossing at different levels, so that sensory impressions are ultimately lodged in the brain on the side opposite that whence they start in the periphery. The so-called muscular sense, perhaps better called the sense of position, is probably conducted upward on the same side in the columns of Burdach and Goll on each side of the posterior median fissure. The exact termination of the sensory processes in the cerebral hemisphere is not known, but they pass up in the tegmentum of the pons and possibly in the internal capsule. It is believed by many that these processes terminate in the optic thalamus, and that from here the impulses are conducted to the cortex by means of another set of neurons. Recent investigations seem to show that the sensory area of the brain is posterior to the Rolandic fissure.

Both motor and sensory spinal nerve roots are connected with definite segments of the spinal cord. They descend a variable distance within the spinal canal, unite within the intervertebral foramen, but external to the point where the roots perforate the dura mater and pass through the foramina as spinal nerves. But in their distribution they do not retain the same definiteness, the same sensory and motor areas being supplied with nerve fibers from different segments of the cord, and there is an overlapping, as it were, of part supplied by different nerve fibers. At the same time, by the combined aid of experiment and morbid physiology, we have learned that movements in certain muscles are accomplished by motor nerves which emanate from corresponding segments of the spinal cord, and that from certain sensitive areas are gathered up impressions which are carried to corresponding sections of the spinal cord. By the same means we have learned that there are areas in the cortex of the brain that preside over certain motions, and areas which have to do with sensation; though with respect to the latter our knowledge is much less definite. We know about as much of the cortical localization of the *special* senses as of sensibility. These facts are the foundation of what is known as *topical diagnosis*, in the case of the brain as *cerebral localization*, by which is meant the inference, from the study of local derangements of sensation, motion, and other functions of the more or less exact site of lesions in the nervous centers. These will be considered with appropriate detail in our study of the diseases of different parts of the nervous system.

## GENERAL SYMPTOMATOLOGY.

### (INVESTIGATION OF A CASE OF NERVOUS DISEASE.)

The advantages of a careful method in the study of disease are perhaps more apparent in the case of the nervous system than that of any other of the anatomical divisions of the human body. This is partly because of the number and variety of the affections to which the nervous system is subject, and partly because of the association of certain identical symptoms with widely different lesions.

The primary steps of family and personal history are the same as for other diseases, including age, sex, occupation, and whether married or single. We may therefore pass at once to the study of such symptoms as are special.

I. PHENOMENA OF MOTION.—It is immaterial whether we examine first sensory or motor phenomena, but it appears somewhat easier to begin with derangements of motion, and of these (1) *voluntary motion* is naturally first investigated. To this end, the patient is asked to move his limbs, while the strength of whatever motion he is capable of is measured by resisting it, and by testing the power of his hand-grasp. For more accurate measurement the dynamometer is used, an instrument devised to measure both compression and traction, although it is more commonly restricted to the former. Advantage may be taken of the fact, too, that the same motion requires different degrees of strength in different posi-

tions of the body. Thus it is easier to draw up the thigh when lying on the back than when on the side, and it may be possible in the former position when it is not in the latter. Both extensor and flexor muscles must be thus tested. By such an investigation we discover the presence of a complete *paralysis* or total loss of voluntary motion, and *paresis* or simple weakening of such power.

By a *monoplegia* is meant an isolated paralysis of one part of the body, as of an arm or a leg. By a *hemiplegia* is meant a paralysis of the entire half of the body, including half of the face, one arm, and one leg, also known as unilateral paralysis. By a *paraplegia* is meant a simultaneous paralysis of corresponding halves of the body. Paralysis of the two arms is known as a *superior, or brachial, paraplegia*, of the two legs as an *inferior,*

FIG. 87.—Illustrating Crossed Paralysis—(after Hirt).

O. Medulla oblongata. *pyx.* Decussation of anterior pyramids. E. Nerve-fiber going to extremities. F. Nerve-fiber to face.

or *crural, paraplegia*, while the word paraplegia alone is often used for the latter condition. A *diplegia* is a paralysis in which upper and lower limbs are affected on both sides of the body, usually attended with spasm of all the extremities, although the term is also employed for bilateral facial paralysis. Though commonly congenital, diplegia may also be acquired.

Impairment of voluntary muscular power, as thus tested, must be the result of structural change in the motor area of the cortex, in the motor tract of the brain or cord, or impairment in the integrity of the efferent nerves, or it may be more rarely in the muscle itself, "myopathic palsy"; or the power of the will may be abrogated. In diseases of the peripheral nerves, when the paralysis is called peripheral, it is limited to the region of distribution of the affected nerves, whether one or many. It may be said in general that hemiplegia is the usual form of cerebral paralysis, while paraplegia is the expression of spinal paralysis. Monoplegias are due to lesions of the cortex, or of the anterior gray matter of one side of the spinal cord, as in poliomyelitis, or are peripheral palsies; cortical monoplegia is rare.

In all hemiplegias caused by lesions above the pons, the palsy, including that of the face and extremities, is on the side opposite the lesion, but in

most lesions in the middle or lower part of the pons there is *crossed paralysis*—that is, there is paralysis of the extremities on one side, and of the face on the other side, provided the central fibers of the extremities and the facial nerve are involved in the lesion. The reason of this is that the central fibers of the facial nerve cross much higher than do the fibers to the extremities, and in such a lesion the intra-medullary portion of the facial nerve, and not the central fibers connecting its nucleus with the brain cortex are injured. The result is a paralysis of the face on the same side as the lesion and of the extremities on the other. This would be the case with a lesion at *b*, Fig. 87. If, on the other hand, the lesion is higher up, above the decussation of both the facial and pyramidal tracts, as at *a*, the paralysis is on the side opposite the lesion in both face and extremities. Other nerves may substitute the facial in this crossed paralysis as the oculomotor (third nerve) or hypoglossal (twelfth nerve) or abducens (sixth nerve). In rarer instances it is possible that a lesion at the decussation of the pyramids, by cutting the motor fibers of one extremity before they cross,

FIG. 88.—Illustrating the possibility of paralysis of arm on one side and of leg on the other.

and those of another after crossing, may produce the very rare condition of paralysis of an arm on one side and of a leg on the other. That this is theoretically possible may be seen from Fig. 88, in which the black lines represent fibers to the upper extremities and red lines fibers to the lower, and the red circle the seat of a small hemorrhage.

(2) Having determined this question of muscular strength, and the corollaries which grow out of it, we have next to ascertain to what extent the power of *co-ordination* is influenced. Every muscular act requires the duly proportioned co-operation of a number of muscles; and as the complexity of the act increases, the number of muscles required to co-operate also increases. Such co-operation is termed *co-ordination*, and its absence is recognized in the staggering gait of the drunkard, and the condition is known as *ataxia*. There are certain parts of the nervous system which preside over co-ordination—such as the cerebellum, the posterior columns, and probably the direct cerebellar tract, of the spinal cord. Disease of any of these may, therefore, produce ataxia. The ataxic or tabetic gait is described under *tabes dorsalis*, p. 1025.

A corollary, growing out of the investigation of the co-ordinating power, is the study of *station*, or the steadiness with which one stands with the eyes closed or open, and it is measured by sway of the head and body, laterally and anteroposteriorly. In health a lateral sway of the head exists to the extent of half an inch (1.25 cm.), and an anteroposterior

sway of an inch (2.5 cm.). A sway much beyond these limits is abnormal. Co-ordinating power is also tested by attempting to bring together the ends of the index fingers with the eyes closed, an effort which will be unsuccessful if co-ordinating power is lost.

(3) After ascertaining the condition of voluntary motion, co-ordination, and station, we must inquire into the question of possible *motor irritation* or *excessive muscular action* or *spasm*. Spasm may be continuous—*i. e.*, lasting for minutes, hours, or days—when it is known as *tonic* or *tetanic*; it may be intermittent or *clonic*; or it may be an admixture of both, when it is termed *tonic-clonic*. Tonic spasm is well illustrated by *trismus* or lock-jaw, while tetanic contraction of the muscles of the back produces *opisthotonos*, in which the vertebral column is arched and the body rests upon the back of the head and upon the heels. Tonic spasms are often attended with pain, probably due to pressure on intramuscular nerves, when they are called “cramps.” Spasm occurs also in involuntary non-striated muscular tissue. The presence of spasms implies irritation of motor centers, motor tract, or motor nerves, but motor irritation may also be excited secondarily by some reflex route, the result being a reflex spasm.

Spasm and paralysis are often associated. Thus, a limb may be paralyzed in a state of contraction, exhibiting a peculiar rigidity, and to such a condition the name *spastic paralysis* is applied. This condition may also exist as a state of persistent contraction of the antagonists of the paralyzed muscles, constituting the so-called *contractures*. Paralyses in which there is no such resistance to passive motion are known as *flaccid paralyses*.

Through the combination of tonic and clonic spasm result different varieties of morbid involuntary movements more or less complex. Some of these are the following:

1. *The Epileptiform Convulsion*.—This consists in a succession of clonic and tonic-clonic spasms extending over the whole or a part of the body, throwing the part involved into violent motion. The masseter and the temporal muscles share in the contraction, whence the tongue is often bitten. The convulsion of epilepsy is the type of this form, but the convulsions of uremia, or hysteria, and of organic disease of the brain may be epileptiform.

2. *Rhythmical Contractions*.—These occur in single groups of muscles, and are sometimes seen in apoplexy, and cerebral sclerosis. They may usher in the epileptiform convulsion, or the convulsion may terminate by a gradual substitution of the rhythmical contractions for the more violent spasms. Among rhythmical movements may be included *athetosis*, a peculiar slow, involuntary rhythmical movement, usually of the fingers and hands, but also of the head and trunk, or of the toes. The fingers make slow movements of the nature of extension and flexion, spreading and approximating each other in a striking way. They are a symptom of certain central nervous diseases, especially of the cerebral palsies of children.

3. *Tremors or Trembling Motions*.—These are limited movements—*i. e.*, movements of short excursion which rapidly succeed each other. “Shaking” is a more pronounced degree of tremor. Tremor is characteristic of paralysis agitans and of some other nervous affections. It occurs in old

persons as senile tremor, and in abusers of alcohol and tobacco. When it occurs or increases during voluntary motion, it is known as *intention tremor*, and is characteristic of multiple sclerosis. The immediate anatomical changes on which tremors depend are not known.

4. *Single Contractions*.—These are either sudden twitchings or slow contractions of muscles, seen especially in diseases of the nerves—as, for example, in old facial palsy. They may be single or multiple and persistent. They may be the result of direct motor irritation or reflex in origin.

5. *Fibrillary Contractions*.—These are contractions of separate small bundles of muscular fibrillæ, comparable to the “quivering” of raw flesh. They are independent of voluntary or passive motion. They may be pronounced and wave-like over the muscular substance. They are seen especially when the motor nerve cells are degenerating, as in progressive spinal muscular atrophy or bulbar paralysis. The “quivering” of the eyelid and of the orbicularis muscle below the eye, the so-called “jumper,” often an annoying symptom, is an instance of this condition.

6. *Choreic Movements*.—These are inco-ordinated movements, usually separated by short intervals of time, often first seen in the face, later in one limb or over the whole body. They may be very complex and general. They are characteristic of chorea, but also accompany other nervous affections, such as posthemiplegic chorea. Under the term posthemiplegic chorea, however, various movements are sometimes included.

7. *Constant or Co-ordinate Spasms*.—These consist in irresistible complicated movements, like moving forward or moving in a circle or rotating on the axis of the body; also complicated forms of spasm resembling jumping, laughing, screaming, all involuntary and forced. The first group of these is especially seen in disease of the cerebellum and cerebellar peduncles, the latter in severe forms of hysteria.

8. *Nystagmus* is a clonic rhythmical oscillatory and involuntary movement of the eyeball, usually horizontal, sometimes rotatory, more rarely vertical. It is noticed in congenital and acquired affections of the brain, including Friedreich's ataxia and insular sclerosis; also in albinism and in *miners* who work in dimly lighted mines, using the pick while reclining and directing the eyes laterally.

9. *Cataleptic Rigidity*.—In this there is also a tonic contraction of muscles whereby a limb remains for a considerable time in any position in which it may be passively placed, the will being abrogated. If the position of the limb be changed, it remains again in this situation, and from a resemblance to the behavior of wax under like circumstances it has received the name of “waxy flexibility.” It is characteristic of certain forms of hysteria, and may be produced at times in hypnotism. In hysteria it is commonly associated with anesthesia and loss of consciousness. It is also associated with psychoses, especially grave forms of melancholia known as *melancholia attonita* and with *katatonía*.

10. *Associated Movements*.—These are unintentional and uncontrollable movements which take place in muscles coincident with other motions actually intended—as, for instance, a motion in the arm when the patient wills to move only the leg.

(4) *Bladder control* and *rectum control* are next to be looked into. Full

control over the acts of these organs implies, first, an integrity of the sacral portion of the cord, in which reside the reflex centers regulating these acts; second, the integrity of volition, which, to a certain extent, fortifies such regulation; and, thirdly, integrity of the afferent and efferent nerve fibers constituting the reflex arcs. Through the operation of the reflex center, bladder and rectum both empty themselves when a certain degree of distention is attained. Through the operation of the will such evacuation is put off to a convenient time. Through an undue irritability of the reflex center such evacuation is imperative, and does not bide the will, or it may take place while the will is in abeyance, as in sleep. Thus may be explained some of the cases of incontinence of urine in children. Again, if will-power

is lost from disease of the cerebral cortex, evacuations of the bowels and bladder take place involuntarily so long as the sacral cord is intact, but not in a normal manner.

On the other hand, if the integrity of the sacral cord is lost, there will be no response to the sensory impressions conveyed from a full bladder or rectum, because the reflex arc is interrupted, and the organ remains unemptied; whence torpor or complete paralysis of the bowels and bladder are common symptoms of spinal disease; and while the repletion of the latter may finally overcome the resistance of its sphincter and lead to dribbling, the rectum may go on filling up until it is emptied by the finger or the handle of a spoon. A lesion situated higher in the central nervous system than the sacral portion of the cord may also cause similar disturbance of defecation and urination, probably because of a spastic condition of the sphincters, so that the latter do not relax until the bladder or rectum becomes distended, and finally they lose all function.

Again, if it should happen that the sphincter center is destroyed while

the detrusor center is intact, there would be dribbling of urine from the outset, but this is not likely to occur.

(5) The state of the *reflexes*, as they are called, is next ascertained. As here used, the term "reflex" is applied to a muscular contraction stimulated by a sensory impression, the simplest illustration of which is the retraction of the leg of the sleeper when the sole of the foot is tickled. For diagnostic purposes the reflexes are divided into the "cutaneous reflexes" and the "tendon reflexes."

The *cutaneous* or superficial reflexes are muscular contractions which take place in different parts of the body in response to irritation of sensory nerves of the skin, as by tapping the skin lightly or drawing the finger or a pointed instrument lightly over it. The sudden application of heat or cold or the prick of a pin or pinching are modes of excitation. The contractions are generally confined to the neighborhood of the locality irritated. The skin reflexes are much more easily excited in children than in adults, and in the lower extremities than in the upper; also with varying facility in different persons. They receive various names, according to the situations where they are readily excited. Thus we have the "plantar reflex," where contraction is excited by tickling the sole of the feet, resulting in a movement of the toes or foot, or even in a drawing up of the leg; the "cremaster reflex," contraction of the cremaster muscle and consequent drawing up of the scrotum on stroking or scratching the inside of the thigh. The retraction may take place on the one side of the scrotum only or on both. Then there is the "abdominal reflex," or a contraction of the abdominal muscles when the skin of the abdomen is stroked or scratched. A subdivision of the latter is the "epigastric reflex," produced by an irritation on the side of the thorax in the fourth, fifth, and sixth inter-spaces. The result is a dimpling of the epigastrium on the side stimulated. Cutaneous reflexes may be brought out in other portions of the body, as in the gluteal region by irritating the skin of the buttock. A contraction of the muscles about the scapula, the "scapular reflex," is produced by an irritation between the scapulæ. To test for the cutaneous reflexes is more important in the lower extremity than in the upper.

The *tendon* reflexes, or deep reflexes, are so called because they are generally elicited by striking upon tendons, while the corresponding muscles are placed slightly on the stretch, care being taken, however, to avoid all active tension in the muscle by the person examined. The blow is made either with the edge of the hand or with a hammer adapted to the purpose, commonly made of rubber. A sharp, sudden contraction of the muscle usually takes place. A similar, though less decided, contraction may be elicited by the mechanical irritation of parts analogous to tendons, as periosteum and fasciæ, and by striking the muscle itself. When the reflexes are in excess, sudden tension alone will excite them.

The most commonly tried of the tendon reflexes is the *knee-jerk*, or *patellar tendon reflex*, produced by striking the tendon of the quadriceps femoris between its insertion and the patella, while the leg is crossed upon its neighbor. The weight of the pendent leg gives a sufficient degree of tenseness. When the knee-jerk is normal, there is a decided rise of the foot with each blow of the hand hammer. This motion may be-

come abnormally increased or diminished. A more limited movement may also be produced by striking the patella itself or the quadriceps tendon above the patella, and, when the reflex is exaggerated, by a very light tap in these situations or even on the tibia. When thus exaggerated, the reflex may also be brought out in bed, as follows: the quadriceps tendon being put on the stretch by pressing the patella downward in the direction of the leg with the finger, the patella is percussed in the same direction. With each stroke there is a contraction, and the finger and patella are drawn upward. A "clonus," or repeated contraction, may even be produced in this way.

Similar is the *ankle reflex*, produced by tapping the *tendo Achillis* when the calf muscles are placed slightly on the stretch by a slight dorsal flexion of the foot. In health the ankle reflex is usually producible, but in disease in connection with this contraction is shown the most remarkable of the exaggerated reflexes, the "ankle clonus" or "foot clonus." It consists in contractions rapidly repeated so long as the tension of the calf muscle is kept up by pressing the foot toward dorsal flexion. From six to nine such contractions may occur in a second, and sometimes the whole leg is thrown into vigorous contractions. Occasionally a rotary or lateral ankle clonus is seen. One of the best ways to obtain the *tendo Achillis* jerk is to have the patient kneel on a chair with the feet projecting over the edge of the chair; the muscles are thus relaxed, and a tap over the *tendo Achillis* produces a movement of the foot.

The Babinski reflex or phenomenon is the extension or turning upward of the toes, and especially of the great toe, obtained by stroking the sole of the foot. In the normal individual, stroking the sole, if it produces any response, causes plantar flexion or turning downward of the toes, especially of the four outer toes. The Babinski reflex usually indicates a lesion or compression of the motor tract in the cord and brain, or probably also of the motor centers in the brain. The response is usually best brought out by stroking the inner surface of the sole from the heel toward the toe, although in marked cases it may be elicited by applying the stimulus to the sole in various positions and directions. In infancy some observations have shown that the toes tend to turn upward normally when the sole is stimulated. The reflex is obtainable in about 70 per cent. of cases of hemiplegia and diplegia, and in about the same proportion of diseases involving the motor tract in the spinal cord. It is found only exceptionally in cases of another class, viz., meningitis, hydrocephalus, poisoning, as for example alcohol or uremia.

Reflexes are also elicited in the upper extremities, but they are much less striking, and occasionally cannot be shown in health. The most important of these are the *arm-jerks*, produced by striking the biceps tendon at the elbow-joint in front, or by striking the triceps tendon above the olecranon. So-called *periosteal reflexes*—reflexes excited by striking the periosteum—may in exaggerated states be produced in the supinator longus and biceps of the upper extremity by striking the lower end of the radius and ulna; also in the adductors of the thigh by striking the internal condyle of the femur.

A *wrist clonus*, resembling the ankle clonus of the lower limbs, may

sometimes be obtained when the tendon reflexes of the upper limbs are much exaggerated. It is produced by pushing the hand of the patient forcibly backward and holding it dorsally flexed; involuntary antero-posterior movements of the hand may then occur. The *jaw-jerk* is produced by tapping on the front of the jaw, while the closing muscles of the jaw—viz., the pterygoids, masseters, and temporals—are placed on the stretch by partially opening the mouth.

The *ophthalmic* (supraorbital) reflex is a pure sensori-motor reflex, elicited by mechanical irritation (tapping lightly with the percussion hammer), or by the application of heat, cold, or pain-stimuli over the distribution of the ophthalmic branch of the fifth nerve, especially in the distribution of the supraorbital branch on the forehead. It is manifested by a fibrillary contraction of the individual fibers in the inferior half of the orbicularis palpebrarum. The sensory impulse travels through the supraorbital nerve (purely sensory) to the pons and thence through the facial fibers (purely motor) to the orbicularis palpebrarum.

The diagnostic value of this reflex lies in the loss of contraction resulting from a lesion cutting the arc in the ophthalmic branch of the trifacial, in the nucleus of the trifacial or of the facial in the pons, or in the fibers of the facial going to the orbicularis palpebrarum. It is therefore of value in localizing lesions of the pons, and differentiating a facial paralysis due to a lesion of the nucleus or its peripheral fibers from a supranuclear or cortical lesion, in which case the reflex is present and increased. It has the same significance as the reflex closure of the eyelids from irritation of the conjunctiva, as this also is a reflex in the distribution of the facial and trigeminal nerves.

*Physiology of Tendon Reflexes.*—The tendon reflexes were first studied by Erb and Westphal, and later by Tschirjew, Gowers, Jendrassik, Weir Mitchell, Lombard, and others. Erb explained the phenomena as purely reflex in their character, requiring the offices of a centripetal and a centrifugal nerve, an intermediate center, and an excitant. Westphal, on the other hand, regarded them as simple muscular contractions, stimulated as are the bared, quivering muscles of the recently killed animal, the tendon being simply the intermediary substance through which the irritation is conveyed. It was early objected to the purely reflex nature of these phenomena that a shorter time is usually required to produce them than to produce an ordinary reflex action, being but from  $1/40$  to  $1/30$  of a second, as compared with  $1/15$  of a second. But the strongest objection is found in the results of the experiment of Tschirjew, who cut all the nerves to the patellar tendon and found that the reflex still remained excitable.

Nevertheless, the tendon reflexes are arrested by any lesion which arrests reflex action. Hence reflex action must somewhere come into play. Accordingly, Gowers suggests that "the irritability is developed by the passive tension. If the muscle is relaxed, the fibers may contract, if they are struck directly, as do the fibers of a separated frog's muscle, but no contraction ensues on striking the tendon. Hence we must assume that the tension excites, by a reflex influence, a state of irritability to local mechanical stimulation, such as a tap on the muscle, its tendon, or even

the vibration from a tap on adjacent parts. But only that form of mechanical stimulation is effective which suddenly increases the previous tension. It is only because the tap on the tendon does this so readily that the tendon is the means by which the contractions are most easily produced, and through which they have been chiefly studied and prematurely named. If the tension put on a muscle is gentle and gradual, it may only develop the irritability, and an additional local stimulation is necessary to produce a visible contraction. If, however, the tension is sudden and forcible, it not only develops the irritability, but produces visible contraction in the muscle thus rendered irritable, as in setting up foot-clonus." Hence, too, according to Gowers, the term "tendon reflex" is altogether too inaccurate, and he suggests the word *myotatic*, from *μῦς*, muscle, and *τατικός*, extended, because tension is necessary for the production of the contractions. Weir Mitchell describes it well in these words: "A muscle moves when struck because of its innate capacity to twitch when irritated, but it does not move when excited by a blow on its tendon unless it has, besides its own excitability, a constant influx of tone-waves from spinal centers."<sup>1</sup>

Hence in a complete examination the "muscle jerk," or idiomuscular contraction, also known as mechanical muscular irritability, should be tested as well. It is done by a sharp, sudden tap on the muscle with the hammer. The response is of two kinds, first as a sudden contraction, and second as a hump-like rise which subsides slowly. The pectoral muscles are favorite sites for eliciting the pure muscle reflexes. It is, of course, impossible to deny that there is nerve as well as muscle irritation in such a blow.

Both the tendon jerk and muscle jerk are capable of re-enforcement by coincident muscular exertion, as in lifting weights or clinching fists, originally discovered by Jendrassik<sup>2</sup> in 1883 in the case of the tendon jerk. Mitchell and Lewis<sup>3</sup> also discovered in the course of their study of ataxic cases that the pure *muscle* jerk or hump could be produced after the tendon reflex could no longer be elicited, and that both could be produced by the re-enforcement referred to after they had disappeared to ordinary conditions.

*Significance of Abnormal Reflexes.*—What are the conclusions to be drawn from modifications in the reflexes? In the first place, it is to be remembered that they vary somewhat within the limits of health. Especially is this true of the cutaneous reflexes, which are also less easily elicited than those of the tendons. In general terms, *diminution* or *absence of a reflex normally present in health* implies either, first, a breach of integrity somewhere in the reflex arc as formed by the centripetal nerve, the motor nerve cells in the spinal cord situated in the anterior cornua of the gray matter, and the motor nerve; or, second, an increase in the reflex cerebral inhibitory influence. The latter would be irritative. Thus, it is well known that disease of one cerebral hemisphere may lessen or abolish the superficial reflexes on the opposite or paralyzed side of the body

<sup>1</sup> Mitchell and Lewis, "Tendon and Muscle Jerk," "Trans. Assoc. of Amer. Physicians," vol. i., p. 13, 1886.

<sup>2</sup> "Beitrage zur Lehre von den Sehnenreflexen," "Deutsches Archiv f. klin. Medicin," vol. xxxiii., p. 175, 1883.

<sup>3</sup> *Loc. cit.*

soon after the onset of a hemiplegia. Breach of integrity may lie in the spinal cord or in the centrifugal or the centripetal nerve. If it is in the centripetal nerve, it may be accompanied by impaired sensation; if in the centrifugal, there will be defective motion. Disease of the centrifugal nerve and of the motor center in the cord may also cause degeneration and wasting of muscle with loss of its irritability.

*Increase of the reflexes*, on the other hand, implies increased irritability of the motor areas of the cord—when the reflexes are spinal (anterior cornua and possibly of the pyramidal fibers) or a withdrawal of cerebral inhibition, as in certain cases of destructive brain disease or disease of the cord high up. In the case of a cortical lesion the increase in the reflexes is greater on the side opposite to that of the brain lesion, but the reflexes on the same side as the lesion may also be somewhat increased. In certain diseases of the cord there is a *delay* in the manifestation of the *cutaneous reflexes* after the irritation has been applied to the skin, an interval of from ten to fifteen seconds being often recorded before the response ensues. *Increase of cutaneous reflexes* is manifested by an unusual readiness of response in the normal areas, or an extension of these areas beyond their normal boundaries.

In general it may be said that absence of the tendon reflexes is especially characteristic of poliomyelitis and tabes dorsalis, and of all peripheral paralyses and neuritis; also of advanced diabetes mellitus. Abnormal increase is present in spastic spinal paralysis and in cerebral paralyses, being due in the latter instance to withdrawal of the normal inhibitory influences.

Appended is a table showing the conditions under which the tendon reflexes as represented by the knee-jerk are increased or diminished:

#### TENDON REFLEXES.

INCREASED.	DECREASED.
Spastic spinal paralysis.	Poliomyelitis, acute and chronic.
Amyotrophic lateral sclerosis.	Tabes dorsalis.
Cerebral paralysis in which the inhibitory center is impaired.	Progressive spinal muscular atrophy.
Lesions of the cord above the reflex arcs.	Muscular dystrophy.
Disseminated cerebrospinal sclerosis.	Peripheral paralysis.
Irritability of cord, as in maniacal hysteria.	Neuritis.
Strychnin poisoning.	Degenerated muscle.
Cerebral palsies of children.	Exhausted spinal centers.
	Poisoning from drugs (?).
	Advanced diabetes mellitus.

#### INCREASED OR DIMINISHED.

Paretic dementia: Diminished as a tabetic symptom; increased in beginning spastic paralysis of the leg.  
Cerebellar tumor, not infrequently diminished.

*Segments of the Cord Presiding over Certain Reflexes.*—Further accuracy in the application of a knowledge of the reflexes and of their modifications is secured by a knowledge of the exact portion of the gray matter presiding over the most important of them. Premising that some of these centers are of considerable extent vertically, the following from Gowers may be regarded as approximate for each of the reflexes named:

*Superficial Reflexes.*—Plantar, opposite second sacral nerve; gluteal,

fourth lumbar; cremaster, second lumbar; abdominal, sixth to seventh dorsal; epigastric, sixth dorsal; scapular, fifth cervical to first dorsal

*Tendon or Deep Reflexes.*—Calf muscles (foot clonus), fifth lumbar and first sacral; knee-jerk, third and fourth lumbar; flexor digitorum and triceps, seventh cervical; biceps and supinator longus, sixth cervical.

(6) *Paradoxical contraction* is a symptom allied to the reflexes for which no satisfactory explanation has been afforded. It was first studied by Westphal, and is only occasionally observed. In the *tibialis anticus* muscle it is induced by forcibly flexing the foot on the leg. As a result, the foot remains thus flexed for a considerable time, after which it slowly

FIG. 90.—Motor Points on Face and Neck—(after Erb and de Watteville.)

relaxes. In one case the flexion continued for twenty-seven minutes. On repeating the flexion, the phenomenon recurs, but the response gradually diminishes in intensity. Contractions induced by faradism may similarly persist. It has been noticed in both spinal and cerebral disease, including the early stage of tabes dorsalis, multiple sclerosis, and paralysis agitans. More rarely it may be induced in the flexors of the leg and forearms.

(7) *Electrical excitation of motion* is an important means of investigation in nervous diseases. In health nerves and muscles are excitable by electricity, and in diseased conditions these reactions are liable to change. Motion may be excited by electrical stimulus applied to the muscle through its nerve or directly to the muscle itself. The latter

is called direct, the former indirect. This is equally true of the constant or galvanic current, and of faradism or the induced current.<sup>1</sup> Hence every complete investigation should include the use of both currents.

In order to test the electrical condition of muscles and nerves, one electrode, the indifferent pole, may be held in the hand of the patient or

Fig. 91.—Motor Points on Upper Limb, Flexor Surface—(after Erb and de Watteville).

placed over the sternum or at the back of the neck, while the other or *testing* pole is applied to the nerve or muscles, selected in accordance with the well-known nerve points of Erb in Ziemssen's plates; or the indifferent

<sup>1</sup> Under all ordinary circumstances electrical contraction produced in muscles is indirect—that is, through the nerve filaments distributed to the muscle. That the two are, however, distinct may be shown through the influence of curare, which destroys nerve irritability, but allows that of muscle protoplasm to remain.

pole may be placed on the nerve point of a given muscle or set of muscles, and the testing pole applied to the belly of the same muscle. The testing electrode should be small enough to permit the isolation of a single nerve or muscle.

With the faradic or galvanic battery contractions may generally be produced in health with great facility, either directly or indirectly,

FIG. 92.—Motor Points on Upper Limb, Extensor Surface—(after Erb and de Watteville.)

although stronger currents are required for direct stimulation. Contractions take place with the galvanic battery only at the making and breaking of the current by the "commutator" or "reverser." A definite law of response exists with galvanism. Thus, beginning with very weak currents, it is observed that contraction first takes place at the moment of that closure which makes the testing pole the kathode or negative pole—kathodal closure (KaCl). As the strength of the current is increased the kathodal closure contractions become stronger, and anodal closure (AnCl) contractions make their appearance. With still stronger

currents the anodal opening (AnO) contraction occurs, and, last of all, when the kathodal closure contractions become tetanic (Te), slight kathodal opening (KaO) contractions appear. *These facts are equally true of normal muscle and nerve and may be formulated.* Representing slight contraction by a small "c," decided contraction by a large "C," and the absence of contraction by a minus sign (—):

With weak currents, KaClc, AnCl—, AnO—, KaO—; with stronger currents, KaClC, AnClc, AnO—, KaO—; with still stronger currents, KaClC, AnClC, AnOc, KaO—; with strongest currents, KaClTe, AnClC, AnOC, KaOc.

In *pathological states* two sets of deviations from the normal reaction to electrical stimulus are observed—viz., *quantitative* and *qualitative*.

FIG. 93.—Motor Points on Thigh, Anterior Surface—(after Erb and de Watteville).

In the *quantitative* deviations there is simply an increase or a diminution of the normal irritability of both nerve and muscle to either faradism or galvanism. These differences are, of course, most easily measured when the alteration exists only on one side of the body, which may then be compared with the other. When both sides are affected, estimates can be made only by comparison with a healthy body or by the galvanometer. For this purpose superficial nerves, such as the facial, ulnar, and peroneal, are usually selected. *Instances:* Increased quantitative changes are found in tetanus and in the early stage of certain peripheral palsies, while diminished electrical excitability is found when the lower motor segments (motor spinal cells, motor nerves, including the muscles) are involved—as, for example, in progressive spinal muscular atrophy, bulbar paralysis, and muscular dystrophy.

More important from a diagnostic point of view, at least, are the so-called *qualitative* deviations from the normal law of contraction known as the *reaction of degeneration*. These are produced by the *galvanic* current only, and may, in general terms, be regarded as a reversal of the usual order of response to interruption of currents and in the substitution of a slow and vermicular contraction for the usual sudden and jerking contraction. The entire group of events is best illustrated by describing the electrical phenomena which present themselves in an ordinary case of peripheral paralysis. In two or three days to a week after its appearance there begins a gradually diminishing response in the *nerve* to both faradic and galvanic currents. This goes on for one or two weeks, at the end of which time it disappears to both currents, even the strongest. The nerve is now dead. During this same time the *muscle* is also losing its responsiveness to the faradic current, but not to the galvanic. There may be also at first a slight diminution to the galvanic current, lasting, say, one week, and constituting the "first degree" or "first stage" of degeneration. But during the second week this is substituted by an increased excitability, so that there is now marked response to weak currents—increased quantitative deviation. But there is also *qualitative* change. The anodic closure contractions become now as strong as or stronger than the kathodal closure contractions. Nay, more: the kathodal opening contractions, which in health were exceedingly weak and could be brought about only by the strongest currents, are now often stronger than the kathodal closure. This state of affairs for *muscle* may be represented thus:

#### MUSCLE CONTRACTION—REACTION OF DEGENERATION.

First stage of reaction of degeneration— one week:	{ Diminished quantitative response to galvanism. No qualitative deviation.
Second stage of reaction of degeneration— four to eight weeks:	{ Increased quantitative response to galvanism. Qualitative deviation as follows: AnCl = or > KaClc. KaOC > KaClc. Contraction prolonged and vermicular.

The phenomena of qualitative change are purely muscular, and it should be mentioned that they are not always typically present. Even more constant and equally distinctive and more reliable as a sign of reaction of degeneration is the second qualitative change in the muscular contractions excited by galvanism in this stage. Instead of being quick or sudden, they become *slow, prolonged, and vermicular*.

The second stage lasts from four to eight weeks, increasing during the third and fourth. In cases of recovery the abnormal muscle irritability to galvanism often persists after return of voluntary power, but it diminishes as the faradic irritability returns. In severe cases, when recovery does not take place and the nerve is not restored to its natural state, *all nerve irritability and faradic muscular irritability* remaining permanently absent, the *increased galvanic muscular irritability* may con-

tinue for months, but ultimately also decreases, disappearing finally with the muscular substance.

Certain exceptions to these laws must be mentioned. Thus, when the nerve lesion is slight, the fall in quantitative *nerve* irritability is sometimes preceded by a corresponding rise, or the rise may persist throughout and such rise may be considered as evidence of a slight lesion. Further, the change is not always the same to faradism and galvanism, and is often brought out much better by the slow interruptions in the faradic battery than by the rapid interruptions in the same or by the galvanic current.

FIG. 94.—Motor Points on Lower Limb. Posterior Surface—(after Erb and de Watteville).

Gowers noticed in one instance moderate but prolonged diminution of faradic irritability when no change could be found with galvanism, and Bernhardt has noticed lessened irritability to faradism with distinct increase to galvanism in an ulnar nerve the seat of traumatic paralysis. Again, *faradic* irritability may not diminish to the same degree in the muscle as in the nerve in mild cases, and conduction of voluntary impulses from the brain may be possible when there is no response to electrical currents, and there may be response to electrical currents when there is no conduction of voluntary impulses from the brain. In still milder

peripheral paralyses there is no reaction of degeneration at all, whence a favorable prognosis may always be made. It is to be especially observed in recovery from nerve lesions that *voluntary* motion often returns decidedly earlier than the electrical excitability of peripheral nerves.

*What do reactions of degeneration teach us?* Simply that the disease is seated in the anterior cornua of the gray matter of the cord, or in the peripheral nerves. They teach us nothing as to the nature of the lesion. Upon the integrity of the cells in the anterior cornua and their "trophic influence" depends the nutrition of the nerve and the muscle over which the cells preside. Hence with disease of the cornua result degeneration of the nerve and wasting of the muscle. The muscular fasciculi become

FIG. 95.—Motor Points on Leg, External Surface—(after Erb and de Watteville).

reduced in size and ultimately totally disappear. This is associated with a certain amount of interstitial overgrowth. In the transition referred to, certain fasciculi assume the yellow, glassy appearance known as waxy degeneration. The *sensibility* of the muscle, if the sensory nerve is intact, becomes increased, and there may be pain, partly due to compression of the nerves by morbid contraction, and partly to a morbid sensitiveness of the nerve-endings and to the interstitial inflammation. The recovery of the nerve is followed not only by gradual restoration of its power over the muscle, but also by restoration of the nutrition and development of the muscle. For this, however, much time is required, and it often remains permanently smaller than normal. The atrophy of muscle can be prevented to some extent by massage.

Lesions of motor nerves, whether inflammatory or traumatic, are followed by similar results—degenerative atrophy of nerve and muscle because of interference with the conduction of the trophic influence. Occasionally in cerebral palsies and in spinal paralyses in which the lesion is above these ganglion cells there is some wasting, but no reaction of degeneration is developed, because the nutrition is maintained by the intact cell body of the lower neuron.

From the foregoing the diagnostic and prognostic value of the reaction of degeneration is at once apparent. The seat of the lesion, whatever its nature, is easily determined, in so far as it is within the cerebral or peripheral motor segments, but we may not be able to say whether the nerve-cells or their peripheral processes (the peripheral nerves) are diseased. We are also informed that recovery, though not impossible, must be delayed in proportion to the degree of degenerative reaction, because of the extensive repair necessitated in muscle and nerve. Much experience with the use of electricity should, however, be had before the physician permits himself to draw conclusions.

II. SENSORY PHENOMENA.—Under this head naturally fall first the *subjective sensations* of the patient. They include, strictly speaking, only the various modifications of sensibility appreciable to him alone and independent of external impression—pre-eminently, *pain*. They also include those peculiar modifications due to internal irritation as contrasted with external impression, and known as *paresthesias*—viz., numbness, tingling, prickling, formication, or a feeling as of ants crawling over the skin; also a sensation like that of the contact of wool or fur—a furry feeling—vertigo, tinnitus aurium, or ringing in the ears, and a sense of unpleasant odors or tastes.

After these come modifications of the different varieties of cutaneous sensibility as excited by external impressions—*objective sensations*. They are of the nature of increase or decrease, the former being known as *hyperesthesias* and the latter as *anesthesias*, the latter being further characterized as partial or complete. To the latter the term paralysis of sensation, partial or complete, is also applied.

1. *Tactile sensibility*, the sense of touch or pure contact, is usually first investigated. The simplest method is by the touch of a finger, cotton wool, or blunt object of about the same temperature as the body, for both heat and cold must be eliminated in this test. The patient should be directed to close his eyes or avert his head. More refined measures are the application of rough, smooth, or coarsely uneven surfaces. More delicate still is the esthesiometer, essentially a pair of compasses with blunt and sharp points and graduated quadrant attached, by which the distance between the two points is accurately measured. By this instrument, in connection with a normal standard of relative sensibility worked out by E. H. Weber, the degree of impairment in delicacy of touch may be measured. Closer approximation may be recognized if the two points of the compasses are put down one after the other and varying the test by touching the same place twice or a different place each time. Weber's table is as follows:

*Minimum distance at which the two points of a pair of compasses in contact with the skin may be recognized as two points :*

Cheek, 11 to 15 millimeters.	Backs of the hands, 31 millimeters.
Tip of the nose, 6 millimeters.	Backs of the fingers, 11 to 16 millimeters.
Forehead, 22 millimeters.	Tips of the fingers, 2 or 3 millimeters.
Tip of the tongue, 1.2 millimeters.	Back, 55 to 77 millimeters.
Back of tongue and on the lips, 4 or 5 millimeters.	Chest, 45 millimeters.
Neck, 34 millimeters.	Thigh, 77 millimeters.
Upper arm, 77 millimeters.	Leg, 40 millimeters.
Forearm, 40 millimeters.	Instep, 40 millimeters.

These figures can, however, only be used within limits, as they are by no means constant for different individuals, or, indeed, for the same individual at different times. Marked deviations from them may, however, be accepted as indicating derangements of tactile sense.

2. *The sense of pain* is of equal importance to that of pure touch, because these two not infrequently fail to diminish or increase *pari passu* in morbid states. Parts insensible to touch may respond decidedly to painful impressions. Pain is most easily investigated by pricking with a pin or pinching a fold of skin, by painful electrical currents or painfully hot metals. The special term *analgesia* is applied to loss of sense of pain while the tactile sense is preserved. Analgesia exists in peripheral and central nervous disease and may be observed especially in syringomyelia.

*Tenderness* or pain on pressure in the course of nerves should be studied in connection with the sense of pain. It is found in nerves which are the seat of inflammation, especially in sciatic neuritis and multiple neuritis.

3. *The sense of temperature* may be roughly tested by ascertaining the power of the patient to discriminate between the warm breath close to the skin and the cooler current produced by blowing from a distance. More precisely, the sense of temperature is studied by testing the ability to recognize differences in the temperature of flat-bottomed test-tubes filled with water of different temperatures and brought into contact with the skin. The therm-esthesiometer has been devised by Eulenburg for the same purpose, but the student is referred to works on nervous diseases for its description.

In health differences of  $0.5^{\circ}$  to  $1^{\circ}$  F. ( $0.27^{\circ}$  to  $0.55^{\circ}$  C.) may be recognized on the fingers and face at temperatures from  $80^{\circ}$  to  $100^{\circ}$  F. ( $26^{\circ}$  to  $37^{\circ}$  C.), while on the back differences to be recognized must amount to  $2^{\circ}$  F. ( $1^{\circ}$  C.).

In disease we sometimes notice complete loss of sense of temperature, while the skin appreciates other forms of irritation, and, again, this state of affairs is precisely reversed; or the temperature and pain senses may be lost or impaired, while tactile sense is preserved, as in syringomyelia. This is known as dissociation of sensation. It occurs most commonly in syringomyelia, but has been seen in other diseases. Strümpell has called attention to a peculiar reversal of the sense of temperature, as the result of which cold objects appear warm. This has been noticed in various diseases.

4. *Sense of Locality*.—By this sense we know, without looking, what part of the body is being touched. While cutaneous sensibility may

remain intact, the sense of locality may be seriously deranged. Thus, a patient may think he is being touched on the leg when the contact is with the foot.

5. *Delayed conduction of sensory impressions* represents a form of modified sensibility of which after-sensations are a further subdivision. In delayed conduction an irritation, more particularly a painful one, like the prick of a pin, is noticed by a patient after an appreciable interval, whereas in health the recognition is instantaneous so far as the unaided perception is able to judge. Touch and pain may even be thus separated, the immediate contact of the pin being promptly recognized, while the sense of pain presents itself a few seconds later. It is likely, also, that the sense of touch may be delayed.

6. *An after-sensation* is a prolonged sense of pain which succeeds a momentary impression. Such is the prolonged burning on the sole of the foot which sometimes succeeds the prick of a pin, or which may occur once or oftener after a short interval, as if additional pricks had been made. Occasionally an isolated prick of a pin is not perceived, and repeated pricks are necessary, the whole producing a painful sensation; this is known as summation of sensation.

These abnormal sensations occur particularly in diseases of the spinal cord or of the nerves, and especially in tabes dorsalis.

7. *The muscular sense*, it were better named the *sense of position*, is that sense by which we become aware of the position of any of our limbs without the aid of vision, as well as of any degree of motion by them. It is probable, however, that the sensibility of the articular surfaces, ligaments, tendons, and skin aids the sensibility of the muscles in furnishing this information, and it is better to call this sense the *sense of position* when we speak of it in reference to the position of the limbs, or *deep sensation*. This power is diminished in nervous diseases, and may be tested by having the patient first touch a certain object with his eyes open and asking him to repeat the act with the eyes closed; or by moving the fingers or toes of a patient and requesting him to give their positions when his eyes are closed and voluntary movements of the parts are restrained.

The "muscular sense" is not only thus estimated, but the strength required to lift a leg or an arm, more plainly evident when one is tired, is also measured through it. It is the muscular sense which causes the paretic to say that his leg feels heavy. By the muscular sense, too, or by the "sense of power," we estimate the amount of strength demanded by any muscular contraction, and thus measure the difference in weight of objects, eliminating, however, the sense of pressure, which may be done by suspending the object in a towel.

In tabes dorsalis, as well as in paralysis of cerebral origin and in cortical lesions, the muscular sense may be defective; also in hysterical affections. It is also found defective in diseases of the peripheral nerves and in diseases of the lemniscus, or of the internal capsule, or of the nerve fibers passing to the cortex behind the fissure of Rolando.

It is disputed whether the muscular sense has a center separate from that of motion in the cortex or from the pain or tactile or temperature

senses, but an observation by Allen Starr<sup>1</sup> would go to show that it has a separate center two inches behind the fissure of Rolando and about an inch and a half to the left of the median line. It seems probable that the posterior columns of the spinal cord and the parietal lobes are especially concerned with the muscular sense.

The muscular sense is also estimated by the amount required to be added to an existing weight on the skin before the addition is appreciated. Thus it has been ascertained that in health an addition of  $\frac{1}{20}$  or  $\frac{1}{30}$  to an existing weight can be appreciated. Thus, if a weight of 95 gm. be placed on the skin, an addition of a single gram will not be recognized, but nearly five gm. must be added before the increase is appreciated, while if considerably more than this is necessary, it means that the sense of pressure is less delicate. Sufficiently accurate measures are coins of different weights. Temperature must be eliminated by placing non-conducting substances between the weight and the skin, while the part to be tested must also be supported.

It is not unusual to find, in paralysis of the muscular sense, failure to recognize a doubling and even tripling of weights. It is more especially in tabes dorsalis that such paralyzes are found while the tactile sense proper is intact, a light touch of the skin being felt, while a considerable pressure is not appreciated.

*Astereognosis* is the inability to recognize objects, their nature and uses, by touch, as the result of cerebral disease, but not because of any affection of the peripheral nerves or spinal cord. Most frequently it occurs in association with incurable hemiplegia, or as a symptom of tumor of the brain. The attempt has been made to limit the term, stereognosis to the recognition of the form and characteristics of an object, while symbolia is employed for the recognition of the object in regard to its uses. This distinction is likely to cause confusion.<sup>2</sup>

8. *Anesthesia* is said to be peripheral, spinal, or cerebral, in accordance with the seat of the broken conduction between the terminal apparatus and the cerebral cortex. *Peripheral* anesthesia occurs after chilling of the skin through the action of ether, from cocain, aconite, veratrum, as well as corrosive agents like acids, alkalies, and carbolic acid. Spasm of the small vessels, forming the so-called spastic anemias, is also attended by anesthesia. The anesthetics of washerwomen, who have their hands in water all day long, may belong to this class. Lesions of nerve trunks by pressure, inflammation, and degeneration may cause anesthesia. The *paresthesias* referred to—numbness, formication, and tingling—are among the effects of such lesions. *Spinal* anesthetics are found, especially in connection with disease of the posterior roots, posterior columns, and posterior cornua of the cord. Such a disease is tabes dorsalis especially. Anesthesia is found, however, also in myelitis, acute and chronic, and when there is pressure on the cord from hemorrhage into the spinal canal or pressure by diseased or broken vertebræ or from tumors. Such anesthesia is usually bilateral and is known as *paraaesthesia*. *Cerebral* anesthesia occurs as the result of

<sup>1</sup> "Psychological Review," January, 1895.

<sup>2</sup> See Burr, "American Journal of the Medical Sciences," March, 1901. "Therapeutic Gazette," Feb. 15, 1904.

hemorrhages, softening, or tumors, which impinge on the posterior limb of the internal capsule, through which the sensory fibers, probably after interruption in the thalamus, pass upward to the cerebral cortex. If the cerebral anæsthesia affects half of the body, it is known as hemianæsthesia, and the half of the body affected is opposite the hemisphere of the brain in which the lesion lies, since the sensory fibers also decussate in their course from the periphery, and most of them throughout the cord very soon after their entrance into the posterior roots.

The hysterical anæsthesias, and anæsthesias due to the narcotics and anesthetics, are regarded as cerebral in their origin. Those succeeding such acute infectious diseases as typhoid fever have been ascribed to both peripheral and spinal origin. The hysterical hemianæsthesia is much commoner than the organic cerebral hemianæsthesia.

III. SENSORY MOTOR PHENOMENA.—These words explain themselves, but in addition to the general application they include such special conditions as *akinesia algæra* in which all sorts of muscular action are attended with pain in the active muscles—even the act of speaking is attended with pain. It is a symptom of several neuroses, among which hysteria and neurasthenia are conspicuous. *Atremia*, which resembles akinesia, differs from it in the absence of tenderness of the muscles affected.

IV. VASOMOTOR AND TROPHIC PHENOMENA. We pass next to the study of *vasomotor* and *trophic alterations*. Two sets of vasomotor nerves have been demonstrated by physiologists—the vasoconstrictors and vasodilators—the former contracting the arteries when stimulated and permitting their dilatation when paralyzed. The vasodilators are influenced in an opposite manner by the same agencies, but their number, so far as proved, is not great, as they include up to the present time only fibers in the chorda tympani, nervi erigentes, and sciatic nerve. Blushing may be the result of stimulation of vasodilators. Moreover, pathology has as yet failed to separate lesions of the two sets of nerves and their effects and vasomotor phenomena are generally regarded as results of a *paralysis* or of an *irritation* of vasoconstrictors. Instances of the former are redness, a feeling of warmth, and sometimes an actual elevation of temperature, sweating, all in circumscribed areas or half the body. They may persist or intermit. Instances of vasomotor irritation are pallor, coldness, accompanied by stiffness, formication, and even pain. These are phenomena of vasomotor spasm. A more or less permanent condition of the hands sometimes results, characterized by a blueness or mottled appearance accompanied by a lowered temperature further augmented by external cold. Still higher degrees are said to have produced circumscribed gangrene (Raynaud's disease).

Symptoms of vasomotor *paralysis* occur in connection with cerebral and spinal lesions and with injuries of the sympathetic system and nerve trunks containing vasomotor fibers. The essential causes of vasomotor *spasm* are less easy to locate. It is found associated with prolonged convulsive seizures, and in angina pectoris at the beginning of the attack, as if caused by irritation of the sympathetic ganglia in the heart.

That *trophic* or nutritive phenomena are closely allied to vasomotor phenomena is commonly admitted. That they are under the control of the same nerves is doubtful, although the proof of the existence of separate trophic nerves is still wanting. Vesicular eruptions in the area of distribution of nerves, such as herpes zoster, certain atrophic skin diseases, pigmentations and depigmentations, such as morphea, Addison's disease and vitiligo, scleroderma, and the glossy skin which succeeds certain injuries to nerve trunks are illustrations of trophic influences. Similar are the changes in the skin, hair, and nails, as the result of which the first becomes dry, the second is lost or becomes rapidly gray, and the last grow brittle, thicken, or drop off. The latter events occur in connection with spinal and even cerebral lesions. The circumscribed edema known as acute angioneurotic edema and the more permanent condition of myxedema are also probably trophic. So, also, are the atrophies which result from disease of the cells of the anterior horns of the gray matter of the cord, or from injuries to nerves by which they are essentially cut off from the trophic cells; also unilateral facial atrophy including even atrophy of bone, and the still more remarkable spinal *arthropathies* of Charcot, as the result of which the joints enlarge or become the seat of effusions.

Finally, there is the acute bed-sore or eschar, so well described by Charcot,<sup>1</sup> beginning in an erythematous patch on which bullæ and blebs are rapidly developed, quickly succeeded by gangrene. While pressure or irritation may be necessary to the production of these sores as exciting causes, they are more easily invited in spinal paralyses than in non-paralytic conditions. Such results follow cerebral lesions and lesions in the medulla oblongata, spinal cord, and sympathetic nerves.

It is well known that the vasomotor nerves surrounding the various blood-vessels are derived from the sympathetic trunks, which, in turn, receive their vasomotor filaments from the roots of the spinal nerves.

V. MENTAL PHENOMENA.—Under this head come the phenomena of consciousness or unconsciousness, coma, the state of the will, the various perversions of mental processes, including delirium, hallucinations, delusions, illusions, and insane acts. *Hallucinations* are descriptions of the special senses which appear to the individual as real. They have no external cause. The victim of delirium tremens who imagines that he is pursued by monsters of various sorts is the subject of hallucination. A *delusion* is a false belief which can not be corrected by argument or experience. The deluded person imagines that he is the happy possessor of millions when he is actually a pauper, or complains of poverty although affluent. An *illusion* is based upon an actual perception, but an erroneous impression arises therefrom. In a hallucination no object is actually seen; there is no sensory impression. The idea of relief obtained on looking at a picture in the stereoscope is an illusion.

*Delirium* is the more or less acute manifestation of one or all these perversions of mental process, associated with muttering or active speech suggested by them or with action growing out of them. Thus consti-

<sup>1</sup> "Lectures on Diseases of the Nervous System," Philadelphia, 1879.

tuted, delirium may be the result of toxic states or acute disease other than of the brain.

The same perversions of mental process continued and unaccompanied by fever constitute *insanity*, which is probably always associated with structural change in the brain or its membranes, although such may not always be demonstrable. Other symptoms are added, however, in insanity, such as extreme depression of spirits, while hallucination, delusion, and illusion may be present in various degrees. Special insane acts should be specified and modifications of normal sleep noticed.

VI. ALTERATIONS IN VISION AND HEARING.—In addition to the ordinary defects of vision, the *response of the iris to light* should be noticed; also its *accommodating power*. The former is absent in three-fourths of all cases of locomotor ataxia, while the latter remains. The iris thus failing to respond to light, but retaining its accommodation to change of distance, is known as the Argyll Robertson pupil. Each eye should be tested separately, the other being covered. Finally, the eye-ground should be examined in every exhaustive study of a nervous case.

Modifications in *hearing* are the nature of increased and diminished intensity, and there is that very common symptom known as *tinnitus aurium*, or ringing in the ears, already alluded to as a good instance of a subjective symptom. Hyperacusis occurs in association with augmented acuteness of the other senses in acute affections of the brain or when there is hyperemia of the brain from any cause. It is also often complained of in hysteria. Deafness, on the other hand, is more frequently the consequence of disease of the ear itself. Ringing in the ears occurs in many conditions, known and unknown. While some more than usual impression on the nerve is a condition of tinnitus, it by no means follows that the cause resides in the nervous system. In addition to the numerous forms of irritation due to ear disease, the blood in an adjacent vessel may be thrown into vibration and produce an audible murmur. On the other hand, tinnitus is sometimes due to intracranial irritation either of the nerve or of the auditory centers.

VII. ALTERATIONS IN BREATHING AND PULSE.—*Alterations of breathing* are very common in nervous diseases. Respiration may be rapid or slow, and labored and sighing, or irregular, but especially peculiar is the *Cheyne-Stokes breathing*, in which, succeeding a long pause, so long sometimes that it seems as though the patient would never breathe again, follows gentle and shallow respiration, which gradually grows deeper and more frequent until an acme of dyspnea breathing is reached, when it again gradually diminishes in depth and frequency until the pause again occurs. It is an arrhythmical breathing of a periodic type. During the pause the pupil often contracts and the heart's action becomes less frequent. Cheyne-Stokes breathing may occur in tubercular meningitis, cerebral hemorrhage, embolism, thrombosis, and aneurysms of the basilar artery; also in uremia, heart disease, and more rarely in other conditions, including the infectious fevers, in which the respiratory center is influenced.

The period of arrest varies from five to forty seconds, and the duration of each cycle may be from 15 to 75 seconds, and may vary.

A modification of Cheyne-Stokes breathing is a form in which there are periods of deep and energetic breathing which begin suddenly, and in which the respirations gradually become shallower until they cease, and after a pause energetically recommence.

Cheyne-Stokes breathing was ascribed by Walsh and later by Traube and Rosenbach to lessened excitability of the respiratory center in the medulla oblongata. Filehne suggested that a periodical vasomotor spasm due to stimulation of the *vasomotor* center by the asphyxiated blood, arrested the rhythmogenic office of the *respiratory* center. The arterial spasm in the medulla oblongata thus caused prolongs the stimulation of the respiratory center as well as that of the vasomotor center by hindering the access of oxygenated blood. The respiratory center being less excitable, the respiratory movements, therefore, continue energetic—run riot as it were—after the blood has become oxygenated. The gradual onset of the breathing may be due to the fact that the reactive vasomotor dilatation exceeds the normal, and thus the quantity of blood reaching the respiratory center lessens the stimulating influence of its quality; but these are merely theories.

The *pulse* is influenced chiefly by diseases of the cranial contents, especially of the medulla oblongata, the cerebrum, and the meninges. It is at times very slow, as in meningitis and apoplexy, or when there is intracranial pressure from any cause or when there is pneumogastric irritation. It may be accelerated when there is inflammatory pyrexia or irritation of the cardiac center. Again, it may be irregular, acting through the nervous system, of which opium poisoning is among the familiar causes; uremia is another cause, rarely also is influenza.

Changes in the order of investigation proposed in this section will, of course, be demanded by circumstances, while at times certain steps may be omitted altogether.

VIII. FOCAL DISEASE AND FOCAL SYMPTOMS.—The terms focal disease and focal symptoms will be often used in the following pages. By *focal disease* in the nervous system is meant a circumscribed lesion, no reference being made to the nature of the lesion as to whether it is softening, a tumor, or compressing clot. By focal symptoms is meant symptoms caused by a lesion in one spot whether in the brain or spinal cord. Cerebral syphilis is a diffuse process, therefore usually not a focal disease. The *general* symptoms of a tumor in the motor cortex are headache, vertigo, choked disk, etc., the *focal* symptoms are paralysis of one or both limbs on the opposite side of the body, convulsions confined to these limbs or groups of muscles. Focal symptoms are localizing symptoms, or symptoms that indicate the focus of the disease or the region affected.

## AFFECTIONS OF THE PERIPHERAL NERVES.

## NEURITIS.

**Definition.**—Neuritis, or inflammation of a nerve, may be confined to a single trunk, whence it is called *localized*; or it may involve a large number of nerves, when it is known as *multiple neuritis* or *polyneuritis*. In *perineuritis* the connective tissue surrounding a nerve is the seat of the inflammation; in *interstitial neuritis* the tissue between the bundles of nerve-fibers is involved, and in *parenchymatous* or *degenerative* neuritis the substance of the nerve-fibers themselves is affected.

## LOCALIZED NEURITIS.

**Etiology.**—Exposure to cold is the most frequent cause of neuritis, and the nerve most frequently thus affected is the facial. Trauma is another cause, including compression, contusions, or cuts, as with glass, or stretching and laceration such as occur when there are dislocation, fracture, and other violent injuries. Neuritis may also occur as the result of extension of inflammation from contiguous parts, as from caries in a bone through which the nerve passes, adjacent joint inflammation, pleurisy, and meningitis. Finally, neuritis may be caused by toxins and morbid states of the blood, such as produce the infectious and constitutional diseases, as diphtheria, syphilis, and gout. The mineral poisons, especially lead and arsenic, are frequent causes. Alcohol is also a cause of this kind of neuritis, although it more frequently produces multiple neuritis.

**Morbid Anatomy.**—An inflamed nerve is reddish, from hyperemia of the *vasa nervorum*, though the stage of demonstrable hyperemia may have passed away when the nerve comes under observation. In *perineuritis* and *interstitial neuritis* the primary change is in the connective tissue—in the former, an infiltration of the nerve sheath with leukocytes, and in the latter, of the interstitial tissue with the same cells. There may even be minute extravasations of blood. These changes are more apt to occur in places along the course of the nerve where it is exposed to special irritation, as in passing through foramina or over bone. The lymphoid cells gradually become fusiform cells, resulting in the formation of true connective tissue. The pressure of this new tissue gradually destroys the nerve itself, the medullary sheath being gradually broken up into drops, which subsequently disappear, while the nuclei of the sheath of Schwann increase; finally, the axis-cylinder also becomes granular and disappears—all this in varying degrees. The nerve-fiber may be substituted by a fiber of connective tissue, in which there may be a deposit of fat, a condition seen in the lipomatous neuritis of Leyden.

In *parenchymatous neuritis* the primary change is in the nerve-fiber itself. Here the medullary sheath and the axis-cylinder are the first involved, the former breaking up into drops, as described, and the latter into granules, both ultimately disappearing, while the interstitial connective tissue remains comparatively unchanged; but the nuclei of the sheath

of Schwann proliferate and become a part of the interstitial connective tissue.

The muscles connected with the inflamed nerve also atrophy—in the case of the motor nerves, at least—being practically cut off from their center of nutrition. The change in the nerve is essentially the Wallerian change noticed in the nerve-fiber of a cut nerve. In some instances the changes noticed in the sheath of Schwann extend over into the interstitial tissue of the muscle.

**Symptoms.**—There is not much constitutional disturbance in localized neuritis, though the thermometer may show some rise of temperature. *Pain*, especially pain on motion, and tenderness, are the salient symptoms. The pain may be confined to the seat of the inflammation or may involve the distribution of the nerve, or the whole limb may be involved. It varies in degree and also in character, being sometimes burning and at other times aching, boring, or shooting. It is likely to be worse at night, and when in situations involving pressure on the nerve itself. The nerve may be swollen appreciably, and rarely the skin over it is reddened.

The pain in the trunk of an inflamed nerve is probably due to pressure on the *nervi nervorum*. Weir Mitchell has especially called attention to this. An interesting fact is that the nerves composed almost purely of motor fibers are less tender than sensory nerves. This would imply that fewer sensory nerves are distributed to the motor nerve trunks than to sensory nerves, or that some pain is felt by the sensory fibers which make up the inflamed trunk.

Mitchell also describes elevation of surface temperature and trophic disturbances, such as sweating, herpes, and effusion into neighboring joints. Other trophic derangements, including muscle wasting, associated with peculiar "glossy skin" or slight edema, may be present. Vesicles, bullæ, and herpetic eruptions may occur. The nails become brittle, rough, and marked with transverse ridges. The bones in the fingers may even become atrophied. There may be thickening of the skin and a condition resembling ichthyosis may be present. Ultimately the hyperesthesia and paresthesia may become anesthesia, though usually limited to small areas.

Motor disturbances, including twitchings and contractions, may be present.

The electrical condition of the nerves and muscles must be studied. It may be normal in slight cases. In more severe cases there may be the reaction of degeneration, with the slow, lazy contraction of the muscles, and the reversed reaction to opening and closing currents, described on page 945.

The course of the disease is variously prolonged. Many acute cases terminate favorably in a few weeks. More cases become chronic, extending over months and even years, after which they may gradually subside.

A rare variety is "ascending neuritis," in which the inflammation extends from smaller to larger branches, until finally most of the nerves of a limb may be involved, or possibly even the spinal cord, producing myelitis, with or without spinal meningitis. Paralysis may result from such a condition. This is possibly the rare form of paralysis that suc-

ceeds visceral disease, as that of the bladder. Even the corresponding nerves of the other side may be involved. It is the opinion of some of the best neuropathologists that this ascending neuritis occurs only from a suppurating wound. The theory of an ascending neuritis is not universally accepted.

ADDITIONAL SYMPTOMS DUE TO NERVES INVOLVED.—(1). In inflammation of the *facial* nerve there may be complete paralysis of all the muscles supplied by the nerve. In inflammation of the *median* nerve there is disturbance on the palmar surface of the thumb, forefinger, and middle finger on its radial side, and there is often intense pain in these same situations.

(2) In inflammation of the *ulnar nerve*, there are pain and loss of sensation in the outer half of the third finger and in the fourth finger, with wasting of the flexor carpi radialis, the intrinsic muscles of the little finger, the interossei, lumbricales, and the adductor of the thumb. Here, in case of long standing, we have the "claw hand," the result of overextension of the first phalanges and flexion of the last two.

(3) In inflammation of the *musculospiral* there are great pain and tenderness of the upper arm and forearm, the region of the brachialis anticus and triceps extensor, the extensors of the wrist and fingers, the two supinators—the back of the hand, thumb, and index finger. In extreme degrees we have the characteristic wrist drop and inability to extend the first phalanges of the fingers and thumb, with partial anesthesia of the base of the thumb and forefinger.

(4) The *circumflex nerve* supplies the deltoid and teres minor. There may be pain or impaired sensation in the muscles and the skin over them, to which may succeed loss of power and atrophy of the deltoid and the arm cannot be raised.

(5) In inflammation of the *brachial plexus*, which is prone to occur in gouty subjects over 50 years old, there may be a combination of symptoms belonging to the last-named four nerves. A subvariety of brachial neuritis is *radicular* neuritis, in which the pain suggests the involvement of the roots of the nerves.

**Diagnosis.**—The disease is chiefly to be differentiated from *neuralgia*. This depends upon pain and tenderness in the course of the nerve and upon the limitation of the symptoms to its distribution. Neuralgia is more intermittent, and is relieved rather than aggravated by pressure. The presence of the paresthesia points to neuritis and the diagnosis is confirmed if there is ultimately lessened sensibility. In neuralgia, nerve and muscle reactions remain normal. It is possible, however, that neuralgia may result in neuritis. The distal pain of *central spinal disease* must be differentiated. In brachial neuritis the pain may radiate to the left side, suggesting *angina pectoris*, and there may even be a tendency to cardiac distress, but there is no tenderness in the course of the nerve in angina.

**Prognosis.**—The prognosis varies greatly, being favorable in mild and in most traumatic cases. Those consequent upon local suppuration are the gravest. In ordinary cases from cold or contusion recovery usually ensues sooner or later, although some last a long time and recurrences

are not unusual, especially in neuropathic dispositions, in which, too, recovery is slower.

*Special Variety of Localized Neuritis—Sciatica.*

**Definition.**—This term is applied to all painful affections in the distribution of the sciatic nerve, some of which may be neuralgic, but the vast majority are inflammatory and perineuritic, as it is the sheath of the nerve that is usually involved.

**Etiology.**—Sciatica is far more common in men than in women, in the ratio of about four to one, while brachial neuritis affects both sexes about equally. It is also a disease of adults, being unknown in children and very rare in the second decade. It is most frequent between forty and fifty, next between fifty and sixty, and next between thirty and forty.

Gout and rheumatism are favoring causes, especially fibrous rheumatism. Very rarely syphilis may be a predisposing cause. Exposure to cold is the most frequent exciting cause, especially after severe muscular exertion; while standing in water, sitting or lying on the cold ground, and the like are frequent causes. Exposure to drafts, though less frequently than of neuritis of the upper extremity, is still a cause. A sciatica may also arise by extension from a rheumatic focus, especially that form of lumbago involving the fibrous attachments of muscles at the back of the sacrum, whence the inflammation extends to the sheath of the sciatic nerve. Pressure by mechanical agents and possibly muscular contraction may be a cause; also pressure by tumors and other new formations within the pelvis. Even the pressure of fecal accumulation may cause it if it is on the left side. In bilateral sciatica the possibility of intrapelvic tumor should be carefully considered. In addition to the intrapelvic causes referred to, secondary sciaticas may be caused by bone disease and other foci of suppuration external to the pelvis.

**Morbid Anatomy.**—The morbid changes are those already described under neuritis.

**Symptoms.**—The leading symptom, is, of course, *pain in the course of the nerve*. Felt first in the back of the thigh, it also travels above the hip-joint, into the sciatic notch, behind the knee, below the head of the fibula, behind the *internal* malleolus, and on the dorsum of the foot. It may be more diffuse, but the course of the main trunk of the nerve is often indicated by it, and the points previously named, especially the back of the middle of the thigh and the sciatic notch, will often be pointed out by the patient as seats of special tenderness. It usually begins gradually, but it may start suddenly, especially in cases of rheumatic origin. Motion, particularly in walking, and positions in which the nerve is put in a state of tension or is compressed, aggravate it. A valuable sign of sciatica is pain produced by passive flexion of the thigh upon the pelvis with the knee extended (Lasègue's sign); by this means the sciatic nerve is stretched, and pain is readily produced if the nerve is inflamed. The characteristics of the pain are those already described under neuritis. The other more unusual symptoms of neuritis may also be present, as herpes, edema, and wasting, but the reaction of degeneration is almost never present. The loss of the *tendo Achillis* jerk is an important sign.

**Diagnosis.**—This is not difficult, although a careful study should be made of each case with a view to determining its primary or secondary origin. *Pelvic tumors*, especially in women, and *rectal accumulations* should be sought for. *Lumbago*, *hip-disease*, and *sacroiliac disease* are all to be recalled, but in none of these is there pain on pressure in the course of the nerve. In the last only is there sometimes pain in the posterior part of the thigh. Pain felt only in the outer side of the thigh is not sciatica. Some writers attribute all sciatica to joint diseases, but this view is not tenable. The rare cases of *sciatic neuralgia* are not characterized by tenderness. They occur in persons subject to neuralgia, and the pain is not influenced by position and motion, but is purely spontaneous. *Disease of the vertebræ*, of the *cauda equina*, and even of the *spinal cord* may produce sciatic pain; but here, again, tenderness is not so common in the course of the nerve, the pain is more likely to be bilateral, and changes in objective sensation may be distinct. Inflammation of the roots of the sciatic nerve, however, may extend downward. Bilateral pain is indicative of disease of the nerve-roots, although bilateral sciatica does occasionally occur. The shooting pains of *tabes dorsalis* are like those of sciatica, but the other symptoms of the former disease are present.

**Prognosis.**—Cases of sciatica, however obstinate, usually sooner or later get well, although they may persist for months. A case came under my observation which lasted seven years, but recovery finally was complete.

**Treatment.**—Here, as elsewhere, if a cause is discoverable, it should be removed. Exposure to cold and dampness should be avoided, pressure by cicatricial tissue or dislocated bones should be relieved, and constitutional states favoring neuritis, such as gout and syphilis, should be corrected.

Of curative measures, rest is the most important. When a limb can be splinted, this should be done, pressure by muscular contraction being thus prevented. Cold may be a useful application, as by an ice-bag. In other instances heat, now dry and again moist, subserves a useful purpose. A blister or blisters may be applied over the tender nerve. Especially convenient is the Paquelin cautery, which should be used earlier than it commonly is; its application takes but a second, and may be rendered painless by previously applying, for a few minutes, a mixture of ice and salt to the spot to be burned, although this has been largely superseded of late by the more convenient ethyl chlorid. Morphin is sometimes indispensable, and the hypodermic method of application is best— $\frac{1}{6}$  to  $\frac{1}{4}$  grain (0.011 to 0.0165 gm.) for an adult. But the morphin habit is easily acquired, and the patient should not be allowed to use the syringe himself. Cocain may be similarly used— $\frac{1}{10}$  to  $\frac{1}{3}$  grain (0.0066 to 0.022 gm.)—and Gowers recommends it highly, more particularly for its power in arresting local transmission of the impulses that cause pain. Eucaïn is even better. Here, too, the injection should be made at the seat of the pain by the physician or a trusted attendant. Gowers, whose large experience always bespeaks respect, considers mercury also a most efficient agent, in the shape of a blue pill, 1 grain (0.066 gm.) once or twice a day, associated, if necessary, with morphin, the con-

stipating effect of which it counteracts. Salicylate of sodium is undoubtedly sometimes useful, as is also more rarely iodid of potassium. Strychnin is also of service. Injection of a considerable amount of normal salt solution into the buttock near the seat of pain has been recommended.

In the chronic form also Paquelin's cautery should be repeatedly used, or if not at hand, blistering may be substituted. Electricity here comes into play, and galvanism is the form to be used, the positive electrode being placed over the nerve or seat of pain, and the negative indifferently placed. A weak current is best, but its strength may be increased if such current be inefficient. The application should continue for about ten minutes. The wasted muscles recover as the inflammation subsides, but massage and galvanic electricity help them. Faradism is less favorably regarded, especially in the active stage.

*Every case of sciatica* should be at once ordered to rest, and the more complete the rest, the sooner the recovery. Splinting of the limb as recommended by Weir Mitchell, is necessary in some cases, and would probably hasten cure if used earlier, but it is so inconvenient that the temptation to temporize is very strong. Rest being secured, I am confident that recoveries would be prompter if Paquelin's cautery were oftener used at the onset. Counterirritation by blisters, mustard, and iodin is relatively inefficient. Treatment by cold along the course of the nerve certainly relieves the pain for a time, but in my experience the relief thus obtained is not permanent.

Attention should be paid to local causes, if these are discoverable, and to constitutional causes as well.

For the relief of mild degrees of pain phenacetin and antifebrin, and especially a combination of phenacetin and caffein citrate, say 10 grains (0.66 gm.) of the former and 3 grains (0.2 gm.) of the latter every two hours is often efficient. For severe degrees morphin is necessary, and is best given hypodermically in doses of from  $\frac{1}{8}$  to  $\frac{1}{4}$  grain (0.008 to 0.0165 gm.). The danger of establishing the morphin habit must always be kept in mind, and cocain should be tried first as a deep-seated injection in doses of from  $\frac{1}{8}$  to  $\frac{1}{4}$  grain (0.008 to 0.0165 gm.). Acupuncture over the course of the nerve is of service for the same purpose—relief of pain rather than cure. Anodyne liniments may be used, and although not curative, do give some comfort and meet the wishes of the patient that something should be done. The internal administration of ichthyol in small doses has been highly recommended by Crocq. Ichthyol locally is sometimes serviceable.

In chronic cases change of scene is often of advantage, and if associated with thermal bath treatment may accomplish a cure in otherwise obstinate cases. The mud-bath is a measure of treatment applied in Europe with some success. In the chronic stage electricity also meets the demands of patients and friends and may do some good. The galvanic current should be employed. Massage is less efficient than in muscular rheumatism, though it should be tried. Nerve-stretching is a very dubious expedient, it may cause serious consequences.

## MULTIPLE NEURITIS.

SYNONYMS.—*Polyn neuritis; Peripheral Neuritis; Korsakow's Psychosis.*

**Definition.**—An inflammatory condition involving many peripheral nerves, either simultaneously or in rapid succession.

**Historical.**—Multiple neuritis is a disease of modern recognition. The symptoms peculiar to the condition were described first, probably, by James Jackson, Sr., of Boston, Mass., as early as 1822. In 1854 Robert Bentley Todd, of London, wrote of lead palsy: "The nervous system in thus first affected at its periphery, in the nerves, and, the poisoning influence continuing, the contamination gradually advances toward the center." Duchenne described the symptoms fully in 1858. Samuel Wilks described alcoholic paraplegia, but the existence of multiple neuritis as an actual disease was first demonstrated by Dumenil, at Rouen, in 1864, and the literature was further contributed to by Joffroy in 1870, Leyden in 1880, Grainger Stewart in 1881, Buzzard in 1886, James Ross, Henry Hun, and Charles K. Mills in 1892. W. R. Gowers' article in the second edition of "Diseases of the Nervous System," 1891, is a very complete one, as is also the work by Remak and Flatau in the Nothnagel system.

**Etiology.**—The causes of multiple neuritis are numerous, and by no means easy of classification. They include:

1. The commonly acknowledged poisons introduced from without: (a) Organic, including alcohol, by far the most frequent cause, ergot, morphin, ether, carbon monoxid, carbon bisulphid, benzine and its products, and anilin; (b) inorganic, including lead, arsenic, phosphorus, and mercury.

2. Endogenous toxins generated in the organism by chemical changes. Such is the cause of the neuritis of diabetes mellitus, whether glucose, oxybutyric acid, diacetic acid, or acetone, all of which are found in the blood in that disease.

3. *Toxins* inherent to the infectious diseases, whether an organism or its product. Instances of the former are malarial neuritis, leprous neuritis, beri-beri or so-called endemic neuritis, also, probably, the neuritis of acute infectious jaundice (Weil's disease). In these instances the cause is an organism. Of neuritis due to toxic products of pathogenic bacteria are diphtheritic neuritis, septicemic neuritis, the neuritis of smallpox, typhoid fever, tuberculosis, and possibly syphilis are instances.

4. Intrinsic states of the blood of undetermined nature, with which cold may or may not co-operate as an exciting cause—viz., rheumatism, gout; also the puerperal state, and chorea. Advanced microbic doctrines would place rheumatic neuritis in 3, while a greater conservatism might place septicemic neuritis in 4. Malnutrition, such as characterizes cachectic and senile states, cancer, tuberculosis, and wasting diseases generally are also causes. It is not impossible that cold alone may, by its operation, generate a poison capable of producing a polyn neuritis, but more probably it acts by lowering the vitality of the nerves and rendering them liable to attacks from other agents.

**Age and Sex.**—Multiple neuritis is a disease of adults. Aside from rare cases of diphtheritic neuritis, the most common form observed in children is a complication of acute anterior poliomyelitis. Gowers says "it may, perhaps, now and then be met with apart from the spinal malady as an infantile variety of multiple adventitial neuritis irregular in distribution." It is not improbable that in some of the cases of poliomyelitis

the changes in the nerves are secondary to alterations of the nerve cells in the anterior horns of the spinal cord.

The remaining chief forms occur usually between the ages of 20 and 50, the alcoholic between 30 and 40 or later, and senile neuritis at a still later age. The alcoholic form is more frequent than all others put together, and of this form 70 per cent. occur among women. This preponderance of the disease in women has been especially noticed in England, where alcoholism among females is more common than in this country. More than one cause may co-operate, when one may be the predisposing and the other the exciting. Cold probably most frequently plays the latter rôle, but there may be others, such as depressing emotions, anemia, and the like.

**Morbid Anatomy.**—The special anatomical feature of multiple neuritis is that it is *parenchymatous*, as contrasted with interstitial and perineural—that is, the changes begin in the nerve-fibers themselves, as described on page 957, rather than in the connective tissue between and around them. Yet this is not invariable. Indeed, it is improbable that either form of neuritis exists without the other for any length of time. It is further characteristic of multiple neuritis that the involvement is symmetrical—that is, the corresponding nerves on the opposite side of the body are affected. The more this is the case, the more likely is it that the change is parenchymatous. The changes are also more marked in the peripheral distribution than in the trunk of nerves. Macroscopic alteration is very rarely appreciable. In acute changes the nerve may be swollen, reddened, hemorrhagic, or in old cases hardened from overgrowth of connective tissue.

**Symptoms.**—The symptoms vary greatly in different varieties of neuritis, but there are some more or less common to all varieties, particularly illustrated by the alcoholic and rheumatic. These common symptoms will be considered first, and afterward some special features of varieties due to specific causes, particularly the metallic poisons, the acute infectious diseases, and the poison of beri-beri.

The symptoms are easily divided into three classes: *Motor* weakness, *sensory* derangement, and *inco-ordination*. The first is the result of the involvement of motor nerves, and manifests itself usually first in the extensors of the wrist and fingers, flexors of the ankle, and extensors of the toes. The sensory disturbances are tingling, numbness, and pain, while the inco-ordination resembles that of tabes. According as one or the other of these sets of symptoms predominates we have a motor form, a sensory form, or an ataxic form.

*The onset may be rapid or slow.* In the rheumatic form, or that due to cold, it is usually sudden, with chill and fever and a temperature of 103° or 104° F. (39.5° to 40° C.), headache, and backache. The slow onset is characteristic of alcoholic neuritis, though it may be precipitated by some exciting cause, as cold, exposure, fatigue, or some other toxic state. Neuritis of slow onset is rarely febrile. In the initial stage *sensory symptoms* are numbness and tingling of the fingers and toes, palms of the hands and soles of the feet, and other parts of the lower arms and legs; then hyperesthesia, tenderness, and pain, more marked in the legs, sometimes

associated with cramp in the calves. These symptoms may in mild degree precede the onset as premonitory for weeks and for months, especially in the alcoholic form.

Very characteristic is the *tenderness of the muscles* themselves, developed as they become weaker, and elicited by grasping them, the slightest pressure often causing the patient to cry out with pain. This is regarded as evidence that all the nerves of the muscles are involved, the sensory as well as the motor. The nerve trunks are also tender, although this tenderness is less marked than in simple neuritis, because the contrast with the hyperesthesia of the surrounding skin is less conspicuous.

The *motor symptoms*, seldom absent, soon follow the sensory phenomena just mentioned. They include palsy or inco-ordination or both in upper and lower limbs, but with this characteristic—that the involvement of the limbs is symmetrical and the distal extremities, as the feet and hands, are affected, the former more frequently. Motor symptoms may exist in the feet and sensory symptoms in the hands, the latter commonly preceding.

The muscles commonly involved are those supplied by the peroneal nerve in the lower, and by the posterior interosseous branch of the musculospiral in the upper extremity. With weakness in the legs comes *loss of knee-jerk* and *ankle-jerk*, quite frequently, but not invariably, depending, of course, on the involvement of the nerves forming these reflex arcs. The muscles above the knee are less frequently affected, and still less frequently those which move the hip-joint.

The paralysis of the muscles innervated by the peroneal nerve gives rise to a peculiar and distinctive walk known as the *steppage* gait, and occasionally it is unilateral, when only one peroneal nerve is affected. It is the gait of polyneuritis in which the foot drops, and in order to raise it from the ground and thereby to "shorten" the limb, the thigh is drawn up unnecessarily high and the knee is flexed excessively so that the gait resembles that of the "high-stepping" horse. The extremity of the foot strikes the ground first, followed by the heel, so that there is often a recognized interval of time between the two events. Closing of the eyes does not affect this gait. Occasionally the anterior tibial muscle may escape when the other muscles of the peroneal distribution are paralyzed.

As contrasted with the *diminished tendon reflexes*, the reflex action from the skin may be increased, especially when there is hyperesthesia, even when there is considerable motor paralysis, the movement being caused by the muscles which escape involvement. In severe cases, on the other hand, when there is much loss of sensation and motion, the skin reflex is absent; exceptionally, it may be absent when sensation is perfect. Myotatic irritability is almost always lost, although in the early stages of the disease, or in those cases in which the anterior crural nerves escape, it may be preserved.

In the arms it is the extensors of the wrist and fingers which are first affected, and these symmetrically, illustrated by one of the best recognized toxic forms of neuritis, lead palsy. In the latter there is paralysis of the extensors while the extensor of the metacarpal bone of the thumb and the supinator longus usually escape, although in some cases of lead palsy these muscles are affected. After the extensors, the flexors of the wrist and

fingers are involved, then the interosseous muscles, and, finally, the thenar and hypotenar muscles are attacked, always to a less degree than the extensors. The muscles above the elbow are less affected.

Occasionally the fibers of the *pneumogastric* are involved, causing frequent pulse-rate and paralysis of the vocal cords, cardiac failure, and death. Still more rarely the diaphragm and muscles of the thorax and abdomen are involved. The facial and motor oculi nerves are possible seats. Neuritis confined to the cranial nerves has been described. The sphincters are also rarely affected.

The muscles exhibit the *reaction of degeneration*, faradic irritability being lost, while galvanic irritability is increased, but not always altered in quality. In the nerves, irritability to both currents diminishes and ultimately disappears, although in the very first stage there may be increased galvanic irritability, as described under the reaction of degeneration. In severe cases total loss of excitability may occur at once because of a corresponding destruction of muscular substance, instead of being preceded by an intermediate state of increased excitability.

*Wasting* of the muscles is sooner or later inevitable, unless the disease is of short duration, although it may be obscured by a temporary edema or a condition of fatty infiltration, in which the fat accumulates between the wasting fasciculi, keeping up for a time the bulk of the muscle. The less affected muscles are likely to undergo shortening and contracture because of maintaining so long a fixed position, either from being given over to gravitation or as a result of an effort to relieve pain. This alteration occurs most frequently in the lower extremity, contributing to intensify the "foot-drop" at the ankle, and more rarely to produce flexure at the knee-joint and to a less degree even at the hip, both of the latter being the result of posture. The foot-drop may be increased by the pressure of the bed-clothes upon the foot.

The sensory and motor phenomena are commonly associated *pari passu*, the latter extending from the hands and feet up the outside of the arm and leg. Very rarely either set of symptoms may occur alone.

*Tremor* is a marked symptom in some alcoholic cases and may precede loss of power.

*Ataxic phenomena* are usually associated with the sensory and motor symptoms. They are manifested by difficulty in balancing while standing, or by inability to execute finer movements with the fingers. Indeed, these may be the first symptoms, and may lead when studied to the knowledge of some defect in extending the wrist and fingers, or in raising the toes, or foot, from the ground while walking. The ataxia is more marked in the lower extremities, and is believed to depend chiefly upon sensory nerve involvement, since these nerves are supposed to have most to do with co-ordination. Involvement of the motor nerves may possibly also cause ataxia. Because of the associated absence of the knee-jerk, the term peripheral pseudotabes has been applied to the ataxic variety. The symptoms may closely resemble those of tabes, but the phenomena always fall short of those of true tabes. It may be said, too, of the ataxic form that the sensory disturbances are sometimes less severe than in other typical cases. Absence of the Argyll Robertson pupil and of vesical disturbance, rapid

development of the disease, a history of the case suggesting a cause for neuritis, and, finally, recovery, are diagnostic points in favor of the ataxic form of neuritis as distinguished from tabes.

*Trophic changes* may occur in prolonged cases, including mainly glossy skin, arthritic adhesions, and thickening; also vasomotor derangement, shown by edema, especially about the ankles and the dorsum of the foot; also pallor of the fingers and changes in the nails and hair.

*Mental symptoms* are found more particularly in connection with the alcoholic form of neuritis. Besides irritability and general ill temper, more active symptoms are at times present. A childish jocularity in women, hysteria, and skilful duplicity in obtaining alcohol are characteristic. The phenomena may be those of delirium tremens or simple hallucination with extravagant ideas. Especially peculiar is the condition described by Wilks, and especially by Korssakow, in which there is a loss of appreciation of time and place, the patient describing with minute detail impossible journeys recently taken and persons whom he imagines he has seen. Convulsions and optic neuritis are rarely present; if present, they are probably due to meningeal inflammation. A simple mild delirium may occur in toxemic cases from the action of the poisons on the brain cells. Mental symptoms are not usually present in multiple neuritis from other causes.

The number and variety of the symptoms vary greatly in different forms, being most widespread in those cases due to alcoholism, to cold, or to combined causes, and limited in the cases due to metallic poisons, as lead. The more acute the case, the more widespread are the symptoms.

**Complications.**—These are the other diseases to which alcoholics are subject—cirrhosis and fatty change of the liver, gastric catarrh, and alterations of the kidneys and their consequences. The chief one in the toxic form is gout due to mineral poisons, almost exclusively lead. Pulmonary tuberculosis is common, and pneumonia, invading especially the middle portion of the lung, and sometimes bilateral, is a frequent cause of death. Patients with multiple neuritis are more liable to infections.

**Diagnosis.**—The diagnosis of alcoholic cases is usually easy from the history, although sometimes skilful deception, especially in women, deprives the physician of this assistance. The distinctive features of the disease are the symmetrical localizations of the sensory and motor symptoms, first and mainly in the extremities, and the tenderness of the skin, nerve trunks and muscles. There are, however, great variations in different cases, even in those dependent on the same cause, some cases being very acute and general and even rapidly fatal, others slow with limitation to groups of muscles; some mainly motor, others sensory and ataxic (pseudotabes).

The possible sources of confusion are *rheumatism*, acute and chronic; *neuralgia*, *tabes dorsalis*, *poliomyelitis*, acute and subacute; *pachymeningitis* damaging the nerve-roots, *acute ascending paralysis*, and *hysterical palsy*.

In *rheumatism* the tingling characteristic of neuritis is not present, and although the tenderness of a nerve passing in the neighborhood of a joint, especially apt to be aggravated in motion, may be mistaken for joint pain, careful examination will elicit its true nature. Neuritis differs from *neuralgia* in the bilateral symmetry of the pain, and in the persistence of tenderness and hyperesthesia as contrasted with the spontaneous pain of neuralgia.

The ataxic form of the disease, especially the form called neurotabes (peripheral pseudotabes), sometimes resembles *tabes dorsalis* very closely. In neurotabes the lesion consists only of the nerve degeneration, while the spinal cord is free, its claim to the title being the fact that the loss of motor power may be slight in neurotabes, as in most cases of true tabes. The diagnosis from tabes may generally be easily made. The association of absolute paralysis or distinct weakness of extensors with inco-ordination would indicate neuritis. The "lightning pains" of tabes are seldom found in neuritis, nor are waist constriction nor pupillary symptoms, while the muscular tenderness is not found in tabes. Rapid onset of the disease and ultimate recovery occur in pseudotabes. The extreme hyperesthesia, so distinctive a symptom of neuritis, may be less valuable in diagnosis, because it is often absent in the ataxic form. Girdle pains, paralysis of the sphincters of bladder and rectum, are much more common in cord involvement, even in alcoholic cases, but may occur in multiple neuritis.

*Poliomyelitis*—inflammation, acute or subacute, of the gray matter of the cord—resembles the rheumatic and toxemic forms of neuritis, which have, like it, a febrile onset, *initial* rheumatic pains, and muscular wasting with the reaction of degeneration. But, again, we contrast the symmetrical distribution of the palsy of neuritis and its limitation to nerve distribution with the random distribution of poliomyelitis. Pain on pressure and subjective sensory disturbances are not prominent in poliomyelitis, but sometimes the symptoms are suggestive of the association of multiple neuritis with poliomyelitis.

In *pachymeningitis* which involves the nerve-roots, producing paralysis, wasting, and anesthesia, the legs do not suffer early in the disease, as a rule; and while the upper parts of the arms and trunk may be anesthetic, there is no tenderness of the nerve trunks, unless these also are inflamed.

*Acute ascending paralysis* (Landry's) resembles the most rapid form of multiple neuritis in some of its symptoms, but the paralysis usually ascends the trunk from the legs to the arms, and does not begin in the hands and feet *at the same time*, nor does it affect the trunk last, as in neuritis. There is, moreover, no anesthesia in typical ascending paralysis. There are, however, transitional cases between multiple neuritis and Landry's paralysis, and the term Landry's paralysis is somewhat in disfavor.

Some assistance in diagnosis may be had from the etiological standpoint; the history of metallic poisoning, of alcoholic excesses, or of exposure to infectious diseases, or the presence of diabetes being suggestive.

**Prognosis.**—A large number of patients with multiple neuritis get well, though slowly, especially if the cause be discovered and removed. Especially is this true of the alcoholic cases, although improvement does not always begin immediately on withdrawing the cause—indeed, the disease may even progress for a long time, and improvement may not be observed for several months. Hence the prognosis should be guarded. The acute and widespread cases are the most dangerous to life, and in such the prognosis should always be guarded. The involvement of the heart and of the muscles of respiration, including the diaphragm, is most to be feared. Pain in the trunk muscles is a grave symptom if the motor power of the limbs has diminished much. Paralysis of the diaphragm may be insidious and un-

noticed until that of the intercostals is added, when there may be accumulation of mucus, bronchitis and death by suffocation. Involvement of the vagus nerves is manifested by frequency of pulse. Superadded involvement of the spinal cord increases the danger. At best, months are required for recovery, and even years may be necessary. Involvement of the spinal cord precludes total recovery. The return of faradic irritability in nerve and muscle is favorable. To sum up with Gowers: "The prognosis is better in the sensory than in the motor form, better when the arm escapes than when all the limbs are involved, better in cases of chronic than acute onset, and better if a case of apparently acute onset is really such, than if it succeeds slight symptoms of longer duration."

**Treatment.**—The removal of the cause, if possible, is a primary step in treatment. Along with this, rest is most important, and the rest should be complete—in bed, and this should be enforced in the earlier stages; later the pain and loss of motor power make rest obligatory. Care should be taken to avoid any pressure of the bed-clothes upon the feet, which might aid in the contracture of the muscles in the position of foot-drop. There should be no compromise with alcohol, although in some cases of great debility, when the cardiac action is feeble, gradual withdrawal may be justifiable. The patient should, on the other hand, be fed on the most nutritious food. Local anodyne applications may be resorted to to relieve the pain, and may be varied according to effect. Dry heat, moist heat, applications of lead-water and laudanum, and ointments of aconite and veratrum are some of those which may be employed. Wrapping in cotton or wool is sometimes beneficial. Warm baths are soothing; sometimes very hot ones give relief.

Postures assumed because of the relief they give to pain should not be too long permitted lest deformity result by contraction and adhesion, difficult or impossible to overcome. Dropping of the feet should be prevented by splints or by support with sand-bags. The same is true of flexion at the knee and hip.

As to drugs, they are of little use; the salicylates, phenacetin, antifebrin, and antipyrin may be useful in mild cases, and should be tried in doses of from 5 to 15 grains (0.3 to 1 gm.), but their action should be watched if the heart be affected. They are more particularly useful in cases due to cold. Extreme pain may demand the cautious use of morphin hypodermically in doses of from  $\frac{1}{6}$  to  $\frac{1}{3}$  grain (0.011 to 0.022 gm.) combined with  $\frac{1}{150}$  grain (0.00044 gm.) of atrophin, which modifies and improves the action of morphin most happily. For the mental symptoms the hydrobromate of hyoscin in doses of from  $\frac{1}{200}$  to  $\frac{1}{100}$  grain (0.00033 to 0.00066 gm.) hypodermically, or hyoscin in doses of from  $\frac{1}{400}$  to  $\frac{1}{150}$  grain (0.00016 to 0.00044 gm.) may be tried. Mercurials, so highly approved by Gowers in simple neuritis, are useless here. The iodids are sometimes beneficial in chronic cases and in cases due to lead absorption.

Roborant medicines, such as iron and cod-liver oil, are indicated to build up the patient, who is generally broken down. Electricity, massage and strychnin are very useful after convalescence has set in.

## ENDEMIC NEURITIS.

**Definition.**—This term is applied to certain forms of multiple neuritis, supposed to be due to vegetable organisms, limited to certain localities. Three separate varieties have been recognized, but others probably exist. The three referred to are malarial neuritis, beri-beri, and leprous neuritis.

1. **MALARIAL NEURITIS.**—This corresponds in its clinical features to the simpler forms of multiple neuritis, and requires no detailed description. Its malarial nature is based on its prevalence in malarial districts and its curability by quinin. While it is believed to be caused by the plasmodium of malaria, I am not aware that this organism has as yet been discovered in the blood of patients suffering from it; the plasmodium, however, has been found in the central nervous system of persons who have manifested various symptoms of nervous disease.

2. **BERI-BERI, THE KAKKE OF JAPAN.**—Beri-beri is a disease prevalent in Japan, the Eastern Archipelago, India, New Zealand, Ceylon, the South Pacific Islands, and the coast of Brazil. It is especially prevalent in the Dutch East Indies among soldiers and in prisons, and has been thoroughly investigated under the Netherlands Government. In this country, J. J. Putman has described a similar disorder among New England fishermen who frequent the Grand Banks of Newfoundland, and Bondurant has observed it among sailors in the Gulf ports of Alabama. It is also not uncommon among Norwegian sailors. Seguin, of New York, has described cases originating in the West Indies and coming to this country.

**Etiology.**—Sheube and Baelz first determined its true nature, but our knowledge has been greatly increased by the studies of Pekelharing and Winkler.<sup>1</sup> It is believed to be due to a special organism, of which rods and cocci have been described, and of which cultures have been made. These, when inoculated, produced peripheral neuritis of the same distribution as beri-beri. Repeated inoculations having, however, been required to produce the disease, it has been reasonably concluded that repeated exposures are necessary before infection results. It is transmissible from individual to individual. The disease is also acquired by residence in certain houses, and patients recover after removal to a district which is free, relapsing on returning. It has been thought that a nitrogenous and especially an exclusive fish diet predisposes to the disease, and, again, a rice diet. Roll<sup>2</sup> has shown that in all probability the disease is transmitted through drinking-water, since he traced two epidemics on board ship to this cause. In both cases the sailors were free so long as they had a supply of European water; but in one instance, after laying in fresh water at Batavia, and again in Mauritius, where the disease prevailed endemically, it appeared among the crew at the end of five weeks.

**Symptoms.**—There are several types of cases. Among the earliest symptoms is a *change in the electrical excitability of the peroneal nerves and the flexors of the ankles*, consisting in a slight degree of reaction of degeneration, quantitative and often qualitative, this even before there are any sub-

<sup>1</sup> Pekelharing and Winkler, "Centralblatt f. Nervenkrankheiten," 1899, and "Deutsche med. Wochenschr.," 1888, No. 30.

<sup>2</sup> "Norsk Magazin for Lægevidenskaben," November, 1895, and May, 1896.

jective symptoms. Sometimes, indeed, the disease goes no further. Generally, however, the subjective symptoms begin as a *sense of heaviness of the legs, a tendency to tire easily, perverted sensation, diminished tactile sense in the lower part of the legs, and irritability of the heart.* In an acute pernicious form the nervous phenomena are less marked. There are *fever, anemia, and general anasarca.* The edema is quite constant, beginning in the legs. The *urine* is scanty, but not otherwise altered, and contains no albumin. A critical increase in the quantity of urine indicates an improvement. In the second group the neuritic symptoms are more marked, there being *numbness, anesthesia, loss of tendon reflexes, muscular atrophy, and anasarca.* In the third group, the *atrophy and paralysis* are most conspicuous, and the clinical picture is that of a rapidly progressing multiple neuritis with sensory and motor symptoms. The mortality varies from three to 60 and even to 70 per cent. The *diaphragm* and *larynx* may become paralyzed, and the cardiac branches of the vagus involved, producing cardiac failure and death.

**Treatment.**—The treatment calls for the removal of the cause by disinfection or removal of the patient from the infected house or district and by the withdrawal of suspected food or drinking-water.

The symptoms are treated as in other forms of neuritis. In consequence of the tendency to cardiac weakness heart tonics may be needed, such as digitalis, strychnin, strophanthus, and caffeine.

3. LEPROUS NEURITIS.—Similar to beri-beri is leprous neuritis, already considered as to its etiology, symptomatology, and treatment. (See Infectious Diseases.) It differs from beri-beri in being transmitted from parent to offspring and in its extreme slowness of development after exposure, as much as ten years intervening. It differs also from beri-beri in that the neuritis is not an essential part of the disease. The neuritis is a symptom of the so-called "anesthetic leprosy." Leprous neuritis differs, further, from the usual forms of multiple neuritis in not being perfectly symmetrical and in being a perineuritis and an interstitial neuritis instead of parenchymatous. The bacillus is also found in the tissue, by its presence causing the inflammation, while in beri-beri the virus circulates in the blood. Hence the irregular distribution of the neuritis in the leprous form, resembling in this respect the more isolated neuritis of syphilis.

**Symptoms.**—The special symptoms are muscular wasting and anesthesia, more marked toward the extremities of the limbs, but not confined to them, being found elsewhere, as in the face, involving the fifth and seventh pairs of nerves. Sometimes tenderness and pain are present; the latter is, however, not severe. There may be tingling, also anesthesia and diminished electrical excitability, with reaction of degeneration. The irregular areas of anesthesia are generally associated with irregular patches of pigmentation and pallor.

The **diagnosis, prognosis, and treatment** are the same as those of leprosy.

## ADIPOSIS DOLOROSA.

SYNONYM.—*Dercum's Disease*.

**Definition.**—A condition first described by Dercum, in 1888, in which there are irregular deposits of fat in different parts of the body which are the seats of pain or tenderness or have been preceded by it.

**Etiology and Pathology.**—The subjects are almost always women. A neuropathic family predisposition has been generally present and the alcoholic habit and syphilis also. Sclerosis with diminution in size of the thyroid gland has been found and in a case of Burr's there was a tumor of the pituitary body. There is sometimes neuritis and later degeneration of smaller nerve branches, the main trunks being intact. The disease is probably a neuritis associated with peculiar fat formation.

**Symptoms.**—Sometimes, after middle life, the patient, usually a woman, acquires irregular deposits or bunches of fat in various parts of the body. These gradually become the seat of burning, scalding, shooting pain and paresthesias. The masses of fat grow larger and become soft and pultaceous, but do not pit on pressure. There remain areas of the body quite uninvolved, especially the peripheral parts of the limbs. Hyperesthesias may alternate with anesthesia elsewhere than in the fatty masses. At times there is mental weakness, even dementia. As the accumulations grow there succeeds muscular weakness, at times extreme; the skin appears normal, the hands and feet remain normal. The skin is at times normal, at others it is pigmented or atrophied.

**Diagnosis.**—The disease differs from simple obesity in the lumpiness as contrasted with the uniform distribution of fat, and by the painfulness and tenderness. From myxedema it differs in the absence of the peculiar facies and other symptoms which attend myxedema.

**Treatment** is without effect. Local anodynes may palliate. Thyroid extract should be tried. Coal-tar derivatives may be employed, especially aspirin and phenacetin. Morphin should be put off as long as possible.

## NEURALGIA.

**Definition.**—Strictly speaking, the term neuralgia should be restricted to such varieties of nerve pain as are unattended with structural changes in the nerve. Formerly, many cases now regarded as cases of neuritis were called neuralgias, and it is probable that, as our knowledge grows, other so-called neuralgias will be eliminated. Finally, the border-line existing between neuralgia and neuritis cannot be drawn sharply, but as far as possible, the term neuralgia should be restricted to nerve pain without organic change.

**Etiology.**—Neuralgia is a disease of adults. It rarely occurs before puberty, and is relatively rare in old age. It is more common in women than in men, although not so very rare in old men. Heredity is responsible for a tendency to neuralgia. According to Anstie, fully one-fourth of all

cases are the result of heredity. It is frequent in so-called neurotic families and in the so-called "nervous" person—*i. e.*, one who is excitable, anxious, and fretful in disposition. In this category, too, are the hysterical neuralgias. The debilitated, anemic, and poorly fed are liable to it. So are they who are overworked and worried.

The most frequent *exciting* cause is cold. Malaria is one of the most common causes, producing, especially, hemicrania, while the malarial cachexia also predisposes to neuralgia. The pain of carious teeth is not regarded as neuralgic, but when such pain causes irritation of the peripheral branches of the fifth nerve, a neuralgia may be produced in the distal distribution.

**Symptoms.**—*Pain* is, of course, the leading symptom. "Spontaneous pain," by which is meant pain independent of neuritis or irritation of the nerve, and the modifications to which it is subject in severity and distribution, constitute, in fact, the disease. This pain is irregularly paroxysmal, shooting, darting, or burning in character, not usually increased by motion and if not relieved by pressure, may be by gentle friction. The more the pain is increased by motion and the more there is pain over the nerve trunks on pressure, the more is it a neuritis and the less a neuralgia. Yet we cannot literally adhere to this, as evidenced by the "tender points" of Valleix, which will be further referred to under the different varieties of neuralgia. Multiple dartings and shootings, separated by seconds or minutes of freedom from pain, are characteristic.

The absence of primary tenderness is also characteristic; but after the pain has continued for some time there often succeed tenderness of the skin and even a redness and swelling, the absence of any unnatural degree of which at the beginning is considered distinctive. These phenomena, including edematous swellings, are regarded as vasomotor in origin. Other vasomotor symptoms are hyperidrosis, increased secretion of saliva and tears, and elevation of temperature. Trophic effects are seen in shedding of the hair and its rapid blanching, and other symptoms to be referred to. Muscular twitchings are also not uncommon at the seat of the pain, and sometimes even muscular spasm.

The duration of an attack of neuralgia varies from an hour or even less to many hours. Sooner or later, if not relieved, it subsides spontaneously, though with a greater tendency to recur than when relieved by treatment.

#### VARIETIES DEPENDING UPON NERVES INVOLVED.

Neuralgias are variously named in accordance with the nerves affected, whence we have the following varieties:

1. *Trifacial Neuralgia (Neuralgia of the Fifth Pair; Tic douloureux; Prosopalgia).*—This form involves one or more of the branches of the fifth pair, rarely all. It is more common than all other varieties of neuralgia combined. Here, doubtless, we have sometimes to do with a neuritis not always easily separable. One or more numerous tender points are usually demonstrable, of which those at the supra-orbital and infra-orbital foramina are the most conspicuous.

Of the branches of the fifth, the *ophthalmic*, or the first division through its supra-orbital branch, is that most frequently affected, giving rise to the well-known supra-orbital neuralgia. The pain radiates from the "tender point" at the supra-orbital notch over the anterior half of the head sometimes to the eye itself, the eyelid, and half of the nose. There may be injection of the eye and suffusion. There is sometimes pain in the occipital protuberance and cervical spines. This supra-orbital form must most frequently be distinguished from catarrh of the frontal sinuses, but the latter is more likely to be symmetrical, and while the pain is severe, it is duller, less shooting, and is accompanied by coryza; it terminates suddenly with a free discharge of purulent matter, sometimes offensive.

When the distribution of the *infra-orbital*, or second branch is involved, the pain occupies the superior maxillary area between the orbit and the mouth, over the cheek to the ala of the nose. The "tender points" are at the emergence of the nerve below the orbit, at the side of the nose, over the most prominent part of the malar bone, and along the gingival line in the upper jaw, rarely in the upper lip.

When there is involvement of the third, or *inferior maxillary*, division, less common as an isolated form—except as to its inferior dental branch—there is a much more extensive area of pain, including the parietal eminence, the temple, the ear, the lower jaw, and the tongue. The "tender points" are in front of the ear where the auriculotemporal crosses the zygomatic arch, where there is often burning pain, and at the mental foramen on the chin. The movements of mastication and speaking may be painful, and there may be salivation. A herpetic eruption about the eyes or lips occasionally present points to neuritis. Atrophy and induration of the skin have been included in the symptoms, but these are ascribable also to a neuritis.

There is a pure *ocular neuralgia* involving the eyeball only. It may or may not be due to errors of refraction. Of these, hypermetropia, or far sightedness, is the most common cause. Either one or both eyes may be affected. It may be accompanied by dimness of vision.

A form of trigeminal neuralgia, called by Trousseau "epileptiform," consists in sudden, severe, and frequent attacks of pain, lasting from a few seconds to a few minutes, many times repeated during the day.

2. *Cervico-occipital Neuralgia*.—This affects the area of the neck supplied by the posterior branches of the first four cervical nerves, and the posterior part of the head supplied by the great occipital branch of the posterior division of the second cervical nerve, at the exit of which there is a tender point about half way between the mastoid process and the first cervical vertebra. Two other tender points are just above the parietal eminence, and between the sternomastoid and trapezius muscles. The pain may extend over the greater part of the neck and head, as far forward as the parietal eminence and the ear.

Exposure to cold or a draft of air is the most common cause of this form. Nephritis has been alleged to be a cause.

3. *Cervico-brachial and Brachial Neuralgia*.—This involves the area supplied by the four lower cervical and the first thoracic nerves, the area of sensory distribution of the brachial plexus.

The tender points are the axillary, the circumflex at the posterior part

of the deltoid, the superior ulnar behind the elbow, and the inferior ulnar in front of the wrist. This form is often confounded with neuritis due to rheumatic affections of the joints or injury.

4. *Neuralgia of the Phrenic Nerve*.—This is rare, the pain in its area during pleurisy and pericarditis being rather a neuritis. The pain is at the lower part of the thorax, at the attachment of the diaphragm. Breathing is shallow, because pain is caused by the breathing movements. Coughing and even deglutition cause pain.

5. *Trunk Neuralgia*.—This naturally divides itself into two subvarieties: dorso-intercostal and lumbo-abdominal.

(a) *Dorso-intercostal neuralgia* covers the area supplied by the intercostal nerves from the third to the ninth, and is characterized by pain along the intercostal spaces or in parts of them. It is sometimes bilateral. There is usually a constant dull pain with or without acute stabbing exacerbations, or the latter may be excited by deep breathing or motion. There may be special tenderness at the points of emergence of the three branches of the intercostal nerve—viz., posteriorly near the vertebræ, anteriorly near the median line, and midway between these two points in the midaxillary line.

The term *pleurodynia* has been used with a good deal of vagueness. Strictly speaking, it should be limited, as it is by Gowers, to neuralgia of the pleural nerves. Consistently with this it should not be applied to pain localized in the course or point of exit of an intercostal nerve. It is very acute in character and excited by expansion of the thorax rather than by lateral movements of the trunk. The pain of herpes zoster is not a neuralgia, but a neuritis.

Another variety in this locality is the inframammary neuralgia of anemic women.

(b) *Lumbo-abdominal neuralgia* involves the posterior branches of the lumbar nerves, especially the ilioscrotal branch. The area of the pain is the region of the iliac crest, along the inguinal canal and the spermatic cord in the scrotum, or round ligament in the labium majus. The pain is often bilateral, sometimes resembling the constricting girdle pains of spinal cord disease, from which it differs, however, by its changing place. It is especially frequent in connection with the diseases of pelvic organs, particularly in women. The testes and penis are the seat of neuralgic pains.

6. *Neuralgia of the spinal column* is the more modern term for the "spinal tenderness" of the older authors. It is common in feeble and hysterical women, and a sequel of the modern railway accident under the name of "spinal congestion." The pain in most cases is felt along a considerable vertical extent of the spine, but is more intense in certain spots. The thoracic region is the most common seat next the lower cervical, and least frequently the lumbar region.

7. *Sacral neuralgia and coccygodynia* are defined by their names. These affections reside in the nerves between the bone and the skin, and are often exceedingly difficult to cure. The pain may really be due to organic lesions in the part.

8. *Neuralgia of the feet* includes painful heel, plantar neuralgia, and erythromelalgia. In the latter, first described by Weir Mitchell, vascular changes, including either acute hyperemia or cyanosis—probably of vaso-

motor origin—are associated with severe pain in the heel or sole of the foot. It is probably a neuritis in some cases.

9. *Visceral neuralgia* means neuralgia affecting the gastrointestinal tract, the kidneys, ovaries, and other pelvic organs. Idiopathic nephralgia, or neuralgia of the kidney, I regard as a rare event. It and testicular neuralgia are more frequently secondary to inflammation of adjacent urinary passages, but idiopathic testicular neuralgia is less rare than nephralgia.

Neuralgias are further classified according to character and cause. Thus, in addition to the epileptiform variety alluded to, there are reflex or symptomatic neuralgias, traumatic neuralgias, herpetic neuralgias accompanying herpes, hysterical, rheumatic, gouty, diabetic, anemic, malarial, syphilitic, and degenerative neuralgias. Many of these terms are loosely applied. The term rheumatic neuralgia is often erroneously applied to muscular rheumatism. It should not be used.

Very interesting and important is the subject of *reflex neuralgias* and *referred pains* which have been especially studied by the late Dr. Anstie in England and Charles L. Dana in this country. Reflex neuralgias are due to disease in organs distant from the actual seat of the neuralgia. The fifth nerve is a favorite seat of such neuralgias. Thus, an irritation of the distribution of one branch of this nerve by a carious tooth may excite a neuralgia in another distribution of the same nerve. Illustrations of referred pain are the "pain in the back" or spinal cord pain in ulcer of the stomach, the left scapular pain in diseases of the liver, the sacral pain in uterine disease, and the testicular pain in renal colic.

**Diagnosis.**—Neuralgia is chiefly to be distinguished from *neuritis* and the effects of *pressure on nerves*; and also *rheumatism*. From *neuritis* it is separated by its unilateral distribution as contrasted with the more frequent symmetrical distribution of neuritis, although neuritis is not infrequently unilateral; also by its numerous remissions and intermissions, and the shifting of the pain from one spot to another. The fixed neuralgias are more difficult of separation from neuritis, especially mild cases. The severe forms of neuritis are soon recognized by the anesthesia which succeeds upon the hyperesthesia in the cases of sensory nerves, and muscular wasting with changes in the electrical irritability in mixed nerves. In the case of *compression of nerves* the pain is continuous, while the symptoms and consequences of neuritis will, sooner or later, show themselves. Nevertheless, doubt and error must not infrequently occur.

*Muscular rheumatism* differs in its localization in muscles or groups of muscles such as the lumbar or shoulder muscles, its continuousness and pain increased by motion.

**Prognosis.**—The prognosis in neuralgia is usually ultimately favorable, although some forms and cases are very stubborn. Especially true is this of neuralgia of the fifth pair. The more frequent the recurrence and the wider the distribution, the more difficult is the cure. On the other hand, the severity of the pain is not, in my experience, a measure of obstinacy to cure, some of the severest cases being easiest relieved. Hereditary cases are the more obstinate. The same is true of cases occurring in the decline of life. Epileptiform neuralgia is said to be incurable.

**Treatment.**—The treatment of neuralgia is divided into that of the

*condition predisposing* to it and of the *paroxysm*. The anemias—especially chlorosis—malaria, and other predisposing causes should be corrected by quinin, iron, and arsenic. Good nourishing food is important. Change of scene and residence is often necessary. Reflex causes should be carefully sought for and removed. Until these predisposing causes are removed, the treatment of the paroxysm affords but temporary relief.

For the paroxysm quinin is by far the most efficient remedy, and will cure many cases. Two or 3 grains (0.12 to 0.194 gm.) should be given hourly until the paroxysm is relieved or decided cinchonism is produced. The salicylate of cinchonidia is a valuable preparation. Some cases are relieved by phenacetin or antifebrin (acetanilid) in from 10 to 15 grain (0.66 to 1 gm.) doses. A combination of phenacetin and caffein, 3 grains (0.33 gm.) of the former and 1 (0.11 gm.) of the latter each, in hourly doses, is often efficient. Some cases can only be relieved by sulphate of morphin. The hypodermic injection is the promptest and surest remedy, in doses of from 1/8 to 1/4 grain (0.008 to 0.016 gm.), but morphin is a drug to be avoided in neuralgia, if possible, as the danger of acquiring the morphin habit is extremely great. The patient should never be allowed to use the hypodermic syringe himself. The use of anodynes is sometimes more than palliative, the repeated removal of the pain tending to prevent its recurrence. The combination of atrophin with morphin undoubtedly modifies the unpleasant effect of the latter drug and increases its efficiency.

Belladonna, and its active principle, atropin, are remedies which have long enjoyed reputation in the treatment of neuralgia, when uncombined with other drugs, but in my hands they have been feeble remedies. The doses recommended are from 1/6 to 1/2 grain (0.011 to 0.03 gm.) of the extract and from 1/120 to 1/60 grain (0.0005 to 0.0011 gm.) of atropin. Aconite and gelsemium have also some reputation, especially in neuralgia of the fifth nerve. Gelsemium may be given in doses of 15 minims (0.92 c.c.) of the tincture, frequently repeated. Gelsemia may be given hypodermically in doses of from 1/60 to 1/30 grain (0.0011 to 0.0022 gm.), and aconitin in doses of from 1/250 to 1/100 grain (0.00027 to 0.00066 gm.), but the latter is a remedy so dangerous that I rarely employ it. Cannabis indica is also sometimes useful in doses of 1/4 grain (0.016 gm.) three times a day or oftener, but the drug varies so much in strength that it cannot be relied upon.

Local applications are sometimes very useful. Pressure relieves many mild cases, especially when associated with gentle friction. Local anesthetics, such as menthol, the ointments of veratria and aconitia, are similarly useful; so is the tincture of aconite painted over the involved area. The local use of opiates, at least without first removing the epidermis, and of atropin (five per cent. strength), is, however, commended. The extract of belladonna, diluted with glycerin so as to admit its being smeared on, is sometimes useful. Frequent renewals of all these local applications should be made in the course of the day. Counterirritation by blisters or sinapisms, by chloroform either pure or variously diluted, and by camphor may be used. The last two may be applied on lint and covered with oiled silk. Both will blister if left on too long.

*Cocain* might be reasonably expected to be useful, but to act through

the skin the ointments and solutions containing it should be strong—from 10 to 15 per cent. For mucous surfaces this strength should be used with caution. A cocain habit is as easily established as morphinism, and is about as unpleasant in its results, though more easily cured. The hypodermic injection of cocain is much more efficient. The usual dose is  $1/4$  grain (0.016 gm.), but smaller doses may be commenced with. The Paquelin cautery is often a prompt and efficient agent.

*Acupuncture* and *aquapuncture* are employed, the latter consisting of injecting water under the skin. For their local effect, also, *chloroform*, *carbolic acid*, and *osmic acid* have been injected *hypodermically*. From 15 to 20 minims (0.92 c.c. to 1.23 c.c.) of the first may be used, from 5 to 10 minims (0.31 c.c. to 0.62 c.c.) of the second, and 1 or 2 drops of a one per cent. solution of osmic acid in water and glycerin. Chloroform should be cautiously used in this manner, as it may occasion ugly sloughing. It is more especially in sciatica that these measures have been employed. *Local* applications of *heat* and *cold* have been found useful—cold by freezing or by the ether spray; heat by the hot-water bag, or in the case of a supra-orbital neuralgia, by the nasal douche. Heat is usually more efficient than cold; indeed, the latter sometimes aggravates neuralgia.

*Electricity* is of uncertain value in neuralgia, but is sometimes very useful. The constant current is the form most frequently used, but faradism may also be employed. It is used in two ways: a strong current is applied at once with a view to removing the neuralgia promptly (this is scarcely to be recommended); in the second method a sedative effect is sought by a weak current, preferably of galvanism, just sufficient to produce a tingling or burning sensation. Experience goes to show that the direction of the current may be ignored, but it is commonly recommended to apply the positive pole to the painful part, the sponge being well wet with warm water, and if faradism is used, it should be with rapid interruptions.

The *surgical treatment* of neuralgia has been followed by brilliant results, and has met signal failures. The most common procedure is division of a nerve, or, better, the exsection of a portion of the nerve. It has been most frequently done in the case of the fifth nerve, and is almost always followed by temporary relief, but, sooner or later, an operation on the Gasserian ganglion usually becomes necessary. Operation is to be recommended in intractable cases, and should be done at a point as near the origin of the nerve as possible, as second operations are not infrequently necessary on account of the recurrence of the pain.

*Nerve stretching* is also performed with a measure of relief less thorough than exsection, but in view of the fact that its disadvantages are less lasting, it is the better operation to do first in the case of certain nerves. It is important to remember that relief does not always immediately follow the operation. The sciatic is the nerve most frequently stretched, but the procedure is not to be recommended. The intercostals and branches of the fifth, including the lingual, have been similarly treated with satisfactory results. The removal of the Gasserian ganglion affords relief in tic douloureux, and, while a serious operation, is to be employed when the pain is intense and does not yield to other treatment.

## TUMORS OF NERVES.

*Definition and Morbid Anatomy.*—Strictly speaking, the term neuroma should be restricted to tumors composed purely of nervous tissue, which are to be distinguished from *fibrous tumors* or *fibromata*, often seated on nerves and known as *false neuromata*. Some, however, dispute the existence of true neuromata, and they are certainly very uncommon. Another form of false neuroma is a variety of the small, subcutaneous, painful tumor—*tubercula dolorosa*—occurring in nerves of the skin in the neighborhood of the joints, on the face and on the breast. Myxomata, sarcomata, and even carcinomata are found in connection with nerves. The latter are commonly the result of extension by contiguity, infiltrating the connective tissue between the fibers. The nervous tissue represented in the true neuroma is usually fibrous, but very rarely ganglionic nerve-cells are found, and in such event the tumor may be regarded either as dislocated nerve tissue or as a glioma the cells of which closely resemble true nerve-cells. The nervous tissue may be of the medullated or non-medullated variety—*i. e.*, myelinic or non-myelinic. Connective tissue varying in quantity is associated with both, producing various degrees of hardness, which is most striking in the multiple fibro-neuroma.

An interesting variety is the *plexiform neuroma*, nodular and tortuous in appearance to the naked eye, the internal structure of which is composed also of interlacing nodular and tortuous nervous cords made up of connective tissue and nerve fibers. It is most frequently found in connection with the fifth pair of nerves in the orbit, on the upper eyelid, or on the temporal bone, but is seen also in connection with any of the spinal and even sympathetic nerves. It grows slowly, and probably begins in fetal life.

Fibromata of nerves are usually small, but may be three or four inches (7.5 to 10 cm.) in diameter and even larger. They are usually found seated in nerve trunks, or at their ends, are often multiple, and their number is sometimes large.

**Etiology.**—Nerve tumors which are not congenital may be traumatic. More than one member of a family has been found affected. Their growth seems stimulated by perversion in the healing process, since they are found on the ends of nerves in cicatrices after amputation. Growths of this character are truly neuro-fibromata, the others are usually fibromata.

**Symptoms.**—Neuromata may be totally without symptoms. At other times they are very painful, the *pain* being aggravated by pressure. There may be *numbness* and *formication* and even *loss of sensation* on the one hand, *muscular twitching* and *paralysis* on the other, the latter especially when the tumor is in the course of the nerve.

Neuromata of the cauda equina may cause paraplegia. Reflex spasm in adjacent or distant muscles, and even epileptiform convulsions, are occasionally present. A neuroma may give rise to visible swelling, or it may be beneath the surface out of sight and touch.

**Diagnosis.**—Except in the case of plexiform neuroma, which has a characteristic form described, the exact diagnosis of the variety of nerve tumor can for the most part be made only by microscopic examination

after removal, since all the symptoms occasioned by true neuroma may be caused by pressure on nerves by any form of morbid growth. Multiple neuromata are usually false neuromata.

**Prognosis.**—Nerve tumors rarely cause death, though they sometimes undergo malignant change, and in this way cause a fatal termination. The extreme pain which is so characteristic may in time exhaust a patient, but the course of the disease is always prolonged.

**Treatment.**—Excision is the proper treatment for neuromata and all other forms of tumors connected with nerves, if they can be reached, and if the symptoms demand active treatment. Often such treatment is not demanded. If syphilitic origin be suspected, syphilitic treatment should be adopted. In operations involving section of a nerve trunk the possibility of loss of function is to be remembered.

Local anodyne applications may be used to palliate in mild cases, but they are useless in severe ones. Cocain in doses of from  $\frac{1}{6}$  to  $\frac{1}{2}$  grain (0.011 to 0.033 gm.) may be injected hypodermically, but morphin should not be used, as the conditions are especially favorable to the production of morphinism.

## AFFECTIONS OF THE SPINAL CORD.

**Anatomical.**—The spinal cord, covered by its membranes, the dura and pia arachnoid, hangs loosely in the spinal canal from the atlas to the second lumbar vertebra. It is, therefore, much shorter than the spinal canal itself. The remainder of the canal is occupied by the cauda equina. Each pair of spinal nerve-roots arises above the foramen of exit, and descends to the latter within the canal. The uppermost cervical roots leave the spinal canal about on a level with their point of origin. The part of the cord whence each pair arises is known as the *segment of that particular pair of nerves*. The following from Deaver's "Surgical Anatomy" locates with sufficient accuracy the origin of these nerves: "The eight cervical nerves arise above the sixth cervical spine, the upper six thoracic nerves between the sixth cervical and fourth thoracic spines, the lower six thoracic nerves between the fourth and 11th thoracic spines, the five lumbar nerves between the 11th and 12th thoracic spines, and the five sacral nerves between the last thoracic and first lumbar spines." (See Fig. 96.)

In transverse section the cord is easily seen by the naked eye to be made up of central gray matter and external white substance. The former is composed largely of cells, the latter of fibers. The gray matter, roughly comparable to two crescents placed back to back, reaches the surface only by its posterior horns, where the posterior roots of the spinal nerves enter. The broad, blunt anterior cornua do not reach the surface, but the white fibers of the anterior roots are seen perforating the white matter to enter the gray. The cord is separated into halves by the anterior median fissure, and by the posterior median septum, which is not a fissure.

At the bottom of the anterior median fissure is the transverse commissure of white matter, in front of the central spinal canal. A short distance to the outside of the posterior median septum is another less distinct septum, the *posterior intermediate septum*, which bounds the *posterior median column* or column of Goll, which does not extend as a distinct column below the thoracic portion of the cord. Outside of this, bounded by the posterior horn, is the *posterior external column*, or column of Burdach, limited in like manner to the cervical and thoracic parts of the cord. The *antero-lateral column* is divided by a line coinciding with the outermost of the anterior nerve roots, and thus is made an anterior and a lateral column. The white matter is composed of the usual medullated nerve fibers unprovided with neurilemma and of neuroglia supporting the nerve fibers. The further divisions of the cord in transverse section are clearly indicated in Fig. 98, representing a transverse section of the cord in the cervical region, with description.

Of these parts, the anterior (or direct) pyramidal tract, the lateral (or crossed) pyramidal tract (adjacent to the posterior cornua), and the anterior cornua may be characterized, generally speaking, as motor, while the posterior columns, the *direct cerebellar tract*, the antero-lateral ascending tract of Gowers, part of the antero-lateral ground fibers, and the *posterior cornua*, may be described as sensory.

The white matter gradually diminishes as the cord is descended. The

FIG. 96.—Diagram from an Original Investigation by W. R. Growers, Showing Relation of Vertebral Spines to their Bodies and to the Nerve-roots.

Only in the lumbar region are the ends of the vertebral spines opposite the middle of their bodies. They correspond to the lower edge of their bodies in the cervical and at the last two dorsal; and to the upper part of the body below them in the rest of the dorsal region. (See also text.)

FIG. 97.—Diagram Showing Relative Size and Shape of the Cord and Gray matter at Different Levels—(after Growers).

gray matter also varies in extent and shape at different levels, which will be appreciated by the examination of Fig. 97, which explains itself. It should be added that certain tracts described, and at present chiefly of interest to the anatomist, are not included in this diagram. Mention should be made of *Clarke's column*, a group of nerve-cells in the inner part of the neck of the posterior horn, from the upper thoracic to the second lumbar, also known as the lateral fascicular column. Scattered cells in the cervical region form the continuation of this column. In the upper thoracic and lower cervical regions, a group of cells projects outward from the gray matter into the lateral column, called by Lockhart Clarke the *intermediolateral process*, but well named also the lateral horn. The *lateral or crossed pyramidal tracts*, representing about three-fourths of the motor fibers passing down from the cortex, decussate at the lower part of the anterior

FIG. 98.—Section of Spinal Cord in the Cervical Region—(after Gowers).

pyramids. The remaining fibers of the pyramidal tract, which do not decussate, pass down the same side of the cord in the inner part of the antero-lateral column, constituting the *anterior or direct pyramidal tract*, also known as *Türk's column*.

At every level of the spinal cord, axis-cylinders leave the crossed pyramidal tract to enter the anterior horns and end about the cell bodies of the lower motor neurons. This tract extends nearly to the end of the cord, but becomes smaller and smaller. The fibers of the direct anterior or pyramidal tract possibly cross at different levels in the anterior white commissure, to end about the nerve-cells in the anterior horn on the opposite side of the cord. If primarily small, this tract may not extend beyond the middle of the cervical enlargement. If originally large, it may be traced as far as the lumbar enlargement, or even into the sacral part of the cord. Throughout the greater part of the cervical and thoracic regions the lateral pyramidal tract is separated from the surface by a narrow layer of fibers, the *direct cerebellar tract*, which in the upper cervical region lies further

forward, so that the pyramidal tract comes to the surface close to the posterior horn.

The axis-cylinder processes forming the *anterior roots* of the spinal nerves start from the nerve-cells in the anterior cornua of the segment

FIG. 99.—Sensory and Motor Paths in the Spinal Cord—(after Barker).

whence these roots arise, and after uniting with the posterior roots within the dura pass out to be distributed to the muscles they supply.

The relation of the axis-cylinders of the *posterior roots* after they enter the cord is not, however, so simple. It has already been said (p. 929) that the single process which leaves the cell in the ganglion on the posterior roots of the spinal nerves (Fig. 86) divides in a T-shaped manner, one limb traversing the spinal nerve to the periphery of the body, the other passing

to the spinal cord as an axis-cylinder. After entering the cord each axis-cylinder process again divides into an ascending and a descending limb, which run in the posterior columns. The descending branch runs a short distance and ends in the gray matter of the same side of the cord. The ascending branch may end in the gray matter soon after entering it or may run upward in the posterior columns to the medulla oblongata, ending probably in the nuclei situated in the posterior columns of the medulla oblongata (nucleus gracilis and nucleus cuneatus), remaining up to this point on the same side of the middle line. From the nuclei of the posterior columns of the medulla oblongata the axis-cylinder processes, after crossing, run toward the brain, form the fillet, into which possibly enter also the ascending fibers of the lateral column containing the crossed fibers of the upper sensory neurons. The exact termination of sensory processes in the cerebral hemispheres is not known. The position of the tract in the crus and internal capsule is posterior. The lower sensory neurons also have endings in the cells or about the cells in Clarke's column, from which cells the axis-cylinders run in the direct cerebellar tract of the same side; also about cells the axis-cylinder processes of which run but a short distance in the cord to end in the gray matter at a different level. Thus the possible paths of sensory conduction, probably many, are not definitely determined, whence disturbances of sensation do not give us so much help in topical diagnosis as those of motion. It may, however, be said in summary that cutaneous sensory impulses in man are conducted toward the brain chiefly on the opposite side of the cord. The crossing of sensory impulses takes place partly in the central gray matter soon after the path enters the cord, and partly after the fibers leave the higher nuclei in the posterior columns of the medulla oblongata.

The *muscular sense* "or sense of position" is probably conducted on the same side of the cord in the posterior columns, to cross in the medulla oblongata, and we have some evidence that the tactile fibers ascend in the posterior columns. *Thermal* and *pain impulses* probably cross to the anterolateral columns of the other side very soon after entering the cord, and possibly ascend in Gowers' tract.

**Spinal Cord Localization.**—It has already been said that the areas of distribution of spinal nerves, sensory and motor, are not sharply defined for each nerve as it emanates from the spinal cord, and that the regions supplied by these nerves overlap. At the same time physiologists and clinicians have been able to map out with approximate accuracy the motor and sensory areas corresponding to the distribution of each pair of nerves emanating from different segments of the cord. Among those who have especially devoted themselves to this subject are M. Allen Starr, Charles K. Mills, and Charles L. Dana in America, and William Thorburn and Henry Head in England.

The results of various observers differ in detail, but agree in essentials. The appended table is that originally devised by Starr, further modified by C. L. Dana and C. K. Mills.

It must not be forgotten that these areas of distribution correspond to a nerve *constituted as it is when it emanates from a corresponding segment of the cord*, and not to a nerve as it is constituted immediately before it begins to spread.

## LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.

SEGMENT.	MUSCLES.	REFLEX AND CENTERS.	SENSATION.
I C.	Rectus lateralis. Rectus capitis. Anticus and posticus. Sterno-hyoid. Sterno-thyroid.		
II and III C.	Sterno-mastoid. Trapezius. Scaleni and neck. Omo-hyoid. Diaphragm.	<i>Hypochondrium</i> (?). Sudden inspiration produced by sudden pressure beneath the lower border of ribs.	Back of head to vertex and neck. (Occipitalis major, occipitalis minor, auricularis magnus, superficialis colli, and supraclavicular.)
IV C.	Diaphragm. Deltoid. Biceps. Coraco-brachialis. Supinator longus. Rhomboid. Supra- and infra-spinatus.	<i>Pupillary</i> (4th cervical to 2d dorsal). Dilatation of the pupil produced by irritation of neck.	Neck. Shoulder, anterior surface. Outer arm. (Supraclavicular, circumflex, external musculocutaneous, cutaneous.)
V C.	Deltoid. Biceps. Coraco-brachialis. Brachialis anticus. Supinator longus. Supinator brevis. Deep muscles of shoulder-blade. Rhomboid. Teres minor. Pectoralis (clavicular part). Serratus magnus.	<i>Scapular</i> (5th cervical to 1st dorsal). Irritation of skin over the scapular produces contraction of scapular muscles. <i>Supinator longus</i> . Tapping the tendon of the supinator longus produces flexion of forearm.	Back of shoulder and arm. Outer side of arm and forearm to the wrist. (Supraclavicular, circumflex, external cutaneous, internal cutaneous, posterior spinal branches.)
VI C.	Deltoid. Biceps. Brachialis anticus. Subscapular. Pectoralis (clavicular part). Serratus magnus. Triceps. Pronators. Rhomboid. Latissimus dorsi.	<i>Triceps</i> (5th to 6th cervical). Tapping elbow tendon produces extension of forearm. <i>Posterior wrist</i> (6th to 8th cervical). Tapping tendons causes extension of hand.	Outer side and front of forearm. Back of hand, radial distribution. (Chiefly external cutaneous, internal cutaneous, radial.)
VII C.	Triceps (long head). Extensors of wrist and fingers. Pronators of wrist. Flexors of wrist. Subscapular. Pectoralis (costal part). Serratus magnus. Latissimus dorsi. Teres major.	<i>Anterior wrist</i> (7th to 8th cervical). Tapping anterior tendons causes flexion of wrist. <i>Palmar</i> (7th cervical to 1st dorsal). Stroking palm causes closure of fingers.	Radial distribution in the hand. Median distribution in the palm, thumb, index, and one-half middle finger. (External cutaneous, internal cutaneous, radial, median, posterior, spinal branches.)
VIII C.	Triceps (long head). Flexors of wrist and fingers. Intrinsic hand muscles.	.....	Ulnar area of hand, back, and palm, inner border of forearm. (Internal cutaneous, ulnar.)
I D.	Extensors of thumb. Intrinsic hand muscles. Thenar and hypothenar muscles.	.....	Chiefly inner side of forearm and arm to near the axilla. (Chiefly internal cutaneous and nerve of Wrisberg or lesser internal cutaneous.)
II D.	.....	.....	Inner side of arm near and in axilla. (Intercostohumeral.)
II to XII D.	Muscles of back and abdomen. Erectors spinæ.	<i>Epigastric</i> (4th to 7th dorsal). Tickling mammary region causes retraction of the epigastrium. <i>Abdominal</i> (7th to 11th dorsal). Stroking side of abdomen causes retraction of belly. Vasomotor centers. Second dorsal to 2d lumbar.	Skin of chest and abdomen, in bands running around and downward, corresponding to spinal nerves. Upper gluteal region. (Intercostals and dorsal posterior nerves.)
I L.	None.	<i>Cremasteric</i> (1st to 3d lumbar). Stroking inner thigh causes retraction of scrotum.	Skin over groin and front of scrotum. (Ilio-hypogastric, ilio-inguinal.)
II L.	Vastus internus.	<i>Patellar</i> . Striking patellar tendon causes extension of leg.	Outer side and upper front of thigh. Lumbar region. (Genito-crural, external cutaneous.)

## LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD—(Continued).

SEGMENT.	MUSCLES.	REFLEX AND CENTERS.	SENSATION.
III L.	Sartorius; adductors of thigh. Flexors of thigh.	. . . . .	Front and outer side of thigh. Inner side of leg and foot.
IV L.	Extensors of knee. Abductors of thigh.	<i>Gluteal</i> (4th to 5th lumbar). Stroking buttock causes dimpling in fold of buttock.	Inner side of thigh, leg, and foot. (Internal cutaneous, long saphenous, obturator.)
V L.	Outward rotators. Flexors of knee. Flexors of ankle. Peronei. Extensors of toes.	<i>Achilles tendon.</i> Overexten- sion causes rapid flexion of ankle, called ankle clonus.	Back of thigh and outer side of leg and ankle; sole; dorsum of foot. (External popliteal, external saph- enous, musculo-cutaneous, plantar.)
I and II S.	Calf muscles. Glutei. Peronei. Extensors of ankle. Small muscles of foot.	<i>Plantar</i> (5th lumbar to 2d sacral). Tickling sole of foot causes flexion of toes and retraction of leg.	Back of buttock and thigh, side of leg and ankle; sole; dorsum of foot.
III to V S.	Perineal. Muscles of bladder, rectum, and external genitals.	Genital center. Vesical center. Anal center.	Circum-anal region, anus, rectum, penis, urethra, vagina, perineum. (Small sciatic, pudic, inferior hemorrhoidal, in- ferior pudendal.)

The preceding table includes only the distribution of spinal nerves.

The following table includes the distribution of nerves starting from the nuclei in the pons and medulla oblongata, so far as these are concerned with motion:

*Nuclei.**Muscles.*

III Cranial.	{ Sphincter iris. Ciliary muscle. Levator palpebræ superioris. Rectus internus in convergence. Superior rectus. Inferior rectus. Obliquus inferioris.
IV Cranial.	{ Obliquus superioris. (Upper facial group.)
VI Cranial.	{ Rectus externus. Rectus internus of opposite side in lateral movements.
V Cranial.	{ Associated movement of levator palpebræ. Muscles of the lower jaw.
VII Cranial.	{ Facial muscles.
XII Cranial.	{ Lower facial group. Muscles of tongue.
IX Cranial.	{ Muscles of pharynx.
X Cranial.	{ Muscles of esophagus.
XI Cranial.	{ Muscles of larynx.

The study of the sensory areas is facilitated by the use of diagrams in which the areas are mapped out and indicated by color or a shading which will permit one to separate them easily one from another, like those annexed, in which, too, the areas corresponding to each spinal segment are indicated by suitable lettering.

Interpreting by the data contained in tables and diagrams such motor or sensory derangements as may be present, one may deduce with more or less accuracy the seat of the lesions in the cord producing them. It has been mentioned that motor localization, being more definite, its arrangement permits more exact inference than sensory derangements.

The union of both adds further facility. Results vary also according as a lesion involves only one-half or a complete section of the cord. Recall-

ing the distribution of the two tracts, as given on page 983, it is evident that an injury involving the *entire transverse section* of the cord must produce, *first*, motor paralysis in all parts supplied with nerves emanating from segments below it. In less complete lesions correspondingly limited degree and extent of motor paralysis succeed. Such paralysis may extend to the bladder and rectum. After complete or nearly complete section the muscles are usually flaccid and the deep reflexes absent. There is no rapidly developing atrophy, and the muscles respond normally to electricity. No satisfactory explanation has as yet been offered of the abolition of the

FIG. 100.—Diagram of Lesion Showing Brown-Sequard's Paralysis—(after Starr).

*L.* Lesion in left half of cord cuts off motor impulses to left leg, sensory impulses from right leg, and sensory impulses from eleventh dorsal nerve.

FIG. 101.—Scheme Showing Chief Symptoms in Left Unilateral Lesion of the Dorsal Cord—(after Erb).

deep reflexes in complete or nearly complete transverse lesion of the cord above the level of the reflex arcs; although neuritis is supposed by some to be the cause of this loss of the deep reflexes, it is probably not the cause in all cases. *Second*, there is impaired sensibility in the parts supplied by sensory nerves associated with corresponding segments below the lesion. Anesthesia does not, however, reach quite to the level of the lesion, because of the overlapping of sensory areas by nerves which enter the cord above the section. Thus, if the section be in the segment of the sixth thoracic, the anesthesia may extend only as high as the area supplied by the seventh.

Moreover, above the anesthetic area there is also at times an area of increased sensibility—the effect of the section possibly being to increase the sensitiveness of the cord above it by increasing its vascularity—due to section of vasomotor nerves by the lesion. By means of these facts we may be enabled to ascertain the level of the disease.

*Muscular* sense or sense of position is lost. *Reflex excitability*, at first slightly impaired, may subsequently be increased when the lesion is not complete and is above the reflex arcs, but may remain impaired in complete transverse lesions of the cord or in those portions of the body whose reflex arcs are situated in the damaged region of the cord.

The phenomena are modified if the lesion be a *hemi-lesion* of the cord. In such an event there is, *first*, motor paralysis in the portion of the body on the same side supplied by nerves whose cells of origin are below the lesion (Figs. 100 and 101), varying, however, with the seat of the lesion. If the lesion is in the cervical part of the cord, the motor paralysis is of the arm and leg on the same side, while if in the lumbar part of the cord there is loss of motion in the leg only of the same side. On the other hand, there is diminished sensibility in the arm and leg of the opposite side. The anesthesia may be to pain and to thermic sense only, the tactile sense being unimpaired. Such anesthesia exists on the *opposite* side, because of the fact, already mentioned, that one of the many routes of sensory impressions crosses the cord soon after it enters it from the periphery.

More than this: the sensibility on the *same* side, below the segment of the lesion, so far from being diminished as to touch, pain, and temperature, may even be slightly increased, possibly owing to the vasomotor paralysis caused by the lesion, in consequence of which, too, there may be a slight rise of temperature on the same side. Slight pricks may be painful, and the soles of the feet may be unusually sensitive. In the area corresponding exactly to the segment involved on the same side there is anesthesia, while just above it on the same side, again, there is a small zone of hyperesthesia. The anesthesia is due to the fact that the sensory nerves coming from the same side are cut just as they enter the cord. It begins somewhat lower down than the exact seat of the lesion, because of the overlapping of the upper sensory area. The hyperesthesia in the lower portions of the body on the side of the lesion has been said to be inexplicable, but may it not depend on hyperemia due to section of vasoconstrictor nerves? It may be for this reason also that the temperature is higher on the side of the lesion—from 1° to 2° F. (0.5° to 1° C.). The upper hyperesthetic zone above the anesthetic area on the side of the lesion may be explained as the result of irritation of sensory nerve fibers entering just above the lesion. The muscular sense or sense of position on the same side is impaired, a condition ascribed by Brown-Séquard to the fact that the fibers of this sense run on the same side uncrossed, and probably in the posterior columns, until the medulla oblongata is reached. Reflex excitability, at first diminished on the side of lesion, is subsequently increased and there is often a good ankle clonus, explainable by the interruption of the inhibiting influence from above.

The phenomena detailed in the foregoing paragraph are those of the so-called *Brown-Séquard's paralysis*, due to unilateral lesion of the spinal

FIG. 102.—Diagram of Skin Areas Corresponding to Different Spinal Segments—(chiefly after Starr. Trunk areas from Head).  
Roman numerals refer to nerves.

FIG. 103.—Diagram of Skin Areas Corresponding to Different Spinal Segments—(chiefly after Starr. Trunk areas from Head).

Arabic numerals refer to vertebrae, Roman to nerves.

cord, caused by knife-cuts, stabs, by pressure from tumors or inflammatory products, especially syphilitic.

On the opposite side muscular power is intact, sensibility is impaired, and the derangement may include the senses of pain, touch, and temperature, or any one or two, touch usually escaping; there is no elevation of temperature, the muscular sense is intact, and reflex action is normal.

All these results, as described, may be produced by the experiments on the spinal cord originally suggested by Brown-Séquard, which included also section along the median line of the spinal cord, which impaired sensation on both sides, leaving motion intact. So far as completed, minute anatomical studies furnish results quite consistent with the derangements of motion produced by diseased states, and, to less extent, also with the morbid phenomena of sensation as illustrated by disease. Thus, anatomy, experiment and pathology contribute to the same conclusion. It should be mentioned, however, that the explanation of the Brown-Séquard type of paralysis here given has not been fully accepted.

More circumscribed lesions produce more limited results. Thus, a local lesion may produce paralysis in only a few groups of muscles. Destructive lesion of the anterior cornua produces lower segment paralysis in the parts innervated by nerves arising in the injured cornua, with secondary degeneration and muscular atrophy, the reaction of degeneration, diminished reflexes, and diminished muscular tension.

Irritative lesions in the central motor tract cause spastic conditions, including exaggerated tendon reflexes, all of which have been described. More commonly such symptoms are the result of diminished inhibition of the brain.

It is also a matter of importance to know whether a lesion lies in a nerve or in the cord itself. Frequently this is at once apparent. At other times it is more difficult to settle. It has already been said that hemiplegias are almost invariably cerebral in their origin, while paraplegias are usually of nerve origin or spinal. It is chiefly with localized palsies that difficulties in diagnosis arise. Etiology aids us somewhat. Thus, localized palsies succeeding localized exposure to cold are likely to be peripheral. Some assistance is rendered if there be an associated anesthesia. Thus, if a part be anesthetic and palsied as to motion, and if the same nerve supplies sensory and motor fibers to the muscles, the lesion is in that nerve. If, on the other hand, the muscles are supplied by several nerves from a given segment of the cord, and the anesthesia corresponds to the area of distribution of nerves from the same segment of the cord, the lesion is probably in the cord or in the nerves at their origin from it.

### Affections of the Membranes of the Cord.

As in the case of the brain, the dura mater and pia arachnoid may be separate seats of disease, chiefly inflammatory, not quite so well understood nor quite so definitely separated in their clinical features. As in the case of the brain, too, we call inflammation of the dura mater pachymeningitis; of the pia mater, leptomeningitis.

## SPINAL PACHYMEINGITIS.

The dura mater is separated by loose connective tissue from the bony canal which surrounds it, and an inflammation may invade this outer or the inner layer, affording a *pachymeningitis externa* or *interna*, though it is not easy to separate these two conditions symptomatically or even anatomically as the external form is likely to extend to the inner layer and even the pia mater.

**EXTERNAL PACHYMEINGITIS.**—This is usually secondary to disease of the vertebræ or similar morbid processes or to trauma or aneurysmal erosion. While an acute condition may thus supervene, it is much more commonly chronic.

**Etiology and Morbid Anatomy.**—Perhaps its most frequent cause is tuberculosis of the spine, with its pathological cheesy product and its traumatic result—the spinal curvature known as Pott's disease. It may be confined to a limited area, corresponding to the primary seat of the disease, or it may extend over a large area of the meninges, corresponding to six or eight vertebræ. As already mentioned, such inflammations spread to the inner layer and pia.

**Symptoms.**—These are those of the vertebral lesion, together with those of the internal form detailed below.

**INTERNAL PACHYMEINGITIS.**—This occurs in two forms, first as an inflammation of the internal layer of the dura, usually confined, primarily, at least, to the cervical part of the cord. It was first fully described by Charcot in 1871, and later by his pupil Joffroy, under the name of "*pachymeningitis cervicalis hypertrophica*"; second, as a *pachymeningitis interna hæmorrhagica*, in every way anatomically identical with the same disease to be described in connection with the dura of the brain.

**Etiology and Morbid Anatomy.**—Cervical hypertrophic pachymeningitis, ascribed to exposure to cold, to the abuse of alcohol, and to syphilis, is a chronic process, consisting in an accumulation on the inner surface of the dura of concentric layers of a firm, fibrinous growth, covering either a small extent or a considerable portion of the cervical enlargement, and sometimes causing adhesions of the dura to the pia.

**Symptoms.**—To the subjective symptoms of the inflammation itself are naturally added compression symptoms, which, in fact, overshadow the former. The former include *pain*, not merely at the seat of inflammation in the back, but also in the area of distribution of the spinal nerves, the roots of which are involved in the process.

The compression of the cord and of the nerve-roots which are involved produces symptoms divisible into three stages:

1. *The Painful Stage.*—In this there is pain in the region supplied by the nerves whose roots are thus compressed—viz., that of the arms, cervical region, and occiput—pain at times of great severity. In addition are observed paresthesia, numbness, and tingling, rarely herpes.

2. *The Stage of Paralysis of the Upper Extremities.*—After two or three months the second period, or stage of paralysis, sets in—an atrophic paralysis in which there is weakness of the arms, resulting from pressure on

the anterior nerve-roots. The wasting affects certain muscular groups, as the flexors of the hands, supplied by the ulnar and median nerves, while the distribution of the posterior interosseous nerve to the antagonistic extensors remains free. The result is the very striking claw-hand, or *main en griffe*. In extreme cases the atrophy of the arms and shoulders becomes very great. There may be anesthesia of the skin at this stage.

3. *The Stage of Spastic Paralysis in the Lower Extremities*.—If the compression of the cord continues, we reach the third stage of the disease. The motor fibers to the lower extremities which pass through the cervical cord become involved, and the result is a spastic paralysis of the lower extremities—a paresis with *increased reflexes*, and without wasting of the muscle, because the trophic centers for the muscles of the lower extremities in the anterior cornua of the lumbar cord remain intact. In cases of long duration, however, the compression of the cervical cord may lead to anesthesia of the lower extremities, paralysis of the bladder, and bed-sores.

The symptoms of the internal *hemorrhagic* pachymeningitis are not essentially different from those detailed, but are commonly superadded to those of hematoma of the dura mater of the brain, with which it is usually concurrent. It has generally been observed in the same class of persons, general paralytics and drunkards. It may occur at any part of the cord, or it may be limited to the cervical region, producing corresponding symptoms, but it is rarely recognized before death and is an extremely rare finding.

**Diagnosis.**—The superaddition to the symptoms of spinal caries of those detailed as characteristic of spinal pressure determines at once the condition. The forms arising in other ways are to be distinguished from *amyotrophic lateral sclerosis*, *syringomyelia*, and *tumors*. From the first it can be differentiated by the presence of the characteristic severe pain in the neck and arms, and by the absence of bulbar symptoms; from syringomyelia, by the absence of the sensory changes peculiar to that disease; but from tumors in the same locality it is often distinguished with difficulty because the pressure symptoms in both are the same.

**Prognosis.**—Cases are described in which decided improvement has taken place, if not recovery.

**Treatment.**—The usual methods of treating spinal caries by extension or operation constitute the treatment of the external forms thus arising. The symptoms are to be relieved by appropriate measures. Baths, iodid of potassium, counterirritation, and electricity have been recommended.

The first three are reasonable; the last is of doubtful value. Iodid of potassium is indicated in cases of syphilitic origin. Joffroy recommends the application of the hot iron to the neck. Paquelin's cautery would answer the purpose as well.

## SPINAL LEPTOMENINGITIS.

### ACUTE SPINAL LEPTOMENINGITIS.

**Etiology.**—As a disease separate and distinct from epidemic cerebrospinal meningitis, described under infectious diseases, acute spinal leptomeningitis may occur:

1. As the result of tuberculosis, its most common cause. When thus occurring, it is as a tuberculosis infection separate and independent of the tuberculosis extension in Pott's disease.

2. From localization of the poison of the infectious diseases, as syphilis and typhoid fever.

3. As the result of extension by contiguity.

4. Possibly as the result of exposure to cold.

**Morbid Anatomy.**—The pathological changes are similar to those of epidemic cerebrospinal meningitis. Injection, accumulation of fluid in the piaarachnoid space, either a serofibrinous or a purulent exudate, round-cell infiltration, and, finally thickening of the membrane, all are more or less in evidence. As determined by the position of the body, the fluid exudate tends to gravitate downward or toward the posterior aspect. Not infrequently the morbid process more or less extensively invades the cord, especially at its peripheral portions, producing a meningomyelitis.

**Symptoms.**—The symptoms are those of the disease with which the meningitis is associated, in addition to fever and such other symptoms as are the result of vascular derangement and mechanical interference. These have already been detailed under cerebrospinal meningitis, including *pain in the back* of varying severity, *stiffness, sensitiveness of the spine*, symptoms of *irritation of nerve trunks*, and *disturbances of sensation*. The *reflexes* may be increased. Kernig's sign of "flexion contraction" at the knee-joint, described in connection with cerebrospinal fever (p. 172), should be looked for. Examination of the fluid obtained by lumbar puncture is of diagnostic value.

*Paralytic symptoms* are a late and also a rare development. At such time the reflexes are sometimes diminished or abolished on account of the destructive involvement of nerve-roots or of the spinal cord. The urinary and bowel functions are sometimes deranged.

**Diagnosis.**—The diagnosis of simple acute meningitis in association with the infectious diseases should not be too hastily made, because of its simulation by these diseases. Such simulation is, however, less common with spinal meningitis than with cerebral. Here, as in cerebral meningitis, the etiological factor may help us out; while, on the other hand, given the disease, the special variety present cannot always be told. The tuberculous form is most easily recognized, because of possible pre-existing symptoms of the disease. Stiffness and pain in the back are not so distinctive as hyperesthesia and pain in distant parts supplied by nerves from the seat of special spinal involvement. Again, cases of spinal meningitis have been found on the autopsy table in which no symptoms were recognized during life.

**Prognosis.**—This is generally unfavorable in all forms. Except in the cerebrospinal form recovery rarely occurs, though it is more likely to occur when the disease is secondary to the infectious diseases.

**Treatment.**—This is mainly symptomatic, and the details are those given under the head of cerebrospinal meningitis.

## CHRONIC SPINAL LEPTOMENINGITIS.

**Etiology.**—So rare is primary chronic meningitis that its existence as a separate disease may be doubted. It may, however, remain as a remnant of an acute inflammation, especially of epidemic meningitis. The possibility of its occurrence secondary to chronic disease of the cord, such as tabes dorsalis, is admitted, but it then almost never gives rise to symptoms. It is regarded as a possible consequence of syphilis and alcoholism.

**Morbid Anatomy.**—The distinctive morbid change would be a thickening and opacity of the membrane, and adhesions between the dura and arachnoid, localized or general. Certain white cartilaginous plates sometimes found on the posterior surface of the spinal arachnoid are not to be regarded as inflammatory.

**Symptoms.**—The symptoms would be those described in connection with the acute form, milder in degree and less definite. In fact, the diagnosis is rarely made. A long-continued, otherwise inexplicable stiffness in the trunk and extremities would justify suspicion.

**Treatment.**—This is symptomatic. Counterirritation would naturally be indicated if the diagnosis be made; Paquelin's cautery is the best instrument for the purpose.

## HEMORRHAGE INTO THE SPINAL MEMBRANES.

SYNONYMS.—*Hemorrhachis; Meningeal Apoplexy.*

Hemorrhage may take place between the dura mater and its bony column, *extrameningeal*, or within the dura mater, *intrameningeal*. A third variety of spinal hemorrhage, *medullary*, into the substance of the cord, is described elsewhere, p. 1002.

**Etiology.**—Extrameningeal hemorrhage is almost invariably the result of trauma, such as concussion or fracture of the spinal column, puncture, or gunshot wound. The blood comes from the rich plexus of veins that surrounds the dura. A considerable amount of blood may be thus effused without compressing the cord. An aneurysm may burst into the spinal canal with fatal consequences.

Intrameningeal hemorrhage is rare, and is naturally more limited, as are the sources of the hemorrhage. Punctiform hemorrhages, such as occur in cerebrospinal meningitis, are possibly of little significance. Intrameningeal hemorrhages occur sometimes in connection with the infectious diseases, and William Osler observed two such cases in malignant smallpox, while they have been found after death from convulsive diseases, such as epilepsy, tetanus, and strychnin poisoning. So, also, in ventricular apoplexy blood in transit from the fourth ventricle into the meninges is not a very rare finding. Aneurysm of the basilar or vertebral arteries is, however, the most frequent cause of this form of hemorrhage.

**Symptoms.**—The symptoms in both varieties are those of pressure on the cord, and may be slight and scarcely recognizable, or decided, with resulting paralysis and pain on the one hand, or anesthesia on the other.

The symptoms are as sudden as is usually the event which causes them. Sometimes, however, the extravasation is slower and the symptoms are correspondingly gradual in their appearance. The absence of all cerebral symptoms from a complex including the above points to spinal rather than cerebral hemorrhage.

The extent of the paralysis and the other nervous symptoms depend on the seat of the hemorrhage. If in the lumbar region, the legs are alone involved, the lower deep reflexes may be absent, and the functions of bladder and rectum are impaired. If in the thoracic, there may be complete paraplegia, while the reflexes are retained, and there may be girdle pains. Herpes may be present. If in the cervical region, arms or legs may be paralyzed, and there may be pain or anesthesia in the upper extremities and neck. Embarrassed breathing, stiffness of the muscles of the neck, and even pupillary symptoms may be added when the hemorrhage is thus situated.

**Diagnosis.**—The diagnosis is based on the absence of brain symptoms in connection with the suddenness of the symptoms due to the disease and the history of possible cause.

**Prognosis.**—In certain cases in which the hemorrhage is small, contraction and absorption of the clot may take place, and the symptoms may pass away. In others the hemorrhage is fulminating and death follows early from involvement of the medulla oblongata in the pressure. In intermediate states there is corresponding improvement.

**Treatment.**—Conditions favoring the arrest of hemorrhage and the absorption of blood should be secured. Absolute rest is most important. If symptoms remain permanent, without aggravation, iodid of potassium may be used to promote absorption, and the usual measures intended to restore muscular and nervous power, such as massage, baths, and electricity, should be employed.

## AFFECTIONS OF THE SUBSTANCE OF THE CORD.

### GENERAL CONSIDERATIONS.

Two separate sets of pathological changes invade the substance of the spinal cord. In one they are confined with marked constancy to certain *definite areas* which have precise functions residing in "systems of fibers," so that the clinical phenomena of the disease are exactly defined. These affections are called *systemic diseases*. They include such as tabes dorsalis, an affection of the posterior column; amyotrophic lateral sclerosis, a disease of the lateral columns and anterior horns. Why certain definite areas of the cord are especially involved, and why this peculiar selective systemic implication, we do not know any more than we know why certain poisons, such as curare, strychnin, and lead, select certain tissues for their operation.

In the second group there is no such limitation of area invaded, but the cord in its entire transverse section is involved in one large focus, or several foci separated by areas of sound tissue are invaded. In this group are included acute and chronic diffuse inflammations, the hemorrhages

and traumatic lesions, multiple sclerosis, etc. These are the *non-systemic diseases*. Since, in the diffuse affections, all the parts involved in the systemic lesions are also affected, the symptoms of the latter are found associated with those growing out of the diffuse lesion. The diagnosis arrived at by a study of these symptoms is still, however, mainly a "topical" one, for it is an important fact growing out of the functions of the cord that all diseases involving certain areas produce the same symptoms, whence we infer the *seat* of the lesion rather than its nature or exact cause. This may, however, be determined with a varying degree of certainty from other symptoms.

A further peculiarity of all diseases of the substance of the cord is that its symptoms are commonly *bilateral*. This depends upon two causes: first, the fact that the two halves of the cord are in such close proximity that almost any cause of a violent kind, such as hemorrhage, affecting one-half, must also extend its influence to the other; and, second, the cause of system diseases commonly select corresponding parts in two halves of the cord for their operation.

Again, symptoms vary according as the lesion affects the conducting path in the substance of the cord, to and from the brain, or a portion of the peripheral system of fibers within or without the spinal canal. The symptoms are accordingly known as "central," and as "root" symptoms.

## SECONDARY SYSTEMIC DEGENERATIONS OF THE SPINAL CORD.

Very important in connection with nervous diseases is the subject of *secondary degenerations*. These succeed cerebral lesions and lesions in the spinal cord itself. They depend upon the fact, several times referred to, that a trophic influence is exerted by ganglion cells upon the fibers originating from them, so that the latter degenerate when the conduction of the trophic influence is interrupted or when the trophic ganglion cells are destroyed. For motor fibers such ganglion cells exist in two situations—in the motor areas of the cortex cerebri and in the anterior cornua of the spinal cord. The former exert on the motor fibers arising from them a trophic influence which extends down the cord as far as the latter. For sensory fibers in the cord the trophic influence resides in cells, probably on the posterior spinal root ganglia, and also ganglion cells in the posterior gray matter. The fibers of the lateral cerebellar column in the periphery of the cord arise in the cells of the column of Clarke, or posterior vesicular column—the group of cells in the inner part of the neck of the posterior horn.

*Secondary Degeneration in the Spinal Cord after Cerebral Lesions.*—If there be disease in the motor area of the cortex or in any part of the motor tract in the brain—that is, in the motor fibers of the corona radiata, the internal capsule, the crus, or the pons—interrupting conduction, a secondary degeneration of the motor fibers takes place below in the related pyramidal tracts, anterior on the same side of the cord, lateral on the opposite side, as far as the anterior cornua of the gray matter. In many cases

there is slight degeneration in the lateral tract on the same side as far as the lumbar region, showing that some fibers of each anterior pyramid find their way to the lateral tract on the same side. The relative proportion of the crossed lateral fibers and the anterior fibers that remain uncrossed varies

FIG. 104.—Secondary Descending Degeneration of the Pyramidal Tracts in a Primary Lesion of the Left Half of the Cerebrum—(after Erb).

The lateral pyramidal tract of *right* half is degenerated down to the lowest part of the lumbar region. 1-8. The anterior pyramidal tract of left half is degenerated to beginning of lumbar enlargement.

within limits. In cases in which no anterior pyramidal tracts exist—that is, where all the fibers pass over to the lateral column of the opposite side—there is no descending degeneration of the anterior column. Fig. 104, after Erb, shows secondary degeneration of the pyramidal tracts succeeding a primary lesion of the left half of the cerebrum. Fig. 105, after Edinger,

shows graphically the descending degeneration in the pyramidal tract due to a lesion in the left internal capsule.

*Secondary Degeneration of the Spinal Cord after Transverse Lesion of the Cord Itself.*—If a lesion be seated in any part of the cord affecting more or less its transverse section, the interruption of conduction in these fibers is also followed by secondary degeneration, which may be traced in two directions upward and downward, ascending and descending. Such lesions may be transverse myelitis, compression of the spinal cord, and tumors—any lesion, in fact, involving the whole of the cord.

FIG. 105.—Diagram of Descending Degeneration of the Pyramidal Tracts Due to a Lesion in the left Internal Capsule—(after Edinger).

FIG. 106.—Secondary Ascending and Descending Degeneration in a Transverse Section of the Upper Dorsal Region—(after Strümpell).

The columns of Goll and the direct cerebellar tracts are degenerated upward, shown in 1 and 2, the anterior and lateral pyramidal tracts downward, as in 3 and 4.

The descending degeneration of the pyramidal tract is like the descending degeneration after cerebral lesions, except that after spinal lesions the degeneration of the pyramidal tract is usually more extensive; as the transverse disease affects the pyramidal tract on the two sides, the secondary descending degeneration will affect both lateral pyramidal tracts below the seat of lesion. The ascending secondary degeneration developing upward from the seat of lesion affects the columns of Goll—*i. e.*, the posterior median columns—and the columns of Burdach—*i. e.*, the posterior lateral columns and the lateral cerebellar tracts on the periphery of the lateral columns, because the conduction in those parts which receive their trophic influence from lower cells is interrupted. The ganglionic cells which act trophically on the fibers of Goll are probably in the ganglia on the posterior roots. The lateral cerebellar tracts share in the ascending degeneration, because

they are cut off from the cells of the column of Clarke, and when this occurs or these cells are destroyed, such degeneration may be traced upward into the restiform bodies. Fig. 106 shows secondary ascending and descending degeneration of the cord as occurring after transverse section in the upper thoracic region.

*Clinical Effect of the Secondary Degenerations.*—This is disputed, Charcot and some of the French clinicians ascribing to them the contractures and increase of the tendon reflexes in the paralyzed limbs of hemiplegia, while Strümpell and others think they have no clinical import. It is more probable that the symptoms are caused by an interruption of the nerve-fibers and that the sclerotic tissue in the degenerated tracts produces no clinical signs of disease.

*Secondary Degeneration in the Spinal Cord after Injuries of the Cauda Equina.*—After fractures, caries, or other injuries to the lower lumbar vertebræ or sacrum producing injury to the cauda equina, or as the result of new-growths in this region, a secondary ascending degeneration takes place in the cord after the rupture of continuity. This is due to involvement of the posterior nerve-roots; whence the degeneration is confined to the posterior columns of the spinal cord, and in its distribution it resembles closely the state of the cord in tabes dorsalis. In the lumbar cord all the posterior columns are degenerated except a small median zone and the most anterior portion. The ascending degeneration grows smaller as we ascend, and finally is confined in the cervical cord to the regions of the columns of Goll, which include, in part at least, the prolongation of the fibers from the root zones of the lumbar and sacral cord.

### Acute Affections of the Spinal Cord.

#### DISTURBANCES OF THE CIRCULATION OF THE SPINAL CORD.

**CONGESTION.**—From the standpoint either of clinical observation or postmortem examination but little is known of the phenomena of congestion of the cord as differentiated from inflammation. It is a well-known fact that active hyperemia may partly disappear after death. Congestion of the vessels is found under so many conditions that a diagnosis of inflammation based on this finding alone would not be justifiable.

**ANEMIA** of the cord has been studied clinically and experimentally. The phenomena of paraplegia which succeed profuse hemorrhages as of the uterus *postpartum*, and from the stomach, are fairly ascribable to anemia of the cord.

This is confirmed by some experiments of Stenson, who compressed the abdominal aorta of an animal with the effect of causing almost immediate paralysis of the extremities; and of C. A. Herter, at Johns Hopkins Hospital, in which paraplegia supervened a few minutes after the application of a ligature to the aorta, followed more slowly by paralysis of the sphincters. Within 36 hours there were marked changes in the

ganglion cells of the anterior horns in the lumbar segment, and, later, signs of myelitis. Within 14 days contracture of the limbs set in with atrophy of the muscles and with fibrillar twitchings. Similar results have followed the experiments of others on animals. Obstruction of the aorta by thrombi and emboli has been followed by similar clinical phenomena, but it is questionable whether the results of these experiments can be applied to man, as ligation of the abdominal aorta in man may be done without causing paralysis. In intense degrees of general anemia, such as is found in pernicious anemia, the cord is not so rarely affected. Observations showing that the posterior and lateral columns are involved in pernicious anemia are numerous.

*Embolism* and *thrombosis* of the spinal arteries have been produced experimentally, with resulting *choreiform movements*. Embolism of the smaller vessels possibly occurs in connection with endocarditis. *Endarteritis* or its results are frequently found postmortem in syphilitic subjects as a nodular periarteritis or endarteritis, sometimes associated with gummy tumors of the meninges; and as an *endarteritis obliterans* with thickening of the intima and consequent narrowing of the lumen, involving chiefly the arteries of medium and larger size. Sudden paralysis of spinal origin is likely to be from thrombosis of the vessels of the cord. *Miliary aneurysm* and *aneurysm* of the larger vessels of the spinal cord are very rare.

#### HEMORRHAGE INTO THE SUBSTANCE OF THE CORD.

**Etiology.**—Hematomyelia is at most a rare event. That it ever occurs primarily independent of disease is reasonably questioned. Its possibility must, however, be admitted, at least, as the result of traumatic causes, such as falls. Great physical exertion is another possible primary cause; so are cold and exposure and tetanic and other convulsions. Repeated coitus is mentioned by Gowers as having been followed by hemorrhage in the gray substance at the top of the bulbar enlargement, and this cause may have operated in a patient of my own who was suddenly seized with a paraplegia during one of a number of closely repeated acts of coition and while in vigorous health. Secondary hemorrhage is more frequent.

**Morbid Anatomy.**—The cord may be distended, infiltrated, or lacerated by the hemorrhage escaping into the meninges; if not too copious, the bleeding may be limited to the gray matter and may extend up and down the cord to a considerable extent. The blood undergoes the usual changes after effusion, *i. e.*, coagulates, becomes darker hued, then yellow, and, finally, at times, the seat of the hemorrhage is occupied by a cyst, while numerous hematoidin crystals will be found in the residue. The blood may remain liquid for a long time.

**Symptoms.**—If the hemorrhage is in the lumbar enlargement or the thoracic region of the spinal cord, the effect is, as a rule, *sudden paraplegia*. If the cervical part of the cord is the seat of the hemorrhage, the arms as well as the legs are involved, and there may be embarrassed respiration, and possibly *sharp pain* in the extremities supplied by the nerves pass-

ing to the cord at the seat of the effusion. *Loss of sensation* follows later, while the reflexes also disappear. Myelitis is often developed as a consequence of the irritative presence of the clot, and there follow its usual symptoms, including *trophic changes* and *fever*.

**Diagnosis.**—This is based upon the suddenness of the consequent events—acute pain and paraplegia—under the etiological conditions described, viz., trauma, and other causes. *Hemorrhage into the spinal meninges* is, of course, equally sudden or nearly so, but the symptoms of injury to the cord are less prominent, and there is little or no fever. In meningeal hemorrhage the pain is more severe and symptoms of irritation are more likely to precede the paralysis, while the paralytic symptoms are less persistent.

**Prognosis.**—The accident is rapidly fatal in the severest cases. In others paralysis may exist for a long time or may be permanent. In others there is slow but persistent improvement, and the patient may even recover. Hemorrhage into the cervical region of the cord is more serious because the center of the phrenic nerve which innervates the diaphragm is likely to be invaded. The presence of trophic changes renders the prognosis as to recovery more unfavorable.

**Treatment.**—This is identical with that for hemorrhage into the membranes. Absolute rest is the primary essential condition. Ice may be applied to the spine over the seat of the hemorrhage, and leeches or wet-cups in the same locality, although the benefit obtained by these measures is somewhat doubtful.

If the case is not immediately fatal, improvement is apt to follow the contraction of the clot, as in cerebral hemorrhage. Then, from the theoretical standpoint, ergot is indicated. Full doses,  $\frac{1}{2}$  dram (2 c.c.) to 1 dram (4 c.c.), of the fluid extract, or from 3 to 5 grains (0.2 to 0.32 gm.) of ergotin, repeated in two or three hours with a view to producing a profound effect early, should be given. Later muscular nutrition should be kept up by massage and electricity.

## CAISSON DISEASE.

SYNONYM.—*Diver's Paralysis*.

**Definition.**—A paraplegic and sometimes general paralytic affection which happens to workers in caissons after their too rapid return to the surface from the compressed atmosphere of the caisson.

**Pathology.**—This is not thoroughly determined. That it is, however, a spinal lesion a study of the symptoms goes to show. It is ascertained that the pressure about the body required to produce it must exceed three atmospheres, that the symptoms do not come on until the patient returns to the surface, and that they are more prone to occur the longer the exposure. Under these circumstances it has been suggested that the symptoms are due to the escape from the blood of gases, especially oxygen and nitrogen, with which it has become charged in breathing in the highly compressed air—gases, which, under ordinary circumstances,

escape gradually by the lungs. Gas escaping in the more rapid manner from nervous tissues may exert a pressure which arrests for a time the function. At one time local hemorrhages were supposed to be the cause, but in the few autopsies which have been made nothing has been found which would explain the symptoms from that standpoint. In a case dying on the 15th day Leyden found small, irregular fissures in the middorsal region, chiefly within the posterior and the hinder part of the lateral column, filled with round cells, but containing no blood-corpuscles. It has been suggested that the fissures were produced by the sudden escape of gas, and were finally occupied by wandered-out round cells. In a case dying at two and a half months Schultzer found these fissures, together with signs of myelitis. Leyden suggests that the thoracic region is affected because of its relative softness as compared with other parts of the nervous system. Andrew H. Smith, of New York City, who had excellent opportunities for studying the disease in connection with the building of the Brooklyn Bridge, ascribed the phenomena to a congestion followed by stasis, supposing that under the high pressure the blood is driven from the periphery into internal organs, especially the cord and brain, dilating and paralyzing the blood-vessels. When the pressure is removed, the blood rushes to the periphery. Smith supposes that within the cord, when the pressure is relieved, the circulation is retarded and a stasis results. Is it not possible that the anemia resulting in the cord from the sudden withdrawal of blood from the brain and cord may cause the symptoms? It should be stated that in three fatal cases studied by Leyden, Schulze, and Van Rensselaer, diffuse parenchymatous myelitis with degeneration was found in the posterior and adjacent lateral columns.

**Symptoms.**—These come on, as stated, not during exposure to the abnormal conditions, but on return to the normal atmospheric pressure, often immediately, always within a half-hour. *Paraplegia* or *hemiplegia* is characteristic and essential, although the onset is usually preceded by *pain in the ears and joints*, especially in the larger joints. The latter may be affected without paraplegia after shorter periods of exposure, and there may be *tenderness in the limbs*, or sensibility may be impaired, though the impairment is imperfect and irregular. The onset of the paraplegia is sudden. Monoplegia and hemiplegia are rare, and when present, they are likely to be transient. In severe cases the sphincters are affected. There may be dizziness and headache or the *cerebral symptoms* may be more severe, amounting to sudden loss of consciousness and continuing as coma. *Abdominal pain* and *vomiting* may be present. Severe cases are usually fatal in a few hours. Those who are less accustomed to the work are the most liable to suffer, but the power of resistance also varies in different individuals.

**Diagnosis.**—The diagnosis is not usually difficult, the history of the case furnishing the conditions and explaining the symptoms.

**Prognosis.**—The prognosis is usually favorable, the symptoms generally passing away in the course of a few days, although in severe cases they may last for weeks or months, and may even be permanent. In fatal cases death may occur in a week, or as late as the end of two

or three months, with the symptoms of myelitis. Of 110 cases occurring in connection with the building of the Brooklyn Bridge, three died.

**Treatment.**—None of an active character is usually required. Morphine may be needed to relieve pain. The prophylactic treatment is of greatest importance. This consists in avoiding too long continuance of work under pressure, and care should be taken to make the transition from the higher to the lower pressure gradually. Andrew H. Smith advises that in passing through the lock, from the low to the high pressure, at least five minutes should be taken.

### DIFFUSE MYELITIS (ACUTE AND CHRONIC).

SYNONYMS.—*Myelitis; Transverse Myelitis.*

**Definition.**—The line of demarcation symptomatically between acute, subacute, and chronic myelitis is not sharp, but the term *acute* is applied to that form of inflammation in which the symptoms come on suddenly. When requiring from two to six weeks for their development, it is called *subacute*. When a still longer time elapses before the symptoms reach a decided degree of intensity, it is *chronic*. At the same time it is plain that no very sharp line of demarcation can be drawn between these forms. When the whole thickness of the cord is involved to a small vertical extent—a common form—it is said to be *transverse*; if an extensive area, *diffuse*; when one small area, *focal*; when many foci, contiguous or distant, it is *disseminated*. Inflammation of the gray matter around the central canal, extending into the intermediate gray substance, is called *central* myelitis, which may be parenchymatous and interstitial.

**Etiology.**—The cause is often undiscoverable. There is an occasional hereditary tendency to it. It may occur at any age, but is more common in adult males. It may result:

1. From repeated exposure to wet and cold, or from overexertion, or from both combined.
2. Rarely from the acute infectious diseases, as smallpox, typhoid fever, or puerperal fever.
3. From syphilis, either as the direct result of primary infection, or secondarily from invasion of the cord by syphilitic tumors; the former appears within a few months or several years after the primary inoculation, the latter as a late manifestation, but a macroscopic gumma of the spinal cord is a very rare finding.
4. From tumors other than syphilitic.
5. From injuries to the spinal column, especially fractures, and from caries of the vertebræ. It is extremely difficult, nay, often impossible, to distinguish the inflammatory results of tumors and caries from those of compression; and, indeed, the symptoms due to tumors and caries are chiefly the result of pressure.

**Morbid Anatomy.**—The seat of invasion varies, the upper half of the

thoracic cord being most frequently involved, but there may be cervical myelitis and rarely lumbar myelitis. There may be a central focus and numerous small foci in the vicinity. The extent of the involvement varies at different levels. The softer reddish conditions indicate the more acute stage; the harder, grayer, and more contracted, the chronic stage—sclerosis.

Considerable experience is necessary to be able to recognize the changes in many cases of myelitis. The separation of the process into different stages is difficult or impossible. To the untrained naked eye the cord often appears quite normal. The expert examiner may recognize by touch that over a certain extent the cord may be either softer or harder and firmer. On section, the substance of the cord rises up more than in the normal state, the contour of the gray matter is less distinct, and sometimes has a hyperemic, reddish coloring, while the white matter is reddish-gray. There may be minute hemorrhages. The consistence may be diffuent, constituting red softening. These foci of hemorrhage may give place to cavities. The gray matter may be involved throughout considerable extent. The meninges may be involved, producing myelomeningitis.

These changes become much more evident if the cord is allowed to remain in hardening fluid, and only after hardening can the lesions be satisfactorily studied.

Microscopic examination of the fresh cord recognizes numerous *granular fatty cells*. *Blood-disks* and *leukocytes* may be present, the latter rarely in quantity to justify the name of pus or abscess. Thin sections stained by carmine give a very different picture even to the naked eye, the diseased tissues taking on the darker staining because of their greater richness in neuroglia. By the microscope it is found that in these portions the normal nerve tissue has partly or almost wholly disappeared. In some places axis-cylinders remain, possibly much swollen, and having lost only their medullary sheaths; in others the nerve tissue has disappeared. The *changes in the ganglion cells* are also definite; they have lost their processes and are rounder, or are entirely destroyed, while the *increase of neuroglia* goes on *pari passu* with the destruction of the proper nervous matter. The neuroglia occupies the enlarged meshes caused by the disappearance of the nervous elements. The cells of the neuroglia increase, and Deiters' spider cells may be numerous. The granular fatty cells may also be recognized, especially by osmic acid, provided no alcohol has been used in hardening. The blood-vessels are dilated and distended, and their walls are hyaline. The sum of these changes constitutes *sclerosis*.

In localized acute myelitis affecting the white and gray matter after injury the cord is swollen, the pia injected and soft, and on cutting the membrane an almost diffuent fluid may escape. In less degree the appearances first described are present. It is these cases which arise particularly by invasion from without or from compression in which the white matter is involved.

Localized areas of softening with blood accumulation constitute *red softening*. Abscess of the substance of the cord may occur, and at

least nine or ten cases have been reported. Pus forms in the cord in considerable quantity only in purulent meningitis.

**Symptoms.**—The distinctive symptoms of myelitis may be preceded by constitutional disturbance, including *headache* and general *malaise*, and even *chill*, *fever*, and *delirium*. A temperature of  $107^{\circ}$  to  $108^{\circ}$  F. ( $41.7^{\circ}$  to  $42.2^{\circ}$  C.) has been noticed. These symptoms are, however, unusual.

The characteristic symptoms vary greatly with the part of the cord involved, and no picture can be drawn to suit such differences of locality. I prefer, therefore, following Strümpell, to describe the symptoms more or less common to all localities, and, after this, such modifications or peculiarities of these as enable us to locate more precisely the process. The former include:

1. *Symptoms of Motor Paralysis.*—They are the most conspicuous and commonly the first recognized sign of developing transverse myelitis. Beginning with a tired feeling in one or both legs, followed by evident weakness and then dragging, the paresis continues to grow until the patient is totally unable to make any active movement with his legs. This implies that the lateral columns of the cord, and especially the posterior part of the lateral columns, carrying the lateral part of the pyramidal tract, are involved, cutting off the motor impulses. In some instances this paralysis occurs very rapidly, and probably is from occlusion of the blood vessels of the cord. The motor paraplegia can occur in every form of myelitis—lumbar, thoracic, or cervical; but in the first two the upper extremities are intact. In the cervical, paralysis of the upper extremities also takes place. If one side of the body is involved more than another, it implies that one-half of the cord is more intensely affected.

2. *Symptoms of Motor Irritation.*—These consist in spontaneous twitchings of the muscles of the paretic limbs, either rapid and short or slow and persistent. They occur at the beginning and during the course of the disease, and are variously severe. It is not always easy to distinguish them from increased reflexes, hence their diagnostic value is not great. Ataxia and intention tremor may occur in connection with involvement of the upper extremities and in the convalescence of acute cases, but they are very rare.

3. *Disturbances of Sensibility.*—These occur in marked degree much later in the disease than the motor phenomena. At the beginning there may be numbness, formication, tingling, and even girdle sensations, but severe pain is rarely present. When pain is present, it is an evidence of involvement of the vertebræ or meninges. In advanced stages, in addition to anesthesia, there may be paresthesia and striking hyperesthesia. The involvement of sensibility probably means that the whole transverse area of the spinal cord is intensely affected.

Disturbances of sensibility are useful in determining the segment of the cord involved because the lesion corresponds very nearly, or sufficiently so for practical purposes, to the level of the seat of the modified sensibility. Thus, in myelitis of the lumbar region the altered sensation extends nearly to the umbilicus, in the lower thoracic to the ensiform

cartilage, in the upper thoracic to the level of the axillæ, while in the cervical the sensibility of the upper extremities is impaired, but total anesthesia is very rare.

4. *The Reflexes.*—The effect of myelitis on the reflexes varies greatly with the seat of the disease and the degree and extent of the lesion. In the very incipency of an inflammation of the cord we may expect all the reflexes, cutaneous and tendon, centering in the part involved to be increased, but with the progress of the disease the effect varies greatly and must be discussed in detail.

(a) *Skin Reflexes.*—The reflex arcs of the cutaneous reflexes are not definitely determined. Their connection with reflex inhibitory fibers from above is to be remembered, irritation of which fibers possibly diminishes, and interruption of which possibly increases the sensitiveness of the reaction. In extensive lumbar myelitis the reflex path is broken and the cutaneous reflexes of the lower extremities are diminished, running about *pari passu* with altered sensibility. In thoracic and cervical myelitis the arc for the lumbar reflexes is intact, and if the reflex inhibitory influence is removed, these skin reflexes may even be increased. Experience shows, however, that the skin reflexes in the leg may be diminished even in dorsal or cervical myelitis, in which event there must be loss of irritability in the fibers. The cremaster reflex has its arc at about the level of the first lumbar nerve, hence its loss means disease there. The lower abdominal reflex corresponds to the lower thoracic cord and the upper to the level of the fourth to the seventh thoracic vertebra. There is much need for careful study on the behavior of the cutaneous reflexes, as this subject is far from being fully understood.

(b) *Tendon Reflexes.*—The reflex arc of the patellar reflex lies at about the level of the second to the fourth lumbar segment inclusive. Hence the knee-jerk fails in disease of the lumbar cord involving the lateral part of the posterior columns and the anterior cornua of the gray matter. The ankle clonus probably has its reflex arc at the level of the first sacral segment. It is always absent in extensive disease of the posterior columns and gray matter of the sacral cord in this vicinity. *The absence of deep reflexes of the lower extremities is, therefore, one of the most valuable signs of myelitis of the lumbar cord.* In almost all inflammations above the lumbar cord—that is, of the thoracic and cervical portions—there is a decided *increase in the tendon reflexes of the lower extremity*, because these lesions destroy the reflex inhibitory influence. When, therefore, alongside of this it is remembered that the fibers which influence the condition of the tendon reflexes run chiefly in the *lateral* columns of the cord, we may conclude that the lateral columns are involved. In cervical myelitis the tendon reflexes of the upper extremities are often increased. It should be remembered that complete or nearly complete, transverse lesion of the cord in the thoracic or cervical region may cause a loss of the deep reflexes of the lower limbs.

5. *Disturbances of the Bladder and Rectum.*—These are common in myelitis. There is, first, delay in micturition, finally accomplished by extra straining, but later all power to empty the bladder is lost—the *detrusor urinæ* is paralyzed. Still later the *sphincter vesicæ* is paralyzed,

and then there is incontinence of urine. These symptoms occur in connection with paralysis in any part of the cord. The ultimate effect is almost invariably a cystitis, the result partly of decomposition, induced by germs introduced through repeated catheterization, even when most cautiously conducted, partly by the entrance of germs through the patulous sphincter. Such cystitis has also been ascribed to trophic influence. To the cystitis may succeed pyelitis and purulent pyelonephritis.

In myelitis there is at first obstinate constipation, followed by paralysis and incontinence of feces. This symptom does not give any information as to the seat of the myelitis. Defecation and micturition are sometimes reflexly aroused in abnormal degree when there is increased reflex irritability. Sexual functions, the centers of which probably reside in the sacral cord, are also often deranged in myelitis.

6. *Trophic Disturbances.*—These are most important symptoms, and valuable also in diagnosis. In cervical and thoracic myelitis the trophic centers in the lumbar cord are intact. The paralyzed muscles, therefore, do not atrophy excessively, though they may be somewhat softened from want of use. They retain their normal electrical excitability, or at least the reactions are not qualitatively altered, although they may be quantitatively. On the other hand, genuine atrophy and the presence of the reaction of degeneration show that the anterior gray cornua or the fibers of the anterior roots of the lumbar cord are involved; in the upper extremities they show that the same portions of the cervical cord are involved. Bed-sores are among the trophic phenomena, the possibility of the occurrence of which should always be vividly present. They are among the most unpleasant and most unmanageable symptoms, yet they may be guarded against; for, although favored by the deranged trophic influence, they require an exciting cause such as pressure, the irritation of secretions, or foreign substances to originate them. They occur over the sacral and gluteal regions, more rarely on the feet and inner sides of the knees. The total anesthesia often associated with advanced stages of the disease co-operates to permit the action of the exciting causes.

Other trophic effects often met are drying and hardening of the skin; glossy skin, also thick and brittle nails. Vasomotor disturbances also occur, producing congestion and mottling, and there may be slight edema of the paralyzed parts; also sweating, which may be localized. The temperature of the affected limbs may be lowered, and multiple arthritis may occur.

7. Disturbances in the area of distribution of the *cranial nerves* almost never occur, though bulbar symptoms are met in rare cases of cervical myelitis, when the process has extended to the medulla oblongata. Optic neuritis and pupillary changes, vomiting, hiccough, slow pulse-rate diminishing to 20 or 30, dysphagia, dyspnea, and syncope, have been observed in cervical myelitis.

By uniting the symptoms detailed and their mode of manifestation we may draw conclusions with a certain degree of positiveness as to the portion of the cord involved. The following table by Morton Prince in Dercum's "Text-book" will be helpful:

	LUMBAR MYELITIS.	DORSAL MYELITIS.	CERVICAL MYELITIS.
Paralysis.	Paraplegia.	1. Dorsal, abdominal, and intercostal muscles, according to height of lesion. 2. Leg.	Neck muscles, diaphragm, arms, trunk, and legs.
Sensation.	Pains in legs, or girdle pains around loins; hyperæsthetic zone around loins; anesthesia of legs, complete or uneven distribution.	Girdle pain and hyperæsthetic zone between ensiform cartilage and pubes.	Hyperæsthesia and pains in certain nerve distributions of arms; below this, anesthesia of arms, body, and legs.
Atrophy.	Of legs.	Of dorsal and abdominal (and intercostal muscles, not subject to examination) corresponding to height of lesion; sometimes mild and slow of legs.	Atrophy of neck muscles (rare) or more commonly of arms.
Electrical reaction.	Reaction of degeneration in atrophied muscles; or, in mild cases, quantitative diminution.	R. d. in dorsal and abdominal muscles; slight quantitative changes only in legs when wasted.	R. d. in atrophied muscles.
Bladder.	Incontinence from paralysis of sphincter.	Retention, or intermittent incontinence from reflex action; later from overflow. Cystitis common.	Same as in dorsal myelitis.
Bowels.	Incontinence from paralysis of sphincter, disguised by constipation.	Involuntary evacuation from reflex spasm, or constipation.	Same as in dorsal myelitis.
Reflexes, superficial.	Lost.	Temporary loss, then rapid increase.	Same as in dorsal myelitis.
Reflexes, deep.	Lost.	Temporary loss, then slow increase.	Same as in dorsal myelitis.
Priapism.		Often present.	Often present.

**Diagnosis.**—The difficulty of diagnosis is sometimes very great, because identical symptoms may be produced by other diseases, especially pressure diseases of the cord, such as are caused by tumors or hemorrhages, possible conditions which must be carefully sought.

*Landry's acute ascending paralysis* and *multiple neuritis* present some striking resemblances, and in some cases Landry's paralysis is due to myelitis. Both Landry's paralysis and multiple neuritis present rapidly progressive motor paralysis, but though sensory derangement may be a late development in myelitis, it is still a symptom belonging to it rather than to Landry's paralysis, which is a motor affection, while the trophic symptoms, the paralysis of the bladder and rectum, rapid wasting, electrical disturbances, and fever, pertain to myelitis. The resemblance to multiple neuritis is closer. In this, however, anesthesia is less complete, the wasting less rapid, and bladder and rectum involvement almost never present, and the parts affected are in nerve distributions.

**Prognosis.**—Almost all cases of myelitis are chronic after a more or less acute beginning, seldom lasting less than a year, often two or three years and even longer. The term acute is not, therefore, applied in its ordinary meaning, implying rapid course and early termination, but it is used to indicate cases which develop rapidly to their acme as contrasted with those that are slow. Even these cases become chronic. There are many who doubt the existence of a myelitis which begins in a chronic form. They hold that all so-called chronic cases of myelitis have an acute commencement. Rapidly developing cases passing to a fatal termination in from five to ten days may occur, but are rare. Moreover, recoveries are not impossible, though also rare. Certain cases, after reaching a given

stage, remain as to symptoms *in statu quo*, by which it is understood that the local lesion has healed, while function has not been regained because of the impossibility of restoring the normal structure of the cord. Remissions and improvements are less infrequent. Death is usually the result of exhaustion, although it may result from intercurrent disease.

**Treatment.**—This is for the most part to be directed to the relief of symptoms, no curative means existing beyond what nature herself provides. In cases with acute onset and pain, cups may be applied to the back. Even in syphilis it is thought by some useless to give the usual remedies, but it is safer in cases of suspected disease to give iodid of potassium in ascending doses to the extent permitted by the stomach, while the mercurial effect should be brought about by inunctions, 30 grains (2 gm.) to a dram (4 gm.) of mercurial ointment being rubbed in daily in different parts of the body, care being taken to select those parts having less hair. Tonics, such as iron, quinin, and strychnin, are useful in this as in other prolonged affections.

The most painstaking attention must be given to the skin by bathing with alcohol and thoroughly drying after all washing, in order to prevent the excoriations which are often the beginnings of bed-sores, while the irritating effects of the excretions must be carefully watched, and if catheterization is necessary, it must be practiced with the closest attention to antisepsis. It may even be desirable to keep a soft catheter permanently in the bladder, to which a long tube is attached and the bladder thus kept drained. Should cystitis supervene, the bladder is to be washed out as directed on page 839. When possible, the rectum should be emptied by enema rather than by purgatives, which should be cautiously used.

Electricity is elaborately directed by the German authors, although they admit that in the majority of instances it is principally a diversion to the patient. In the later stages, however, of the forms in which there is atrophy of the muscles, some advantage may be expected. The constant current is most highly commended, by large electrodes placed over the vertebral column, and a moderate stable current or slowly labile current is passed for four or five minutes through the supposed seat of the disease. Peripheral galvanization or faradization of the paralyzed muscles and nerves should also be employed. Massage is useful, perhaps more so than electricity. The bladder may also be treated by electricity.

The bath treatment is carried out to various degrees of elaboration. The simple tub-bath with warm water furnishes the easiest form and may be quite useful, at a temperature of 85° or 90° F. (24° to 26° C.), in the cases with spastic symptoms. The baths should be at first limited to 10 or 15 minutes three or four times a week, and if well borne, may be increased to an hour daily. The water may be impregnated with sodium chlorid, using either the sea-salt or common salt, from 4 to 6 pounds of the former or from 5 to 10 pounds of the latter to the bath. When the patient is able to travel and avail himself of the actual sea-baths they may be expected to be beneficial. The Hot Springs of Arkansas and Virginia in this country may be resorted to. In Europe the thermal waters at Rehme and Nauheim in Hesse, Ragatz, in Switzerland, Teplitz in Austria, Wildbad in Wurtemberg, Gastein in Salzburg, Austria, and

Wiesbaden in Baden are among those recommended; also the mud-baths of Carlsbad and Marienbad in Bohemia and Elster in Southern Saxony.

### ACUTE ANTERIOR POLIOMYELITIS OF CHILDREN.

SYNONYMS.—*Myelitis of Children; Spinal Paralysis of Children; Atrophic Spinal Paralysis; Infantile Palsy; Essential Paralysis of Children.*

**Definition.**—An acute febrile disease of children, usually under three years of age, in which there is paralysis with rapid wasting of certain muscles.

**Historical.**—The clinical phenomena of this disease were described as early as 1840 by Jacob von Heine. The same physician 20 years later suggested that a spinal malady lay at the bottom of it, but it was reserved for Prevost and Velpeau, Charcot and Joffroy, to demonstrate the lesion which justifies the use of the term "spinal paralysis of children," for the older term "essential paralysis of children."

**Etiology.**—Especially a disease of later infancy, it may occur at all periods of life, but is ten times more frequent in the first decade than in all the rest of life. It is rare before the fifth month and often the fourth year. It is more common in boys than in girls, and in the warm months, as pointed out by Wharton Sinkler, who ascertained that in Philadelphia four-fifths of the cases occurred in May to September. There seems to be a slight family tendency. It has appeared in epidemic form in Stockholm, where Medin reports 29 cases from August 9 to September 23. A very remarkable epidemic in this country, occurring at Rutland, Vt., was reported by Caverly in the "New York Medical Record," volume ii., 1894, in which 190 cases occurred during the summer, of which 85 were under six years of age, and 18 died. Other epidemics have been recorded during the past few years. Acute anterior poliomyelitis has been ascribed without foundation to dentition, to cold, and to overexertion, and is very frequently erroneously attributed by parents to falls and the carelessness of nurses. Most children are attacked while in perfect health, although previous exhausting diseases may reasonably be held responsible. It is probably an infectious disease due to bacterial invasion. Among predisposing diseases are typhoid fever, measles, and diphtheria. Strümpell, however, says that though the paralyzes arising after these diseases are of spinal origin, they cannot be identified with the idiopathic spinal paralyzes of children.

**Morbid Anatomy.**—The disease occupies more frequently the cervical or lumbar enlargement. The usual lesion found in old cases, which are those which commonly come to autopsy, is an *atrophy of one anterior cornu*, which is changed to a dense sclerosed tissue, whence the ganglion cells have almost or totally disappeared, often pierced by thickened and dilated vessels. The seats are the corresponding cornua of the cervical enlargement if the paralysis is in the arm, and of the lumbar if in the leg. If bilateral, both cornua would be involved. The corresponding anterior nerve-roots are atrophied and the muscles supplied by them are wasted, undergoing a fatty and sclerotic change. The white matter of the cord in the vicinity may be involved to some extent, resulting in sclerosis and slight reduction in size. Opportunities for autopsy in the

earlier stages are rare, but a condition of acute myelitis predominating in the gray matter, with degeneration and rapid destruction of the ganglion cells, has been found by a number of investigators.

**Symptoms.**—*Sudden onset* is characteristic of the disease, although there may be, and probably oftener than is noticed, slight previous indisposition with feverishness. A child, apparently perfectly well and lively, may be suddenly taken with *fever*,  $101^{\circ}$  to  $103^{\circ}$  F. ( $38.3^{\circ}$  to  $38.9^{\circ}$  C.), sometimes reaching  $105^{\circ}$  to  $106^{\circ}$  F. ( $40^{\circ}$  to  $41^{\circ}$  C.); *headache* and sometimes *pain* in the *loins* and *limbs* and *aching* in the *joints*, *drowsiness*, and even *stupor*. Rarely there may be *convulsions* and *loss of consciousness*. These initial symptoms do not often last longer than a couple of days, when *paralysis* sets in abruptly, reaching its climax usually in 24 hours. The extent varies, involving one or both arms, one or both legs, more rarely one arm and one leg, or there may be crossed paralysis, as of the right arm and left leg. Groups only of muscles may be affected, as those of

FIG 107.—Section through the Cervical Enlargement in Anterior Poliomyelitis; the Left Anterior Column (b) is very much contracted and is without Ganglion Cells—(from Charcot and Joffroy).

the upper or lower arm, upper or lower leg, corresponding to the nerve-cells involved. Less frequently the paralysis comes on more slowly, taking from three to five days to develop. It commonly also diminishes in extent after its first invasion, in rare cases even totally disappearing, but usually withdraws itself to a definite set of muscles, which remain more or less permanently affected. In the legs, the flexors of the foot, the tibialis anticus and extensor groups of muscles are more commonly affected than the glutei and the hamstrings; in the arm, the deltoid. The child, in the meantime, has regained its health in other respects.

At first the affected limbs remain natural, and hence the child, too, appears vigorous, especially as the face is not involved. This may be the case for some time, but usually in a few weeks *atrophy* sets in and progresses rapidly, producing a soft, flaccid, wasted limb. The *changes in the electrical reaction* of the nerve and muscle appear at the same time, commonly more rapidly than the visible atrophy. Usually as early as the first week the reaction of degeneration is present. Faradic excitability of both nerve and muscle is gone, and galvanic excitability in the nerve. In muscles there is at first increased responsiveness to galvanism with a

predominance of slow anodal closure contraction (An Cl C), while after two or three months even galvanic excitability falls decidedly, though the muscular contraction maintains its characteristic slow vermicular quality.

Often the growth of *bone* in the affected limb is delayed, and even arrested, and a stunted development results. After a time there also ensue *relaxation of the joints* and deformity from secondary muscular contraction. In the lower extremities the paralytic club-foot (*talipes varo-equinus*) develops, resulting from the paralysis of peroneal muscles and the tibialis anticus, permitting the point of the foot to drop, while a contracture develops in the antagonistic muscles of the calf. In paralysis of muscles of the calf there results, on the other hand, a moderate degree of *talipes calcaneus*, from contraction of the antagonistic muscles. In the arms numerous *contractures and deformities arise*, mainly due to the contracture of unparalyzed antagonistic muscles and to external mechanical conditions, such as weight and pressure. In some instances the abdominal muscles are paralyzed.

*Sensation* remains intact, as also does, fortunately, bladder and rectum control. At the onset *micturition* is sometimes slightly deranged, but subsequently becomes normal. The tendon *reflexes*, and almost always the skin reflexes, are *lost* in parts affected by the atrophy. The skin sometimes exhibits trophic disturbances, being cool and cyanotic.

**Diagnosis.**—This is usually easy. There are few diseases in which one can reason so soundly from characteristic symptoms to morbid states causing them. The paralysis of one or more limbs, the flaccidity, the rapid wasting, the reaction of degeneration, and the absence of reflexes, with integrity of sensibility and undisturbed mental state, point only to disease of the anterior cornua. The pseudoparesis of *rickets* presents some similarity in paretic and muscle phenomena. There is not, however, in rickets true paralysis—simply pain on motion, to which are added the peculiar head-sweating and hyperesthesia, together with rachitic symptoms elsewhere.

**Prognosis.**—This is always unfavorable so far as recovery is concerned, but improvement, at first general, and afterward in groups of muscles, is often decided, so much so, indeed, as to be somewhat delusive. In protracted cases we must expect the superaddition of contractures, while deformities must be mentioned to parents as possible. The initial period passed, there is no danger to life, and subjects may live to old age.

**Treatment.**—Notwithstanding the unfavorable prognosis, treatment should not be ignored. Paralysis is established, of course, before the diagnosis is made, and atrophy nearly as soon. The early symptoms can, therefore, only be treated symptomatically. An aperient should be given and febrifuges ordered. Should an opportune circumstance favor an early diagnosis, cold applications may be made to the spine; it is doubtful whether they will accomplish much. Paralysis supervening, the little patient must immediately be put at rest in bed and wrapped in cotton. No active measures should be taken at this stage.

The acute stage passed, electricity is the most important therapeutic measure to be employed. It is used both for curative purposes and to keep up the nutrition of the muscles. In attaining the former, galvanism

is preferred, a broad electrode being placed on the vertebral column over the spot supposed to be diseased—on the cervical region, if the upper extremity is paralyzed, and over the lumbar if the lower—while the other pole is placed over the paralyzed muscles and nerves. The latter is moved about, the current being at times reversed. Interruptions may also be made. While the galvanic current is commonly employed, faradization may be used.

The second purpose of the electrical treatment, keeping up the nutrition of the muscles, is more likely to be effectual. For this purpose massage and baths, after the method laid down under treatment of myelitis, are also useful. The electrical treatment must be persisted in for months and even years in order that the muscles may be in a condition to resume their function should the integrity of the cord be restored. Both massage and electrical treatment may be carried out by members of the family after a little instruction.

Tonics are employed for the usual purposes, and orthopedic appliances may be necessary to overcome the effect of muscular relaxation on the one hand and of contractures on the other.

## ACUTE POLIOMYELITIS IN ADULTS.

SYNONYM.—*Acute Atrophic Spinal Paralysis of Adults.*

The existence in adults under thirty of a disease with all the clinical manifestations of the one just described as comparatively frequent in children must be admitted, since an undoubted anatomical lesion of the same kind, associated with such manifestations, has been found by investigators. On the other hand, it must be conceded that the disease is very rare and that many of the cases so diagnosticated were really cases of multiple neuritis. Landry's paralysis in some cases may be the clinical manifestation of poliomyelitis. In view of the fact that the symptomatology is almost the same as that of the infantile form, no separate description is necessary. Among peculiarities may be mentioned the possible involvement of all four extremities, as contrasted with a monoplegia or a paraplegia at other times. Again, there may be the involvement of groups of muscles. Thus, in paralysis of the crural region the sartorius muscle often remains free. In the leg the tibialis anticus may be separately involved or the extensor digitorum. In the forearm the supinator longus supplied by the musculospiral nerve may remain free while all the other muscles on the extensor side of the forearm are paralyzed, furnishing "the forearm type" of E. Remak; or the supinators may be paralyzed alone or together with the biceps, brachialis anticus, and deltoid, furnishing "the upper arm type" of Remak. The latter form is said to correspond to a lesion at the level of the fifth and sixth cervical roots, and the former to a lesion of the eighth cervical and first thoracic roots.

**Diagnosis.**—This is mainly from *multiple neuritis*, in which the palsy is symmetrical instead of irregular in distribution, pain is more characteristic and persistent, while the nerve trunks are inflamed and painful.

**Prognosis and treatment** are similar to those of the same affection

in children, except that the prognosis is rather more favorable, recovery being reported, though such cases may have been multiple neuritis.

#### SUBACUTE AND CHRONIC POLIOMYELITIS.

SYNONYMS.—*Subacute and Atrophic Spinal Paralysis; General Anterior Spinal Paralysis, Subacute of Duchenne.*

All that was said of the probable confounding of acute poliomyelitis of adults with acute multiple neuritis may be said of the subacute and chronic forms. Yet it would seem that undoubted cases have been studied. Oppenheim especially studied a case—in which the anterior cornua of the cord were found markedly diseased at necropsy, and other cases are found in the literature. There were, clinically, paralysis and atrophy of all four extremities without sensory disturbance. The cases differ from the acute form in the absence of the severe initial symptoms, fever, headache, somnolence, delirium, and vomiting.

#### ACUTE ASCENDING SPINAL PARALYSIS.

SYNONYM.—*Landry's Paralysis.*

**Definition.**—A disease first described by Landry, in 1859, characterized by an advancing paralysis beginning in the lower extremities, passing upward to the trunk and arms, and finally to muscles supplied from the medulla oblongata, including those of respiration; sensibility and bladder and rectum control remaining intact.

**Etiology and Pathology.**—It is most common in men between 20 and 30, and usually those who are strong and healthy. Cases have, however, been seen in children and old persons. *No anatomical lesions pathognomonic of the disease have been shown to be associated with it.* Hence attempts have been made to classify it elsewhere, and H. Oppenheim, James Ross, Neuwerk, Barth, and others regard it as a form of peripheral neuritis, Ross having found an interstitial form confined to nerve roots, while Neuwerk and Barth described a case confined to peripheral nerves. Other carefully studied cases failed to disclose such lesion. In some cases myelitis, especially poliomyelitis, is the cause. A toxic cause seems not unlikely. It is quite consistent with such cause that it should leave no local lesion, as well as that it should always seek the same spot. Gowers is especially disposed to ascribe the disease to such a cause. Some cases have, however, followed trauma.

**Symptoms.**—The characteristic symptoms are commonly preceded by a prodrome, in which *loss of appetite, general malaise, moderate fever, headache, backache, and tingling in the extremities* are conspicuous. These symptoms vary in severity and last from a few days to several weeks, when a *paresis* suddenly sets in, first of one leg and then of another, increasing rapidly, so that in a few days, sometimes in a few hours, an almost total motor *paraplegia* is developed. The paresis next extends to the trunk; in a few days or even less the arms are paralyzed. The muscles

of the neck are next involved, and ultimately those of respiration, deglutition, and articulation, producing bulbar symptoms. Finally, facial paralysis and other disturbance of facial muscles may ensue. The paralysis is a flaccid one, and there is no tendency to spasm or resistance to passive motion. There is *not* usually a *change* in electrical reaction, although there is sometimes a rapid loss of faradic muscular excitability. The *reflexes are diminished* or absent, but the *muscles do not waste*, because death usually occurs before atrophy has had time to develop.

There is *no definite loss of sensation*, but in addition to the primary tingling referred to there is sometimes *hyperesthesia* and *muscular tenderness*. In other characteristic cases sensation is intact. More rarely there is a *blunted* and *delayed sensation*. The *special senses* are not affected, nor are the *bladder* and *rectum*. Sometimes there are *vasomotor edema* and *sweating*. The *spleen* has been found enlarged and slight albuminuria has been observed.

**Diagnosis.**—This is not always easy, the disease being simulated by *multiple neuritis*, *acute anterior poliomyelitis*, and *ascending myelitis*. All these may cause difficulty, and sometimes a distinction clinically and pathologically is impossible. The rapid motor paralysis, advancing from below, in the feet and hands, instead of from above, the absence of anesthesia, of wasting, and of electrical changes, are characteristic of *Landry's paralysis*.

**Prognosis.**—This is grave, and the possibility of a rapidly fatal termination, even in a few days, is to be remembered, the danger being from interference with the cardiac and respiratory functions of the medulla oblongata. Other cases terminate similarly in three or four weeks. If, on the other hand, the acute stage passes off, the symptoms of paralysis may cease to extend, and recovery is possible and has occurred in some cases.

**Treatment.**—The patient should be put to *bed* immediately, and *counterirritation* should be applied to the back by dry cups, and maintained by gentler means, as by a mustard plaster. The thermocautery has been recommended, but is of doubtful value. Paquelin's cautery is, at least, harmless.

Of internal remedies the apparent results from *ergotin* and *mercury* justify their further use. Gowers relates a remarkable case of recovery under the use of the former drug, 20 grains (1.32 gm.) having been given in the course of a night in divided hourly doses. Likewise cases of syphilitic origin have been reported, in which the *iodid of mercury* has seemingly proved of service. The *biniodid* may be given in doses of from 1/50 to 1/30 grain (0.003 to 0.006 gm.). The *salicylates* have been advised. Both remedies are indicated if its toxic origin be admitted. *Perchlorid of iron* is recommended in traumatic cases, especially when there is evidence of septic poisoning.

If *swallowing is difficult* the patient must be nourished by the rectum or through the nasal tube, and if symptoms of respiratory failure come on, electrical stimulation of the phrenic nerve and respiratory muscles may be used. If the acute symptoms pass away and paralysis persists, the usual application of galvanism and faradization may be made for restoring muscular and nervous power.

## Chronic Affections of the Spinal Cord.

## SPASTIC SPINAL PARALYSIS.

SYNONYMS —*Primary Lateral Sclerosis; Spasmodic Tabes Dorsalis.*

**Definition.**—A chronic disease of the spinal cord, characterized by stiffness and weakness of limbs with greatly exaggerated tendon reflexes, but without atrophy or sensory or vesical derangement.

**History.**—In 1875 Erb, and independently Charcot, called attention to a form of paralysis characterized by "a gradually increasing paresis and paralysis, usually advancing from below upward, with muscular tension, reflex contractions and contractures, with marked increase of the tendon reflexes and *complete absence of sensory and trophic disturbances of vesical and sexual weakness, and of any cerebral disturbance.*" Both observers agreed on a "primary symmetrical sclerosis of the lateral columns" as the anatomical condition of the disease. Since then numerous cases have been observed corresponding in clinical features, but while the anatomical features described as essential have been found, they have, with one or two exceptions, been accompanied by other lesions, which are not alike in different cases. A few cases have been described, which seem to show the possibility of the occurrence of primary lateral sclerosis, without complications, but most foreign writers discard the name of lateral sclerosis, and some speak of it by its most prominent symptom, spastic paraplegia.

**Etiology.**—The etiology is not always apparent, although the causes are probably many. The cases mostly begin between the 20th and 40th years. It may occur in children. It has been traced to syphilis, several times to trauma, to acute infectious fevers, lead-poisoning, and the puerperium; the diagnosis in such cases usually has been without anatomical confirmation. Strümpell has called attention to a hereditary family type, found in male members, between the 20th and 30th years, and in some families the symptoms are first manifested in early childhood. A form closely related, but resulting from arrested development rather than from atrophy of the central motor tracts, is the spastic paraplegia occurring in children born prematurely, and sometimes classed as one type of Little's disease.

**Morbid Anatomy.**—The lesion which would be expected in spastic spinal paralysis is degeneration of the pyramidal tracts. In point of fact this condition is found, but it is likely to be part of a mixed lesion which may include that of myelitis, meningomyelitis, multiple sclerosis, compression of the cord by tumors or by caries of the vertebræ. In a few cases, however, the lesion almost uncomplicated has been found by Strümpell, Dejerine, Sottas and others.

**Symptoms.**—The conditions may begin with a sense of *fatigue and weariness* in the legs, but the two essential and predominating symptoms are *increase of the tendon reflexes and motor paresis*. The first is the more unmistakable, constant, and characteristic. In decided degrees of this increase the contractions come on even with that amount of tension on the tendons which is produced by the weight of the limbs or any active or passive movements, while the reflex muscular tension or rigidity opposes any attempt at motion. The muscles feel rigid and firm, and the legs are found in almost permanent extension, while the feet are in plantar flexion. Any attempt, especially if sudden, to flex the leg at the knee

or the foot dorsally meets with resistance. Yet if slow effort is made, flexion may generally be accomplished, the leg, while undisturbed, remaining in the position assumed, whence the graphic term of Weir Mitchell "lead-pipe contraction." If the thigh be placed over the edge of the bed, the traction of the leg on the quadriceps extensor may be sufficient to excite vigorous extensor tetanus and a convulsive tremor of the whole leg, like that of ankle clonus. If the patient is examined in a bath, the spasms are less violent because the effect of the weight of the legs is diminished. The superficial reflexes are also increased.

*Walking* is interfered with in two ways, first by the *stiffness* in the legs, and second by the *paresis*. The legs are only partially, if at all, flexed at the knee, and the foot is not raised, but is pushed along the floor in short, difficult steps. Owing to the contraction of the calf muscles the toes are brought to the ground, and thus the patient walks on his toes; sometimes an ankle clonus is developed by contact of the toes with the ground. The legs are kept close together, the knees touch, and in certain cases adductor spasm may cause cross-legged progression. Stiffness is not always so marked. The effect is the so-called *spastic gait*. In some cases there is no paresis, and the peculiarity of the gait depends purely on the muscular spasm. The effect is what Strümpell calls *pseudo-paresis*, or spastic pseudoparesis. The absence of actual paresis is shown by the fact that, notwithstanding the stiffness in the gait, the patient can still walk some distance, even miles.

With all this, the *patient is well nourished* and there is no wasting of muscles, which may even be hypertrophied, and outside of these symptoms he may enjoy excellent health. *Nor is there vesical disturbance*. There is no *sensory derangement*. Ocular symptoms are rare.

The tendency is to grow gradually worse, but very gradually; finally the patient cannot walk at all, nor can he stand. Rarely the muscles of the trunk and arms become involved, presenting also a paresis with decided increase in the tendon reflexes without disturbance of sensibility or muscular atrophy. Such is the picture of spastic palsy, rarely, perhaps, seen in an uncomplicated form.

**Diagnosis.**—As stated at the outset, there is absence of sensory and trophic disturbance. The onset may be sudden, but is never so in typical cases, with progressive loss of strength, but no emaciation. Spastic symptoms, with increased knee-jerk, appear, followed by gradually developing paresis. The arms are often affected, but less so than the legs, and may escape. The course of the disease is slow, and mental symptoms similar to those of dementia paralytica may be present at the close. It resembles amyotrophic lateral sclerosis, but it differs in the absence of muscular atrophy.

Hysterical spastic paraplegia may furnish in the most striking manner the symptoms detailed. Every symptom to be mentioned may repeat itself more or less identically. It is, therefore, not necessary to name them. Moderate wasting is sometimes added. It occurs more commonly in women, and usually careful examination will reveal some distinct stigmata of hysteria.

**Prognosis.**—Spastic paraplegia of all forms except the hysterical

is of long duration with little prospect of recovery. The upper extremities are tolerably free from derangement, and the mind is usually clear. Hysterical spastic paraplegia may end in recovery, if properly managed. When the cause is transient, also, recovery may be expected with removal of pressure, as in caries.

**Treatment.**—If *caries* is present, mechanical measures should be used to remove pressure. If *syphilis* is suspected, treatment by *iodids* and *mercurials* should be persevered in. Mercurial inunction is the most ready way of bringing about mercurialism. *Galvanism* and *faradization* are less useful in spastic conditions of the muscle than in those in which nutritional changes are more decided, but in hysterical spastic disease they are of signal use for their moral effect. The electrical brush is here the most useful instrument. It should be associated with *massage* and *passive motion*, and early attempt at locomotion should be encouraged and a positively favorable prognosis made. These, at least, tend to defer the immovable stage.

In any case friction, massage, and forcible flexion may be of benefit, but should be used cautiously, as the irritation produced in this way may possibly hasten premature contracture. Hydrotherapy is commended. The effect of the prolonged warm bath at 90° to 95° F. (30.2° to 35° C.) is often an amelioration of the spastic symptoms. The bath should be kept up for half an hour and manipulation practiced during it.

## TABES DORSALIS.

SYNONYMS.—*Posterior Spinal Sclerosis; Duchenne's Disease; Locomotor Ataxia.*

**Definition.**—A disease especially characterized clinically by loss of co-ordinating power, and by sensory and trophic symptoms; anatomically it is pre-eminently a disease of the posterior spinal roots and posterior columns of the cord, although the cerebrum does not always escape, and the optic nerves are commonly affected.

**Historical.**—Inco-ordination of movement in cases of spinal cord disease was noticed in the first third of the last century, but the cases in which it was present were not separated from those with loss of power. The association of this distinctive symptom with disease of the posterior columns was first announced by Stanley in 1840, and the first accurate account of the disease was published by R. Bentley Todd in 1847. He distinguished inco-ordination without weakness from paraplegia, inferred involvement of the posterior columns, and confirmed his inference by autopsy. In 1851 Romberg described the disease and the lesion in the posterior columns, but failed to eliminate loss of power from the symptoms. In 1855 Russel Reynolds accurately described the symptoms and ascribed ataxia to muscular anesthesia, giving thus the first correct explanation of this symptom. Türck first recognized with the microscope the wasting of the fibers in the posterior columns of the cord. In 1858-59 Duchenne, without adding anything essential to the symptomatology or pathology of the disease, published a monograph which so attracted attention that the disease has come to be called by his name, although, as Gowers correctly says, if the name of any man should be associated with tabes dorsalis, it is that of Todd.

**Etiology.**—The etiology of tabes dorsalis is not a satisfactory chapter. The disease is more common in cities, affects ten men to one woman, is rare in the negro, and is pre-eminently a disease of middle life, about

one-half the cases beginning between 30 and 40, one-fourth between 40 and 50, and less than one-fourth between 20 and 30. It has been met as late as 66, and occasionally before the age of 20. Direct inheritance, independent of inherited syphilis, is unknown.

Of the direct causes, syphilis is believed to be the most frequent. From 50 to 90 per cent. of cases have been ascribed to it by different authors, Erb and Strümpell leading with the latter figure. Möbius even believes that all cases of tabes are due to syphilis, a view which Mott shares. Yet there are difficulties in tracing the relation growing out of the facts, first, that the pathological product is not anatomically a syphilitic one, and,

FIG. 108.—Lumbar Region. *g g*, degenerated posterior roots. *h h*, normal anterior roots. *f f*, degenerated posterior columns. *e e*, ventral fields of the posterior columns intact—(after Spiller).

second, that it does not respond to the treatment of syphilis. A reasonable explanation of these difficulties is one which ascribes tabes to a toxin analogous to that of the paralysis which follows diphtheria, acting especially on the centripetal sensory fibers. Indeed it may well be questioned whether tabes ever occurs without previous syphilitic infection.

Prolonged exposure to cold and wet, such as belongs to certain occupations, as lumbering, has been an admitted cause, but simple over-exertion, physical and mental, especially sexual excesses formerly held responsible, are probably not causes. Alcoholism is also held responsible less commonly than formerly. On the other hand, Tuczek, has shown that in chronic ergot poisoning symptoms like those of tabes develop, and with them a lesion appears in the posterior columns of the cord.

Traumatism affecting the spine has been believed to be a cause in a few instances, but this relation has not been established.

**Morbid Anatomy.**—*Tabes dorsalis* is pre-eminently a disease of the posterior spinal roots and posterior columns, although the cerebrum does not always escape, and the optic nerves are usually affected.

Directing our attention to the spinal cord, in which are found the most manifest changes, we find that, at times, even when inclosed in the membranes, its smallness and thinness are noticeable, while through the pia we may see the *posterior columns* distinctly as a gray band throughout the length of the cord. The pia is, however, commonly thickened and opaque, especially on the posterior surface, sometimes more firmly adherent than is natural, while the blood-vessels also show signs of arterial sclerosis. The

FIG. 100.—Thoracic Region. *d d*, degenerated posterior roots. *c c*, degenerated posterior columns. *b b*, degenerated columns of Clarke. *a*, small group of normal fibers from one or more posterior roots, lower in the cord, which were not entirely degenerated. *e*, normal anterior root—(after Spiller).

contraction of the posterior columns is more conspicuous on section. These columns are flattened instead of convex, while the gray translucent appearance of the posterior column is also evident, being due to the fact that the nerve-fibers have been substituted by neuroglia tissue. Hence, also, the name "gray degeneration." In the cord hardened in Müller's fluid the difference in hue is even more striking than in the fresh state. The posterior cornua and the posterior nerve-roots are small and gray.

On minute examination, in transverse sections stained by carmine or other staining fluid, the affected areas are more conspicuous, because of the deeper staining of the sclerosed tissue, while all parts of the posterior columns are not equally affected. In the *lumbar cord*, which, with the lower thoracic region, is usually the most frequently and seriously involved, the change affects chiefly the middle and posterior parts of the columns,

while the extreme anterior portion, the so-called ventral fields, remains intact. The sclerosis is commonly most intense in the part adjacent to the posterior cornua, into which the posterior roots enter, also near the surface of the cord. Ascending into the *thoracic cord*, the intensity of the disease in many cases gradually diminishes in the external parts of the posterior columns, and increases in their median portions. It presents in this way the distribution of an ascending degeneration, which in fact it is, receding from the commissure in the upper cervical region.

In the *cervical cord* the columns of Goll are chiefly affected, sometimes with the fibers in the root zones—that is, those portions of the columns of Burdach in which fibers enter directly from the posterior nerve-roots,

FIG. 110.—Cervical Region. The degeneration of the posterior columns is now nearly limited to the columns of Goll, *e e*. *b*, normal fibers from roots lower in the cord. Figures were not entirely degenerated—(after Spiller).

Figures 105, 106 and 107, from an advanced case of tabes.

and from which fibers may be traced further into the gray matter of the posterior cornua; but two anterolateral areas in the columns of Burdach remain free from disease, at least for a long time.

Fig. 111 shows how the beginnings of the disease are localized in the posterior columns. It is in consequence of involvement of the *posterior roots* that the corresponding posterior cornua into which they enter are also affected. The same is true of the medullated *fibers of Clarke's columns* (Fig. 109), which are also direct processes of the posterior roots, while the cells of the columns remain normal. Lissauer's tract, a narrow strip at the periphery of the posterior cornu, is early involved.

In advanced cases, in the *larger peripheral nerve trunks*, such as the sciatic, and in the finer branches of the sensory nerves, many degenerated fibers can be recognized. Some of these atrophies may be secondary, but modern clinicians are disposed to regard the peripheral degenerations of tabes as independent and primary, especially since, in addition to these,

decided degenerative processes sometimes occur in the trunks of certain cranial nerves, such as the optic and oculomotor, and more rarely the vagus and auditory. They will be referred to in treating the diseases of special nerves.

Finally, there are even *cerebral changes* of various kinds. While the spinal ganglia on the posterior roots have been found invaded in a few cases only, it is the disposition of some observers to place the initial changes of the morbid process constituting tabes dorsalis in these ganglia, and

FIG. 111.—Lumbar Region. *h h*, posteromedian root zones (Flechsig) only slightly degenerated. *i*, middle root zones (Flechsig) degenerated. *g*, normal ventral fields. This section represents the earlier lesions of tabes.  
Figure 111 should be compared with Figure 108—(after Spiller).

thence the fibers ascending into the posterior columns. Thus considered, tabes dorsalis would be a general disorder of the central and peripheral nervous system, but limited mainly to sensory tracts, though motor ganglia and nerves do not altogether escape.

Other investigators place the primary lesion at the point where the roots penetrate the dura; and still others at the place where the posterior roots pass through the pia to enter the posterior columns of the cord.

**Symptoms.**—The characteristic symptoms of tabes are easily divisible into three sets: *motor*, *sensory*, and *reflex*. In addition to these there are others not essential, but striking, including modifications of *special*

sense and certain *visceral symptoms* characterized by pain and known as "crises." The special sense modifications include especially that of vision, while of "crises" the gastric is most striking.

The *motor phenomena* are usually the most prominent, whence the disease takes the name of locomotor ataxia, but this symptom may be absent for years, and hence the inappropriateness of the term. The distinctive symptom is a *loss of co-ordinating power* in the legs, having its simplest illustration in the unsteady gait of a drunken man. It is intensified when the patient attempts to walk with his eyes closed, and, indeed, in its early development does not appear except when the eyes are closed. It is usually *unaccompanied by a loss of power or muscular wasting*, but the latter may be extreme. On the other hand, *inco-ordination is by no means always the earliest symptom* and it may, indeed, never be developed, while there is usually a preataxic stage in most cases of tabes. The inco-ordination may be shown sometimes, before otherwise evident, by directing the patient to place the heels and toes together and then to close the eyes, when a swaying appears, as though the patient were going to fall—*Romberg's symptom* or "tabetic swaying." In health a slight unsteadiness under these circumstances is present which varies in different persons. Higher degrees develop the "sway" even when the eyes are open. The symptoms often exist for a long time before being recognized by the patient. Soon the peculiar gait is noticeable. The foot is thrust forward too far, and brought down suddenly, with the heel first on the ground, with a stamp. This is the typical tabetic or "heel" gait. The patient cannot walk in a straight line, and the staggering becomes worse when the eyes are closed, because the power of orientation through vision is lost. The movements of the lower limbs are excessive and unnecessary. Ultimately, he can walk only with the aid of a cane or by keeping the eyes fixed upon the floor. He rises from the sitting posture with difficulty, often after three or four efforts. The loss of co-ordinating power may also be shown in the recumbent posture when the patient attempts to touch the knee with his heel, when he will carry it around and in front and behind without accomplishing his purpose. The ataxic gait is not confined to tabes, but may occur in disseminated sclerosis and cerebellar disease. In the latter closure of the eyes may not increase the ataxia of the gait.

A peculiar symptom called by Fränkel *hypotonia* is noted in this stage or earlier, viz., a peculiar muscular relaxation which permits the joints to be placed in a condition of hyperextension and hyperflexion which may give an appearance of backward curve to the lower limb. Sexual power diminishes or disappears with the development of ataxic symptoms.

*Inco-ordination* also develops in the hands, but much more rarely, and late in the disease, though it may appear in them first. It is shown in connection with more delicate acts, such as picking up a pin, buttoning, and writing. It may be demonstrated also by asking the patient to bring the ends of two of his fingers together with his eyes closed, or to touch the end of his nose with one, which he may not be able to do.

<sup>1</sup> This symptom is classed by Strümpell among those of impaired sensibility in the soles of the feet and the muscles, whence follows defective control of muscular movements necessary to equilibrium.

With all this ataxia the *muscular power remains intact*. The patient lying in bed can kick out with great force, and resist successfully any effort to flex the extended leg, while the grip of the hand is strong.

J. H. W. Rhein<sup>1</sup> reports a case of locomotor ataxia with a tremor resembling that of paralysis agitans which he regards as possibly one of tabes associated with paralysis agitans.

The *sensory symptoms* are less distinctive, especially at first. The most frequent of these—indeed, among the most frequent of all symptoms—are *pains* of a darting, shooting, or stabbing character, whence they are called *lightning-pains*. They are said to occur in nine-tenths of all cases. They resemble closely those of neuralgia, lasting but a second or two. They are most common in the legs, and are often accompanied by burning or tingling, especially in the feet. They may be felt in the trunk, arms, and even in the head. Commonly they do not correspond with nerves or affect joints. They are often considered by the patient as rheumatic pains. A *sensation of cold* is felt, also a feeling as though the limb were immersed in cold water. The pains are induced by fatigue or excesses or by temporary ill health from other causes, and are likely to come on at night. They may last hours or a day or two. There may be areas of *hyperesthesia* and *anesthesia*. A very curious sensation is felt in the soles of the feet when walking, a feeling as though *soft carpet or cotton were interposed* between them and the floor. A painful sense of constriction about the limb or waist or around the entire trunk—*girdle pain*—is regarded as characteristic.

There are other disturbances of sensation, such as retardation of tactile, and more especially of pain sensation, wherein the prick of a pin, instead of being instantaneously felt, is *delayed* for several seconds. Another sensory symptom is difficulty in localization, manifested, for example, in referring a pin-prick to the right foot when it is made in the left—*allochiria*—or it may be felt in both feet—*polyesthesia*. In advanced stages the *muscular sense* is also impaired, and the patient is unable to indicate correctly the position of a limb. There may be other perversions of sensibility. The sense of pain may be lost or perverted; also the temperature sense—that, too, without derangement of the pain-sense or common sensibility. All varieties of sensation may be lost in the most diverse parts of the body and most irregularly.

*Viscera' pains*, known as tabetic crises, among which the gastric is the most common, are also among the sensory phenomena. They may be laryngeal, rectal, nephritic, urethral, etc., and are sometimes exceedingly severe. The gastric crises are sometimes accompanied by vomiting of strongly acid gastric secretion. On the other hand, the vomited matters may be alkaline, the result of a reflux of the intestinal contents into the stomach. Nor are gastric crises limited to tabes. They may occur in other cerebrospinal disease, including general paralysis, *sclerose en plaques*, and subacute or chronic central myelitis. The laryngeal crises may be associated with spasm and dyspnea, with noisy breathing. Death is a possible termination from this cause. Rectal crises consist

<sup>1</sup> Rhein, J. H. W.: "A case of Locomotor Ataxia with a Tremor resembling that of Paralysis Agitans." Sec. on Nervous and Mental Diseases of Amer. Med. Assoc., at 55th Annual Session, June, 1904.

in paroxysmal pain and tenesmus, with a sensation as of a foreign body in the rectum.

The *reflex symptoms* consist in *impairment in reflexes* both tendon and cutaneous. The loss of the knee-jerk is one of the most frequent and early of these, occurring sometimes years before ataxia appears. Of itself it is not diagnostic, as it may be absent in healthy persons, but in association with lightning pains and ocular symptoms it is almost conclusive evidence of the disease. In by far the greater number of tabetics—at least 70 per cent.—the patellar reflex is wanting, with or without the Argyll Robertson pupil. The skin reflexes fail *pari passu* with the loss of tactile sensibility, and it is doubtful whether they are ever present without this. The plantar skin reflex is that most frequently impaired, and after this are successively involved the gluteal, cremasteric, and abdominal. It happens rarely that in the early stages of the disease the skin reflex is increased, sometimes, considerably, but even then the knee-jerk is absent or diminished.

Of the remaining symptoms the *ocular* are the most important. They include *ptosis* of one or both eyelids, producing a very striking appearance. It may be unaccompanied or associated with *external strabismus* and *double vision*. Rarely there may be paralysis of all the external muscles of the eye, producing *ophthalmoplegia externa*. The most remarkable eye symptom is, however, the *Argyll Robertson pupil*, in which there is loss of reflex contraction of the iris in response to light, while the contraction in accommodation and convergence remains. According to Gowers, the loss of this reflex occurs in five-sixths of all cases. The contraction in accommodation is, however, not always maintained. Very rarely the reverse of the Argyll Robertson pupil exists. Wendell Reber has made a clinical study of the correlation between the iris and patellar tendon reflexes, and finds that in non-specific cases of tabes they are both involved in 70 per cent., and in the specific cases in 77 per cent. He holds that the co-involvement of these distant reflexes is evidence in favor of the view held by Sachs, Trevelyan, and Hirt, that tabes is a secondary degenerative process in which the entire nervous system takes part, and of Nageotte that the three separate clinical pictures of general paresis, tabes, and cerebrospinal syphilis are only the result of the preponderance of the inflammatory process in different localities, the nature of the process being essentially the same, the initial change being vascular starvation.<sup>1</sup> Often the dilatation of the pupil which takes place in health when the skin of the neck is pinched cannot be produced and coincident with this is often unnatural smallness of the pupil—spinal myosis.

Finally, there is sometimes *atrophy of the optic nerve, producing the amaurotic form*. When it occurs, it is often an early symptom, usually commencing before inco-ordination; and, what is more singular, the ataxia often does not supervene—that is, there seems to be a tendency for the spinal malady to become stationary when the optic nerve is affected early. The failure of vision usually begins with peripheral limitation and pro-

<sup>1</sup> Reber's paper, published in the "Annals of Ophthalmology and Otology," vol. v., No. 3, July, 1896, showed that in *nonspecific cases* the patellar reflex alone was involved in 23 per cent., the iris alone in 77 per cent.; in *specific cases*, the patellar reflex alone in seven per cent., and iris alone in 16 per cent. It must be recognized that often much uncertainty exists in obtaining a history of syphilitic infection.

gresses slowly to total blindness, sometimes to a considerable extent before the patient notices it. Occasionally it ceases, and there may even be slight impairment.

*Deafness* may be present from disease of the auditory nerve; also, more rarely, *anosmia*, from atrophy of the olfactory nerve. Attacks of *vertigo* occur in some cases. Abnormalities in function of other cranial nerves may be due to similar involvement. Among these may be mentioned pain at one time and anesthesia at another in the area of the fifth nerve; also unilateral atrophy of the tongue.

There may be *delayed micturition* from weakness of the detrusor muscle of the bladder, or *incontinence* from paralysis of its sphincter, with partial evacuation of the bladder, and resulting cystitis. The anal sphincter is less frequently affected.

*Vasomotor and trophic phenomena* also occur, and may be predominating symptoms. They include local sweating of the palms and soles, or of half the head, edema, skin ecchymoses, herpes, and modified hair growth, loss of pigment from hair and skin, thickening of the epidermis of the sole, succeeded by blisters under it. Alteration in the nails, and onychia with ulceration, may be present; also decay of the teeth and the so-called *perforating ulcer of the foot*, which is almost peculiar to this disease. Only late in the disease may atrophy of muscles, sometimes associated with neuritis or involvement of the anterior cornua, occur. *Paroxysmal diarrhoea* occurs, and has been regarded as vasomotor in origin.

The so-called *arthropathies* are an interesting trophic symptom and are directly the result of the disease. The most common is that known as Charcot's joint, anatomically similar to chronic affections in which the disease begins in the bone as contrasted with the synovial membrane, resulting in atrophy and in the destruction of bone and cartilage, while brittleness of bones, attended with spontaneous fracture or luxation, may occur. If union takes place, there is a superabundance of callus, with ossification or calcification of adjacent structures and of any newly formed inflammatory tissue. The large joints are those commonly affected and are painless when the seat of arthropathy. There may be effusion and even pus in the joints, but pus is not likely to form unless the joint has been injured. The arthropathies may occur in the preataxic stage. They may be excited by injury. The joints may also become greatly relaxed, while changes in the tarsal bones and articulations may cause the foot to become flat, with projection backward or inward of the tarsometatarsal articulations and of the tarsal bones, producing the "tabetic club-foot."

*Cerebral symptoms* also occur, but are rare, and may resemble those of *dementia paralytica*. It is not always easy to decide whether the dementia or the tabes is primary. The final stage of the disease, in which the patient is bed-ridden, is known as the *paralytic stage*.

**Diagnosis.**—The diagnosis, commonly easy when the characteristic symptoms are developed, may demand critical judgment in the early stage. The combined presence of lightning pains, absence of knee-jerk, early ocular palsies, including the Argyll Robertson pupil, ptosis or squint, and ataxia are conclusive. Lightning pains and ocular palsies should

always stimulate to thorough examination. The same is true of severe attacks of gastralgia in middle-aged men.

*Differential Diagnosis.*—*Disease of the vertebral column* with resulting compression of the spinal nerves is also associated with lancinating pain and absence of the patellar reflex, but the later symptoms are widely different. The same is true of deep-seated tumors impinging on the spinal cord.

Peripheral *alcoholic neuritis* and *arsenical neuritis* also may be associated with diminished knee-jerk, a pseudotabetic gait, and sharp pains, but the gait differs from the true tabetic gait, the leg being lifted high in order that the *toes* may clear the floor. The pain also follows the course of the nerves, which are tender on pressure, and there is none of the shooting character. Nor is there reflex immobility of the pupils, and seldom bladder disturbance. *Multiple sclerosis* in rare instances presents similar symptoms, but defective speech, nystagmus, mental weakness, and ultimate apoplectiform seizures serve to distinguish it, and the tendon reflexes are usually exaggerated. In *diphtheritic palsy* there is absence of knee-jerk, but the history of the case, the throat palsy, and all absence of pain are distinctive. *Ataxic paraplegia* also displays ataxia, but here symptoms of implication of the pyramidal tracts are present. In *cerebellar disease* there is also loss of co-ordination, and the knee-jerk may be absent, there may be headache, optic neuritis, and vomiting, but no lightning pains or sensory disturbance. Occasionally neuritis may present a clinical picture closely resembling tabes, known as peripheral pseudotabes. The rapidity of development, the absence of the Argyll Robertson sign, and of implication of the bladder, and in some cases recovery, are the most important differential features.

*General paresis* and *tabes* sometimes merge, the latter developing on the former, or the former on the latter toward the end. Rapidly developed ataxia with mental symptoms often resolves itself into general paresis. Yet acute involvement of the posterior columns may be possible, producing ataxia.

Finally, there is the *nicotin* tabes of Strümpell, who has twice met, in men long working in tobacco factories, a set of symptoms consisting in painful sensation, absence of patellar reflex, contracted pupil, with reflex immobility and uncertain gait, differing, however, from tabes in the presence of tremor and marked increase in the skin reflexes, especially in the lower extremities.

*Course and Prognosis.*—It is generally conceded that no case of thoroughly developed tabes has ever recovered. The disease may, however, be arrested. This happens especially if optic nerve atrophy has set in early, after which ataxia rarely develops further, while the other symptoms subside. In most cases of the disease, however, the advance is slow but irresistible. The duration of the first stage, characterized by absence of knee-jerk, and by the presence of the Argyll Robertson pupil and of lancinating pains, lasts from a few months to 20 years, or longer. The second stage—that of ataxia—from which, indeed, the patient often dates the disease if the initial symptoms were slight, may then supervene gradually or suddenly. Finally, the paralytic stage supervenes, to be

soon followed by death. Tabes is believed by many to assume a milder type more commonly now than was the case 20 or 25 years ago.

**Treatment.**—While recovery from tabes dorsalis probably never occurs, much may be accomplished by treatment in arresting progress and relieving symptoms. There is no specific treatment, although this effect has been claimed for more than one remedy. *Nitrate of silver*, first recommended by Wunderlich, has probably had most reputation, but has latterly fallen into disuse, and coincidentally the number of cases of chronic argyria has diminished. The dose administered is from  $1/6$  to  $1/4$  grain (0.011 to 0.0165 gm.) three times a day. A proper question is as to the length of time the remedy may be used without danger of producing this unfortunate result. Professor E. Harnock asserts that in no recorded case of argyria were less than 450 grains (30 gm.) of the salt taken before the discoloration appeared. To consume this much in  $1/4$  grain (0.0165 gm.) doses three times a day would take 600 days. If, therefore, it is given in the usual doses for a month and then suspended for one week, as commonly directed, it does not seem possible that unpleasant effect can result. In this manner, then, it may be kept up indefinitely; or it may be alternated with *arsenic*, of which last Gowers at least says that it does distinct good more frequently than any other remedy. The favorite preparation in this country is Fowler's solution, of which 5 minims (0.3 c.c.) are given three times a day for an adult. The edema beneath the eyes, which results from its accumulated effect, is a sign that the dose should be reduced or the drug temporarily suspended. Arsenious acid in doses of from  $1/30$  to  $1/20$  grain (0.0022 to 0.0033 gm.) or sodium arsenite in doses of from  $1/30$  to  $1/10$  grain (0.002 to 0.006 gm.) may be substituted. Sometimes a smaller dose only is borne. Gowers has also found the *chlorid of aluminium* useful in doses of from 2 to 4 grains (0.132 to 0.264 gm.) three or four times a day. More recently it has been recommended in doses of 5 to 10 grains (0.33 to 0.66 gm.) three or four times a day.

The supposed frequent causal relation between syphilis and tabes renders the antisyphilitic treatment appropriate in all cases in which such relation can be traced. To this end *mercurials* are to be administered until the specific effect is produced. This is best accomplished by inunction, a dram to a dram and a half being rubbed into different parts of the body daily, to be discontinued when the gums are affected. After this the *bichlorid* may be given in doses of  $1/24$  grain (0.0027 gm.) three times a day, in association with the *iodid of potassium* in ascending doses if well borne, or the *biniodid of mercury* may be given in doses of  $1/24$  grain (0.027 gm.) three times a day. If this treatment is found effectual, the iodid should be continued in the minimum doses, which will keep up the effect. The antisyphilitic treatment is more successful in those cases in which cerebrospinal syphilis simulates tabes. It may be harmful in true tabes. *Calabar bean* in doses of from  $1/10$  to  $1/5$  grain (0.0064 to 0.0128 gm.) three times a day and the fluid extract of ergot in doses of from 5 to 30 minims (0.3 to 1.6 c.c.) or more are recommended, but the results have not been such as to give them a permanent reputation. Iodid of potassium may be tried apart from the indications

of syphilis. The rest *treatment*, originally suggested by Weir Mitchell, has been found useful in arresting the disease, but I do not know that it has been followed by permanent results. *Extension of the spinal column* and presumably of the cord by suspension of the body for from one to three minutes daily was used for a time, among others by Mitchell, but it has been discontinued, perhaps too soon, for instances of undoubted improvement have been reported under its use: *vide* one reported by Charles S. Potts in the "University Medical Magazine" for September, 1891, and several by De Forest Willard and Guy Hinsdale in the "Medical News," November 24, 1894.

In Germany *electricity* is still a popular remedy, and failure with it in this country may be due to imperfect and too brief trial. Erb's directions for galvanism are to place a moderate-sized anode in the vicinity of the sympathetic in the neck, and a large kathode on the side of the vertebral column for four or five minutes, moving it at intervals from above downward. Severe pain and vesical weakness are treated by galvanization and the faradic brush. The latter, as recommended by Rumpf, should be brushed over the skin of the back and extremities for five or ten minutes, using a strong current. Counterirritation by blisters is of no use, although simple rubefacients may relieve slight degrees of pain.

*Hydrotherapy* likewise maintains its popularity in Germany, although claimed by some authorities to be sometimes harmful, especially in the shape of hot baths and vapor baths and wet packs. The *tepid bath* is entirely safe and often symptomatically useful. Its temperature should be from 80° to 90° F. (26.6° to 32.1° C.), accompanied by gentle rubbing. *Wet compresses* upon the abdomen or legs at night sometimes relieve the pains. In Germany, too, there are numerous water-cure establishments in the hands of experienced directors, to which patients may be advantageously sent, but, unfortunately, there is nothing of the kind in this country which can be recommended. Oeynhausien-Rehme in Minden has the best reputation for its carbonic acid thermal salt baths, but the baths at Nauheim in Hess are similar. Mud and iron baths are found at Pymont, near Brunswick; Driburg, in Westphalia, Prussia; Elster, pleasantly situated in Saxony; Karlsbad, Marienbad, and Frazenbad, in Bohemia.

The *painful attacks* are often not relieved by the measures thus far suggested, and require more powerful treatment. The first to be used should be *phenacotin*, *acetanilid*, *exalgin*, *salophin*, *aspirin*, and *antipyrin*, while *morphin* should be deferred as long as possible. It may, however, be necessary, when it should be used hypodermically. *Cocain* used in the same manner in doses of from 1/6 to 1/4 grain (0.011 to 0.165 gm.) is also sometimes efficient, while *cannabis indica* in doses of 1/4 to 1/2 grain (0.0165 to 0.033 gm.) of the extract may also be tried. Bandaging with a broad flannel bandage from toes to thighs has been recommended for the sciatic pain and pressure for the relief of painful spots. Massive doses of strychnin have been suggested for the same purpose.

*Fatigue* of all kinds as well as anxiety of mind should be *avoided*, while moderate exercise may be encouraged. The bladder should be emptied at regular intervals even though there may be no desire for micturition. Vesical anesthesia may lead to retension. Excessive use of

the eyes should be avoided, as reading by a poor light or in a railroad train. Excesses in smoking, and especially in the use of alcohol, are harmful, as is also too frequent sexual indulgence. Overeating and the use of indigestible articles of food should be avoided, as gastric crises are invited by them. Excessive use of iodid may produce pseudo-crisis.

Great benefit has been obtained by the Fränkel movements. They are "based upon the education of the central nervous system by means of repeated exercises, whereby it is enabled to receive sufficiently distant stimuli from the limbs as to their position and so on, although the available quantity of sensation is rather small. It is necessary, of course, that the movements be attempted and carried out repeatedly and with great attention." They are too complex to be repeated here, and the student is referred to Fränkel's book.<sup>1</sup>

### HEREDITARY ATAXIA.

SYNONYMS.—*Hereditary Ataxic Paraplegia; Friedreich's Disease.*

**Definition.**—A disease whose clinical features are especially ataxia and paraplegia, occurring in families and at an age much earlier than ordinary tabes, from which it differs also in the addition of peculiar symptoms associated anatomically with lesions in the posterior and lateral columns.

**Historical.**—Friedreich reported in 1861, six cases of this disease and a further number in 1870, whence the association of his name with it, but as the name Friedreich's disease is also applied to *paramyoclonus multiplex*, confusion results. On the other hand, the term hereditary ataxia is scarcely correct, because while sometimes it is hereditary and even congenital, it is not always so. It usually occurs in families, several brothers and sisters being, as a rule, affected. Yet isolated cases occur. In one case of William Osler's three generations were involved. A neurotic tendency is sometimes noticed. Alcoholism and syphilis were present in parents in a few instances, consanguinity of parents in a very few only.

**Etiology.**—Its etiology is unknown. It is more common in males than in females, affecting 86 males and 57 females out of 143 cases collected by J. P. C. Griffith. Strümpell makes the opposite statement as to sexes, but other observers agree with Griffith. Of Griffith's cases, 15 occurred before the age of two, 39 before the age of six, 45 between six and ten, 20 between 11 and 15, 18 between 16 and 20, and six between 20 and 24. Cases have followed the acute infectious diseases.

**Morbid Anatomy.**—The whole cord is smaller than in health. There is a decided degeneration of the posterior and lateral columns, and the degeneration in the posterior columns may extend throughout the cord, involving the whole of Goll's column and nearly all of Burdach's, leaving a narrow band of normal tissue near the posterior cornua. Different opinions are held in regard to the condition of the posterior roots. The degeneration of the lateral columns involves the area of the crossed pyramidal tracts, the direct cerebellar and Gowers' tracts as well as the column of Clarke with degeneration of its ganglion cells. As yet no changes

<sup>1</sup> "The Treatment of Tabetic Ataxia by means of Systematic Exercise," Freyberger's Translation, Philadelphia, 1902.

have been found in the cells of the posterior horns. The pia mater over the posterior column is sometimes thickened.

The disease seems to consist of a double morbid process, consisting in early degeneration of nerve elements, associated with a tendency to overgrowth of interstitial or neuroglia tissue. According to Dejerine and Letulle, it is a gliosis of the posterior and lateral columns, due possibly to defect in development.

**Symptoms.**—The essential symptoms are *ataxia with paraplegia*. Initial pains are rare. The ataxia is, however, peculiar. As in tabes, it begins in the legs, but it is swaying and irregular, more like that of drunkenness, more like cerebellar inco-ordination. The feet are not often raised too high, and while there is stamping, as in true tabes, it is less marked. Tabetic swaying may or may not be present. If present it is not increased when the eyes are closed. Ataxia is present in the reclining position.

The ataxia of the arms occurs early and is striking, the movements being choreiform, jerky, irregular, and swaying. The hand first moves an object in its efforts to secure it and then pounces upon it. There seems to be a superabundance of effort in voluntary movements, action is overdone, and prehension is claw-like. Again, the fingers may be spread out or overextended. The first manifestation of the disease in children is often a tendency to fall.

As the disease advances, irregular, *jerky movements* affect the head and shoulders, sometimes tremor-like. In most cases there is *nystagmus* when the eyes are moved laterally or upward, usually a late, sometimes an early, symptom. *Atrophy of the optic nerve* is rare, and the pupils are normal. *Speech* is sometimes impaired, generally as a late symptom—three, five or ten years after the initial symptoms. Syllables are elided—the speech is *scanning*—with occasional movements of the tongue, but no twitching of the lips.

The *paresis* is at first slight—indeed, the power of the muscles is at first unimpaired—while there is rarely ever total paralysis. Some patients, however, never walk. The nutrition of the muscles is good. The *knee-jerk generally disappears early*, or is at least absent when the cases come under observation. In a few this symptom appears late, while in some atypical cases this reflex has been reported increased. *Sensory symptoms are not usually conspicuous*. There may be none, even in bad cases. At times there is delayed sensation or impaired sensibility to pain and temperature. Increased sensitiveness may be present. *No visceral crises occur*.

While trophic lesions of the usual kind are rare, there occur peculiar *deformities*, especially of the feet. There is talipes equinus or equinovarus, and the patient walks on the outer edge of the foot. The *great toe* is overextended or dorsally flexed, and occasionally this is the first sign of the disease. There may be *lateral curvature of the spine*. The disease may last from 20 to 40 years.

**Diagnosis.**—This is not difficult, although sometimes the disease is confounded with *chorea*, with the hereditary form of which it has certain points in common. The ataxia in early life, the club-foot, overextended

great toe, spinal curvature, lost knee-jerks, nystagmus, and scanning speech form a complex of symptoms not found in any other disease.

It resembles *ataxic paraplegia* or combined lateral and posterior sclerosis in more than its symptomatology, but the increased knee-jerk, foot clonus, and spasms of the latter disease are wanting. In cases of combined sclerosis in which the knee-jerk is absent, the family history and youth of the subject can alone settle the question. The loss of iris reflex in children points to tabes, the result of inherited syphilis. *Disseminated sclerosis* presents inco-ordination, nystagmus, and defective articulation, but the knee-jerks are almost always exaggerated, and intention tremor is characteristic.

**Prognosis.**—This is invariably bad, so far as recovery is concerned, although the disease lasts many years.

**Treatment.**—There is no treatment except such as will overcome tendency to deformity. The remedies used in locomotor ataxia may be tried.

CEREBELLAR HEREDITARY ATAXIA has been described by Marie, Sanger-Brown, Klippel, and Durante. It starts after 20 years of age. There are ataxia, disordered speech, nystagmus, and heredity, but the knee-jerks are normal or exaggerated, there is Argyll Robertson pupil, optic nerve atrophy with limitation of the field of vision, while there is no scoliosis or club-foot. The opposite is true of hereditary ataxia. Many do not recognize the cerebellar hereditary ataxia as a distinct symptom-complex.

PROGRESSIVE INTERSTITIAL HYPERTROPHIC NEURITIS OF CHILDHOOD is also a family disease. The symptoms are a combination of those of tabes dorsalis with those of neurotic muscular atrophy (peroneal type of progressive atrophy). There are hypertrophy and hardening of peripheral nerves. It was first described by Dejerine and Sottas.

TOXIC SCLEROSIS, especially of the posterior and lateral columns, results from such diseases as pellagra, ergotism, and pernicious anemia.

## ATAXIC SPASTIC PARAPLEGIA OR COMBINED SCLEROSIS.

SYNONYMS.—*Progressive Spastic Paraplegia; Combined Lateral and Posterior Sclerosis.*

**Definition.**—A chronic disease of the spinal cord, characterized by symptoms which point to lesions of both lateral and posterior sclerosis, including, therefore, both spastic and ataxic features, the symptoms of one lesion being more or less modified by the other.

**Etiology.**—This is obscure. It is more common in males, is a disease of adult life in which overexertion, exposure, spinal traumatism, and sexual excess each have been antecedent events. Less frequently than tabes does it follow in the wake of the syphilitic taint. It is always associated with general paralysis of the insane. Heredity has been observed in one-tenth of the cases, and the neurotic constitution seems to favor it. It is probably most frequently associated with anemia.

**Morbid Anatomy.**—As the name suggests, lesions are found in both posterior and lateral columns. In the posterior columns they resemble those of uncomplicated tabes dorsalis, and are most intense in the cervical

and thoracic portions of the cord, variously distributed, sometimes equally, at others preponderating in one or the other. The changes in the posterior root zones are less pronounced than in true tabes. In the lateral columns the crossed pyramidal tracts and in the anterior columns the direct pyramidal tracts are chiefly involved, though the mixed zones of the lateral columns, the lateral limiting layers, and the direct cerebellar tracts may also be invaded. The gray matter and membranes remain intact. Most cases are not truly systemic but are examples of diffuse lesions with secondary degeneration. This is especially true of the cases due to anemia.

**Symptoms.**—The symptoms are slow in their development, though occasionally a more rapid course is pursued, the only modification in this being that occasionally months instead of years are sufficient to develop the distinctive features. Those of either lesion may predominate at first. More usually those of ataxia are the first to appear, including fatigue and even pain after comparatively slight exertion, unsteadiness of gait, increased with the eyes closed, though an associated stiffness, may prevent the typical gait of tabes. There is also more or less paresis.

Sensibility is also diminished in combined sclerosis, but less so than in pure tabes. There may be dull pain or numbness in the lower extremities and in the back or sacral region, but the lightning pains of tabes are rarely present; nor is the girdle sensation, while visceral crises very rarely occur. The Argyll Robertson pupil is, also, commonly absent, but nystagmus is not infrequent.

The most striking difference in the symptomatology of ataxic paraplegia, as contrasted with true tabes, is the presence of *exaggerated reflexes in the former*, including knee-jerk and ankle clonus. Simple tapping of the patella or the belly of the quadriceps extensor brings out the former. The upper extremities are also often involved, and the chief symptoms here are weakness, inco-ordination with exaggerated wrist- and elbow-jerks.

Electrical reactions are unaltered, at least in the early stages of the disease. With advance of the disease the features of a purely lateral sclerosis become very pronounced; those of tabes less so. Muscular paresis and rigidity become marked, and the patient is unable to leave his bed. There is no localized *atrophy* of the muscles, although general wasting is not uncommon in the late stages of the disease. Very rarely there may be atrophy of the optic nerve, the ocular muscles remaining intact. The sphincters of the bladder and rectum are sometimes involved; at others not, that of the bladder more frequently, producing difficult micturition. On the other hand, by rest and tonic treatment the spastic symptoms may be diminished, while ataxia remains unchanged. The mind remains normal.

**Diagnosis.**—This is usually easy, enough of the symptoms of each lesion being present to show the existence of a combined disorder. The *absence of co-ordination on the one hand and increase of knee-jerk on the other* are the two antipodal symptoms around which others of each lesion cluster. The presence of the Babinski reflex is regarded as distinctive of organic as distinguished from functional paraplegia. So it is in association with other signs indicative of organic disease. It is not, however, pathognomonic and may be found in pure functional conditions, as, for

example, uremia affecting the brain. Its presence, when of the typical type—*i. e.*, when the upward extension of the big toe, especially, is slow—strongly suggests organic disease of the central motor tracts.

Then, as to differential diagnosis, *myelitis* may present similar symptoms. On the other hand, *myelitis* is usually a disease of sudden development, characterized by a rapid increase of symptoms as contrasted with the slower course of the disease under consideration. *Friedreich's ataxia* resembles ataxic paraplegia closely in its pathology, but the exaggeration of the tendon reflexes and the spasticity are absent in the former. *Cerebellar tumor* may be mentioned with better reason as a disease which may be confounded, but in this headache, optic neuritis, and vomiting are peculiar, and while there is ataxic gait, it is the reel of a drunken man, and not the inco-ordination of tabes. So, too, there may be spastic symptoms in cerebellar disease, but they are less decided than in combined sclerosis. *Disseminated sclerosis* is a disease with which combined sclerosis may be confounded, and although it is the less pronounced forms of each which give rise to doubt, it is important to remember that the disseminated sclerosis has been found postmortem in cases which presented the clinical symptoms of spastic paraplegia during life. Whence it is not impossible that it may also present in its earlier stages symptoms of ataxic paraplegia.

**Prognosis.**—This is unfavorable as to recovery, but the disease is so slow in its development that death commonly results from intercurrent disease or from complications favored by the disease itself, such as disorders of the urinary organs, bed-sores, and septic complications. The disease may be arrested for a time.

**Treatment.**—The treatment is mainly symptomatic: warm baths and a warm climate for the spastic symptoms; massage and exercise for the ataxic symptoms. Electricity and spinal stimulants like strychnin are contra-indicated as calculated to increase the spastic symptoms, while bromids and belladonna may be of service in controlling these. If a specific history can be traced, the disease should be appropriately treated by iodids or mercurials, and when anemia is present the treatment should be directed to the improvement of this condition.

### SYRINGOMYELIA.

**Definition.**—A term applied to all cavities in the spinal cord, most of which are surrounded by an overgrowth of neuroglia.

**Etiology and Morbid Anatomy.**—The cavities are formed by defective closure of the central spinal canal or by the breaking down of residual embryonal tissue or of gliomatous tissue. The cavity of a syringomyelia is usually in the posterior part of the cord, extending toward the posterior cornua. It may prevail throughout the entire extent of the cord, but in most cases involves only the cervical or thoracic regions or more limited areas. The transverse section is oval or circular, but it may be fissure-like or quadrilateral, even irregular. On the other hand, a primary hemorrhage of traumatic origin, or even without trauma, may be the starting-point of a

syringomyelia, and it has been supposed that such a hemorrhage into the spinal cord, occurring at birth from difficult labor, may later in life cause the symptoms of syringomyelia. So, also, compression of the cord due to fracture or dislocation may furnish the condition which will result in cavity formation. The cavities may be multiple. The term hydromyelia, applied to the forms in which the cavity is merely the dilated central canal, is falling into disuse, and there is no real difference between this and the other varieties. It is probable that hydromyelia may change into syringomyelia.

**Symptoms.**—The milder degrees are without symptoms and are often overlooked. Symptoms usually make their appearance about the period of adolescence. They are mostly gradual in development, and are partly the result of the secondary processes of distention which derange natural function. The symptoms are influenced also by the situation of the cavity, which is found most frequently in the cervico-thoracic region, whence the arms and neck are correspondingly affected. They depend also on the greater involvement of the gray matter of the cord.

The essential symptoms are modified *sensibility*; chiefly to *pain, temperature*, and to a *less degree* simple touch; also muscular *atrophy*, the latter progressive in development; and *trophic disturbances*. The sensory symptoms are the earlier and more constant. The sense of tactile impression may be lost by involvement of its path, which, as has been said, is not precisely known after it enters the posterior roots, though it is probably, partly in the posterior columns. The comparative rarity of this involvement may be said to be due to the difficulty in destroying this path completely. Derangement of the sense of pain and thermal sense is probably due to implication of the central gray matter, since it is through it that these impressions probably radiate to the white conducting tracts of the opposite side. The extension of the process to the lateral columns probably explains the derangement of pain and thermal sensations, in portions of the body below the level of the cavity in the spinal cord. There may not only be a loss of thermal sense, but it may be reversed in that heat is felt as cold, and vice versa. So, also, subjective sensations are felt, including heat and cold, or, in their absence, pain, which may be neuralgic in character and irregular.

The muscular atrophy is the result of injury to the motor cells of the anterior cornua from compression or destruction of these cells. This cause's degeneration of the nerves and wasting of the muscles, and along with it is a lowered electrical irritability. There is also *muscular weakness*, involving the trunk muscles, and possibly to this is due the lateral curvature. If the legs are affected, it is generally from simple spastic paralysis from pressure on the pyramidal tracts, but sensory changes in the lower limbs occur. Great wasting of the legs indicates lumbar involvement, and the presence of ataxic symptoms points to involvement of the posterior columns. The remaining symptoms are not essential, but may be incidentally present from the action of the causes which usually produce them.

The *reflexes* may or may not be increased, and *myotatic irritability* may in rare cases be lost, while *tremor* of the limbs has been noticed in some cases.

*Trophic* symptoms are not rare in the parts affected by sensory loss. The skin may be glossy and thin, or thick and horny, while there may be

eczema, herpes, bullæ, and even ulceration and gangrene. The nails may become fissured and drop off. There may be deformity and absence of the end phalanges and lingual hemiatrophy. *Vasomotor* disturbances are more common, including coldness, lividity, or redness with swelling and heat. There may be sweating, brittleness of bone, and joint changes like those of tabes.

The area of the *cranial nerves* may be invaded when there is involvement of the medulla oblongata. The phenomena may include paralysis of one vocal cord, the tongue and face, difficulty in swallowing, of breathing, and embarrassed heart's action. The eyes may be disordered, and the pupils unequal, but the other special senses escape.

**Diagnosis.**—This is based upon the sensory symptoms, and of these thermo-anesthesia and analgesia rather than tactile insensibility, together with muscular atrophy succeeding after some interval. *Cervical pachymeningitis* causes like symptoms similarly distributed. J. Hendrie Lloyd, in an important paper,<sup>1</sup> has also called attention to certain traumatic affections of the cervical region of the cord simulating syringomyelia. Cervical pachymeningitis runs a more rapid course; the anesthesia includes all varieties of sensation and corresponds more nearly in its distribution to that of the muscular atrophy, pain is more conspicuous, and the reaction of degeneration is commonly present in the wasting muscles, and later, signs of compression of the cord are observed.

The symptoms of syringomyelia are sometimes simulated by the anesthesia and wasting of *anesthetic leprosy*, but in the latter disease the trophic changes are more marked, the phalanges often drop off, while the sensory symptoms include all varieties of sensation.

*Progressive muscular atrophy* differs in the absence of altered sensation. An intramedullary *spinal tumor* in the same situation as a syringomyelia furnishes almost identical symptoms, and may have an identical origin if it starts from the neuroglia, but the symptoms may be more rapid in their development.

The diagnosis of syringomyelia is sometimes exceedingly difficult to make, as the characteristic disturbances of sensation may be absent.

**Prognosis.**—This is ultimately fatal, although the course is slow, extending over a period from 15 to 20 years. Toward the end the course is more rapid, death resulting from exhaustion or interference with the functions of the medulla oblongata.

**Treatment.**—This can only consist in measures to combat symptoms and tendencies to them, such as cystitis, bed-sores, and the like.

#### MORVAN'S DISEASE.

**SYNONYMS.**—*Analgetic Panaritium; Analgesic Paresis with Panaritium; Painless Whitlows.*

**Definition.**—This term is applied to a chronic affection described in 1883 by a Breton physician named Morvan, which is characterized by neuralgic pains, tactile and thermal anesthesia, analgesia, and painless

<sup>1</sup> Read before the Philadelphia Neurological Society, March 26, 1894.

destructive felons (paronychia). The disease is probably in most cases the same as syringomyelia; in some instances it is leprosy. Twenty cases were recognized in a population of 50,000 in Brittany. One or two cases have been reported in America.

Zambuco, of Constantinople, found in the broken-down matter of the syringomyelic cavity of what seemed a typical case, Hansen's lepra bacillus. In two well-studied cases reported by Marinesco and Jeanselme to the Société Médicale des Hôpitaux de Paris, February 12, 1897, the typical lesions were found, but no bacilli.

## COMPRESSION OF THE SPINAL CORD.

SYNONYMS.—*Compression Myelitis; Pressure Paralysis of the Spinal Cord.*

**Definition.**—Under this head are included all forms of paralysis due to gradual compression of the cord from whatever cause.

**Etiology.**—A large number of causes may operate in the way indicated, among which are tumors or inflammatory new formations, including syphilitic products either in the membranes or outside of them, caries of the vertebræ, especially the form known as Pott's disease or tuberculosis of the vertebræ, cancer of the vertebræ, echinococci and cysticerci in the vertebral canal. Extraplural causes may also produce erosion of the vertebræ and compression of the cord; among these are aneurysm of the aorta, retroperitoneal sarcoma, lymphadenoid growths, and suppurating kidney; also retropharyngeal abscess. Pott's disease is by far the most frequent cause.

**Morbid Anatomy.**—The changes in the cord as the result of compression are best studied in the compressions due to dislocation of the vertebræ in the breaking down of the bodies of one or more from tuberculous infiltration, or as the result of intrusion into the spinal canal of foci of cheesy pus from the posterior surface of the bodies of the vertebræ. Macroscopically, the cord is often smaller, softer, and sometimes bent. In old cases it may be harder. The term myelitis has been applied to the changes thus produced in the cord, but careful examination fails in most cases to find any of the usual histological products of inflammation. In the early stages the axis-cylinders are swollen, and fatty granular cells may be present. The nerve-cells undergo more or less alteration depending on the degree of pressure. At a later stage may be seen a secondary overgrowth of neuroglia, replacing the destroyed nervous tissue, first loose, later firm and fibrillated. After a certain duration there may be ascending and descending secondary degeneration of certain systems of fibers in the spinal cord.

**Symptoms.**—When tuberculous disease of the spine is the cause, the resulting deformity—kyphosis—is usually seen long before the symptoms of compression of the cord are present. On the other hand, when the erosion is due to aneurysm or growths within the thorax or abdomen, the subjective symptoms appear before the deformity, or more frequently

without external deformity. The first of these symptoms is usually *pain* at the seat of the compression, which often does not amount to more than a dull ache, while at another time it is extremely severe. It is also aggravated by bending or straightening the body. Again, the pain is distributed along the course of the nerves, when the compression is exerted on the nerve-roots. Previous to such pain and associated with it are *paresthesias* of various kinds, such as numbness, tingling, and formication. More rarely there is *impaired sensibility*, the same degree of pressure which deranges the function of motor fibers having often no effect on the sensory. Marked anesthesia is rare, and then only in the last stages. When the lesion is confined to the thoracic region, there may be *girdle sensation* and *pain* in the course of the intercostal nerves.

With the foregoing soon become associated *motor symptoms*, which may consist in *stiffness*, giving rise to difficulty in moving arms or legs, with peculiarity of gait, or there may be simple weakness or *paresis*, increasing to complete motor *paralysis*. These symptoms rarely affect both arms or legs at once, but rather first one and then the other.

The seat of the more pronounced sensory and motor symptoms varies with the segment compressed. Thus, when the caries is in the *upper cervical region*, between the axis and the atlas, or between the latter and the occipital bone, there may be *spasm of the cervical muscles*, the head may be fixed, and movements may either be impossible or extremely painful. Retropharyngeal abscess may be the cause of such a symptom, as in a case in the Montreal General Hospital mentioned by Osler, where movement was liable to be followed by transient instantaneous paralysis of all four extremities from the compression of the cord, the patient dying in one of the attacks.

If in the *lower cervical region*, there may be *dilatation of the pupils* from interference with the ciliospinal center or nerve-fibers arising in this center. There may be *flushing* of the face and ear on one side or *unilateral sweating*, *rigidity of the muscles* of the neck, while the sensory and motor symptoms described, if present, will be found in the arms. The deformity of tuberculous caries is not always marked in this locality, but after recovery evidence of its presence may be found in a conspicuous *callus*, which may cause permanent rigidity of the neck. The cortical inhibitory influence being suspended, both tendon and cutaneous *reflexes* are increased, sometimes so markedly as to produce in the lower extremities a pronounced type of the spastic paralysis, with increased patellar reflex and ankle clonus. The increase of the skin reflexes is less marked than that of the tendons.

When the *thoracic* and *lumbar* segments are involved, only the *lower extremities* suffer from the effect of compression; commonly the paresis is late, though rarely it may appear before the deformity of Pott's disease. Girdle sensation and pain in the course of intercostal nerves were named above as sensory symptoms of compression of the dorsal cord. Here, as elsewhere, motion is affected before sensation. As to the reflexes, since the reflex arc for the lower tendon reflexes is in the lumbar region, compression of the *thoracic* cord should produce an increase in them, and this is usually the case. On the other hand, they are diminished

when the *lumbar* cord is compressed. If the lower thoracic and lumbosacral region is affected, the sphincters are apt to be involved, and there is, first, difficulty in micturition, then retention, and finally incontinence with cystitis, but the sphincters may also be involved from lesions higher in the cord. Yet all these symptoms may disappear, and recovery take place after many months' duration of the disease.

*Trophic symptoms* may be present in the paralyzed parts. These may include herpetic eruptions in the course of the nerves, at other times derangement of nutrition, manifested by bed-sores forming on slight irritative provocation, rapid shedding of the epidermis and brittleness of the nails. With the involvement of their trophic center the muscles may waste.

**Diagnosis.**—This is easy when there are evident signs of caries of the spine, manifested by prominence of spinous processes of the vertebræ and by tenderness on pressure. Repeated examination of the spine should be made. Nerve-root symptoms, or symptoms resulting from pressure of nerve-roots, as they pass out between the vertebræ, are always significant. They include radiating pains, girdle sensation, and hyperesthesia or anesthesia, spasm and wasting. Stiffness on motion in separate parts of the spinal column is also significant. Root symptoms are said to be more common in cancer than in caries, but any of the symptoms named have increased diagnostic value if there has been cancer elsewhere, especially of the breast, and if the age exceeds 40. There is much more pain attending the paraplegia of cancer—whence the term *paraplegia dolorosa*, when the pain is referred to areas anesthetic to tactile and painful impressions. Such is the case whenever erosion is wrought from the abdomen outward, as by retroperitoneal growths or aneurysm.

**Prognosis.**—This is unfavorable in all cases except tuberculous spondylitis, which often terminates in cure, for, sooner or later, especially with suitable treatment, the tuberculous process may cease and the symptoms of paralysis disappear, although, of course, the kyphosis remains. Some cases perish from miliary tuberculosis, others from the exhaustion incident to bed-sores, cystitis, and pyelonephritis.

**Treatment.**—Only when tuberculous spondylitis is responsible is there hope of cure. The treatment is general, by the usual measures found useful in tuberculosis, such as cod-liver oil and creasote or creasotol, with such tonics as iron and iodine, good food, fresh air, and mechanical appliances suggested by the orthopedic surgeon. These should be so adjusted as not to produce pain. Their object is to produce extension and thus relieve compression, and if this is not accomplished, they are useless. The method of extension by suspension, originally suggested by the late J. K. Mitchell, and more recently revived by Weir Mitchell and extensively practiced of late years, has again fallen into comparative disuse, partly because of the difficulties in carrying it out, and perhaps because there have been some unfortunate accidents. Good results have, however, followed its use. Especially may such results be hoped for if the extension is used early, although they have followed even after paralysis had supervened.

Along with the extension, rest in bed is a most important measure,

and many cases are arrested by such rest. Local measures, like counter-irritation and the hot iron, are of no use—rather harmful than otherwise. The same may be said of electrical treatment and massage, except so far as they are useful to keep up the nutrition in the paralyzed muscles. On the other hand, warm bathing is useful in relieving pain and allaying discomfort.

*Operative treatment*—laminectomy—has lately been practiced with a good showing of result, and it should be considered, at least, after other measures have failed. Treatment should be persevered in, as recovery takes place sometimes after paralysis has long persisted, and in no form of tuberculosis has the general treatment previously recommended been so useful.

In the incurable forms anodynes must be resorted to to relieve pain, including even the hypodermic use of morphin, which should never be used without bearing in mind the possibility of the patient acquiring the morphin habit.

### TUMORS OF THE SPINAL CORD AND MEMBRANES.

Both the membranes and the substance of the cord may be seats of tumors, while the cord may also be invaded from the spinal column by enchondroma or sarcoma.

**Varieties.**—From the spinal column, enchondroma, sarcoma, and cancer may intrude into the canal. External to the dura mater in the extradural space occur fatty and malignant tumors, while parasites are also found in this region. The extradural tumors, all rare, may spring from the dura or from the tissue between it and the bone, or may arise outside and pass through the intervertebral foramina. Within the dura are found myxomata, fibromata, lipomata, and neuromata on the nerve-roots. Subdural tumors may arise from the inner surface of the dura, the arachnoid, or from the pia, and may include sarcomata, syphilitic, tuberculous, and parasitic growths. The last two are rare, but both echinococci and cysticerci have been met, developing in the meshes of the arachnoid. Schlesinger collected 44 cases of echinococcus disease. When the parasite is intradural it is round or oval and compresses the cord. The dura is not usually implicated, merely distended. Of the 44 cases only five were intradural, so that the extradural location is seven times more frequent than the intradural. The cysts are usually on the posterior surface of the cord and in the thoracic portion of the vertebral canal, at least in the extradural variety. They may be the size of a pea, of a walnut, or even larger. Their contents are clear and they often contain daughter cysts. Their growth is usually slow. It is said that the hydatids are sometimes found in the substance of the bone.

Fatty tumors are also rare, but have been found and are probably congenital, because they were usually found associated with spina bifida. In the cord itself occur tuberculous, syphilitic, and gliomatous tumors; sarcomata and myxomata have been found. Glioma and sarcoma are the most common. Some of these tumors spring from the pia mater, but

tuberculous growths also develop in the gray matter. Some tumors are compound, as myxosarcoma, etc. Sarcomatous or carcinomatous meningitis occurs infrequently.

The size attained by tumors of the spinal cord and membranes is necessarily limited by the surrounding space. The largest do not exceed two inches (5 cm.) in diameter, and many are very small, not larger than a pea. They are usually single, rarely multiple, as seen in the instance of neuromata, and occasionally sarcoma. The so-called neuromata are usually fibro-neuromata. Tumors developing within the cord may lead to syringomyelia.

**Symptoms.**—These vary with the seat of the tumor and the degree of pressure exerted. When the latter increases slowly, the growth may

FIG. 112.—Sarcoma of the Lower Cervical Cord—(Adamkiewics).

FIG. 113.—Sarcoma Compressing the Cervical Cord—(E. Long Fox).

reach quite a large size before serious symptoms occur. *Pain* is a frequent and conspicuous symptom, and is likely to be maintained by pressure on nerve-roots which are in the way of the growth. The seat of pain varies with the course of the nerves impinged upon, and may be of every variety, such as "burning," "tearing," "stabbing," "aching," "girdle sensations," and the like. It may be unilateral or bilateral, and is worse, according to Horsley, when the tumor presses forward. Sometimes the pain is in the spine itself, which may also in rare instances be tender to pressure. When the growth is in the lower lumbar region, the pain may be referred to the soles of the feet, and may ascend from this seat. In other cases there is hyperesthesia of the skin, which may be associated with pain felt at the level of the tumor, or pain may be felt in anesthetic areas. Very rarely pain is absent, chiefly in extradural lipoma.

*Muscular spasm* is also frequent, especially when the tumor springs from the membranes, when it may be very decided. There may be rigidity

at the seat of the growth, most marked when the disease is at the more mobile parts of the spine, as the cervical region. Then there is apt to be pain in the vicinity, increased by motion. Spasm in the abdominal muscles may also be associated with *girdle pains*. *Contractures* may arise in the limbs, both those supplied by nerves directly irritated by the tumor and by those given off lower down. It is important to note the seat of the rigidity and its character, which may aid us in diagnosing the seat of the tumor, whether it is on the nerve-roots or conducting tract of the cord. Thus, a tumor in one-half of the cord, in the cervical region, may cause persistent contraction of the arm and leg on the side of the growth, and in the early stage of thoracic tumors one leg only may be rigid at a time or one may be more so than the other. In the thoracic region the level of the pain is likely to be a little below the level of the growth, and the reflexes centering at this level may be lost, but retained in the legs.

*Paralysis* occurs sooner or later as constantly as pain, increasing gradually with the pressure. Paraplegia is more common, but all four limbs may be paralyzed by a tumor in the cervical region, one limb being usually affected before the other, though when the tumor is exactly central, both sides are affected simultaneously. Loss of sensation follows paralysis sooner or later. It corresponds in distribution to the motor palsy when the tumor is in the lumbar region of the cord, but if higher and on one side, the sensory loss may be greater on the opposite side; especially is this the case when the tumor is within the cord, when the symptoms may be those already described under the head of Brown-Séquard's paralysis.

*Atrophy* follows involvement of the anterior cornua, and *vasomotor* disturbances may be marked. In cases of prolonged interruption *ascending and descending degenerations* may occur. Tumors not infrequently cause subacute or acute myelitis, whose symptoms may mask the clinical picture.

**Diagnosis.**—The characteristic symptoms are slow development of severe and constant unilateral root symptoms, later bilateral, at the level of the growth, and a progressive paralysis, motor and sensory. The radiating pain is usually at the level of the tumor or below. Pain in the spine itself is an important sign. Rigidity of the muscles of the spine, muscular contractions in the limbs, early and marked exaggeration of reflex action when the cord itself is involved, are also important signs, especially when associated with the history of syphilis or tuberculous disease. *Caries of the spine* may produce the same symptoms, but the radiating pains are less severe and the effects of compression of the cord are more likely to be bilateral, either from the first or soon after their commencement. Tenderness of the spine may generally be elicited by careful examination, while irregularity of surface, from the breaking down of the bone, sooner or later makes its appearance. When the *tumor is in the bone itself*, the symptoms at first scarcely differ from those of caries, though the pain on motion is usually worse in the former.

The symptoms of *cervical meningitis* also closely resemble those of tumor. They are, however, usually bilateral from the first and have considerable vertical extent. Central tumors covering a like area may produce identical symptoms, except that pain is usually unimportant.

Pain and muscular atrophy in the arms without wasting occur in both extramedullary tumor and meningitis, but wasting is likely to develop later, and the diagnosis between the two conditions may be extremely difficult.

*Chronic transverse myelitis* also closely simulates tumor in its radiating pain, sense of constriction, progressive paralysis, and a differential diagnosis is sometimes impossible. The symptoms here, too, are from the first bilateral, while the radiating pain is commonly not severe in myelitis, which invades also larger areas of the cord.

*Circumscribed serous spinal meningitis* may closely simulate clinically tumor of the spinal cord. It has been found in association with necrotic osteitis of the vertebræ, pachymeningitis, caries of the vertebræ, adhesions between the dura and pia, bony projection on the inner surface of a vertebra, and meningo-myelitis. A few cases are on record in which no complication seemed to be present. At operation or at necropsy a collection of clear fluid, resembling cerebro-spinal fluid, is found in a cyst, the wall of which is made by the delicate pia. Nothing is really known as to the cause of this apparently idiopathic collection of fluid. Inasmuch as it is strictly circumscribed, it produces the symptoms of pressure upon the spinal cord, and cannot be distinguished clinically from spinal tumor. Removal of the fluid by operation may give complete relief from the symptoms, and there may be no tendency to recurrence. The recognition of the condition by surgeons is therefore of much practical importance, especially as the disorder is probably more common than the paucity of reports indicates. Sometimes the meningitis is circumscribed without cyst formation.

As to the exact seat of the tumor, in general terms it may be said that *when within the cord*, the symptoms are those of a gradually increasing paraplegia or of a Brown-Séquard's paralysis, while vasomotor disturbances are marked, and reflexes are bilaterally influenced, according to the law explained. Atrophy means involvement of the ventral cornua. Acute or subacute myelitis may be associated and complicate the clinical picture. Tumors in the *membranes* are characterized by early "root symptoms," including radiating pains, girdle sensation, and hyperesthesia or anesthesia. Irritation of motor nerves may cause spasm or wasting, with paralysis late in the disease.

The nature of the tumor may be inferred only from the history of the case, syphilis and tuberculosis giving the most valuable assistance. Its seat is suggested by the level of the transverse symptoms. It is never below these, while it may be a distance of three or four vertebræ above the nerves corresponding to the highest level of anesthesia or pain. The diagnosis of tumor from other transverse lesions of the cord may be at times impossible.

**Prognosis.**—In all forms the symptoms gradually increase until paralysis results, unless operative interference produces a more favorable termination—a practice which modern methods are rendering more frequent and justifiable.

**Treatment.**—When there is reason to believe syphilis is present, the antisyphilitic treatment may be used with reasonable expectation of suc-

cess, as some cases of syphilitic meningitis simulate tumors. Beyond this, symptoms must be met as they arise. Attempts made of late years to formulate the laws governing surgical operations in these cases have been more or less successful, but wider experience is necessary before they can be thoroughly relied upon. I may, however, close this subject with the advice of Victor Horsley, whose studies on surgery of the nervous system entitles his opinion to the highest respect: "If it is clear that the growth is not syphilitic, and that no good can be done by other treatment, delay in an operation can only cause harm—can only result in a less favorable state for the proceeding, less chance of recovery, longer and greater suffering, and should, on every ground, be avoided."

### LESIONS OF THE CAUDA EQUINA AND CONUS MEDULLARIS.

The *cauda equina* is the bundle of nerves coming off from the lower cord and occupying the spinal canal from the second lumbar vertebra downward. At this vertebra the cord itself terminates in the *conus medullaris*, prolonged into the thread-like *filum terminale*. Fractures and dislocations in the lumbosacral region may impinge on these parts, while the filaments of the nerves of the cauda equina may be invaded by tumors or compressed by cicatrices.

**Symptoms.**—*Compression* of the *conus* and of the *last sacral nerves* given off from it, such as may be caused by a dislocation of the first lumbar vertebra, produces paralysis of the bladder and rectum and loss of sexual power, whence it has been inferred that the anovesical center and the center for the sexual functions are seated in this part of the cord. This paralysis may be the only symptom or it may be associated with disturbance of sensation about the anus and in the perineum and external genital organs except the testicle, the latter being supplied with sensation from a higher segment of the cord.

When the *lumbar nerve-roots*<sup>1</sup> are involved, from the *second to the fourth* inclusive, there is paralysis embracing all the muscles of the thigh and leg except the outer rotators of the thigh, the flexors of the knee and of the ankles, the peroneal muscles, the long flexors of the toes, and the small foot muscles. There is also loss of sensation in the front, inner, and outer parts of the thighs and the inner side of the leg and foot.

Involvement of the fifth lumbar and first and second sacral nerves produces paralysis of the muscles just excepted, and loss of sensation in the outer and posterior part of the leg, foot, and sole of the foot. *Lesion of the third, fourth, and fifth* sacral and *coccygeal* nerves causes paralysis of the peroneal muscles, the bladder, rectum, and of the external genitals, the coccygeus, with loss of sensation in the back of the thigh, anus, perineum, genital organs, and skin about the anus and coccyx.

<sup>1</sup> Of the lumbar nerves, the first root appears between the first and second lumbar vertebrae, the fifth between the last lumbar and the base of the sacrum. The four upper sacral nerves pass from the spinal canal through the sacral foramina, the fifth between the sacrum and coccyx.

## SPINA BIFIDA.

SYNONYMS.—*Split Spine; Hydrorrhachis; Myelocoele; Meningocoele*

**Definition.**—A name applied to a congenital defect in the closure of the spinal canal, through which protrudes a sac-like portion of the dura containing cerebrospinal fluid, at times a part of the cord, either normal or altered, and forming also, as a rule, an external prominence of tumor covered by skin.

**Description.**—The tumor is found commonly in the lumbar and sacral portions of the spine, rarely in more than one place, very rarely throughout the whole column. Its size ranges from that of a small nut to that of an orange, and occasionally it is so large as to interfere with the birth of a child afflicted with it. On section of the skin the protruding sac of the dura is seen and beneath this the arachnoid. Rarely is the dura cleft so that the sac is formed by the arachnoid only. There may be a dilatation of the central canal—hydromyelia—when the substance of the cord is found more or less atrophied, while the central canal communicates directly with the cavity of the spina bifida. At other times the cord is normal, while its lower end may be adherent to the sac. A tumor of similar character is occasionally seen protruding through the skull.

**Symptoms.**—At first there are usually no clinical symptoms. By pressure the contents of the tumor can often be forced into the spinal canal, causing expansion of the fontanels and increase of cerebral pressure with its consequences—viz., somnolence, with changes in the pulse and breathing, which may be fatal if the pressure is continued. The absence of such symptoms goes to show that communication of the tumor with the spinal cord is cut off.

With the lapse of time the tumor usually grows slowly, and the effects of pressure on the spinal cord or cauda equina appear. These are paralysis, atrophy, anesthesia, bed-sores, vesical derangements, talipes varus, and trophic phenomena, of which perforating ulcer of the foot is one. The sac may burst, or the walls become inflamed, converting the contents into pus.

**Prognosis and Treatment.**—Unless removed by surgical interference, the child dies sooner or later of exhaustion. The tumor has been rarely obliterated by gradually increasing pressure or by injecting the cavity, after evacuation of the fluid, with iodine, producing obliteration through an inflammatory process. Other surgical measures may be found in text-books on surgery.

## PROGRESSIVE BULBAR PALSY.

SYNONYMS.—*Polioencephalitis inferior chronica; Glossolabio-pharyngeal Paralysis; Paralysis of the Tongue, the Soft Palate, and the Lips; Duchenne's Disease; Atrophic Bulbar Paralysis.*

**Definition.**—Bulbar palsy is a progressive paralysis invading the lips, the tongue, the palate, the pharynx and larynx, and in more advanced

cases the lower face muscles due to lesion of the motor nuclei in the medulla oblongata (or bulb), whence arise the nerves distributed to those parts.

**Historical.**—Bulbar palsy was first completely described in its clinical aspects by Duchenne in 1860, but the exact seat of the disease was not determined until 1870, when Charcot in France and E. Leyden in Germany confirmed the earlier suggestion that it was a progressive degeneration and atrophy of the nuclei in the medulla oblongata.

**Etiology.**—Primary progressive bulbar palsy is difficult to account for. It is more frequent in men, and sometimes heredity or family tendency is noted. It has been ascribed to the overuse of the muscles of the mouth, as in the blowing of wind-instruments; to a tumor in the medulla oblongata or vicinity; while syphilis, to which so many of the unaccountable lesions of the nervous system are ascribed, is less commonly held responsible for this affection than for some others. Cold, emotional excitement, and extreme fatigue have all been named as causes. Most frequently, however, no cause is traceable.

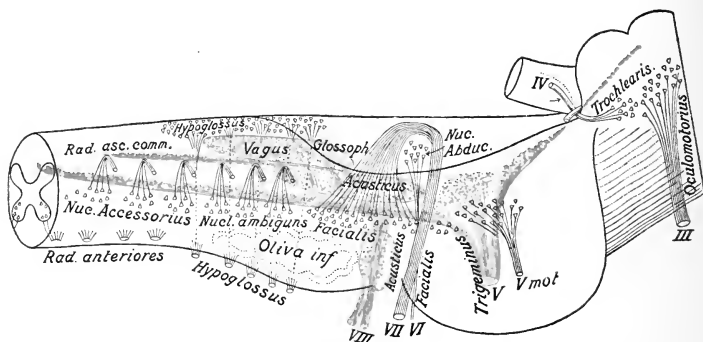

FIG. 114.—Situation of the Cranial Nerves—(after Edinger).

Cranial nerve nuclei, oblongata, and pons represented as transparent. Motor nuclei, black; sensitive nuclei, red.

**Morbid Anatomy.**—Most writers concede that the lesion starts in the motor nuclei of the medulla oblongata. It may be that the entire motor apparatus from the muscular fiber to the ganglionic cell is invaded simultaneously. Certain it is that bulbar paralysis is often associated both with progressive spinal muscular atrophy and amyotrophic lateral sclerosis, the symptoms now of one and now of the other preceding. There can be no doubt that these three conditions are closely allied. The nature of the lesion is the same in each, the motor cells in each are involved, the muscles are wasted in each, though the particular ones involved vary as the situation of the motor cells is different.

The anatomical lesion is an *atrophy of the motor cells of the medulla oblongata*. The nucleus of the hypoglossus, the nucleus of the pneumogastric, to a less degree that of the facial and that of the glossopharyngeal are all involved, while the *sensory nuclei are intact*. Very rarely the nuclei of the ocular nerves, third, fourth, and sixth, are involved.

From these nuclei the degeneration extends to the *nerves* which have their origin in them, and thence to the *muscles* to which they are distributed.

The nature of the degeneration is a more or less complete destruction of the motor cells. In addition, there is an overgrowth of neuroglia tissue and a thickening of the walls of the blood-vessels. The nerve-fibers of the pyramidal tract may undergo degeneration.

**Symptoms.**—The symptoms of progressive bulbar paralysis are exceedingly gradual in their development. The first symptom noticeable is usually a *difficulty in the pronunciation of words* containing letters which require the use of the tongue in their formation, such as E, R, L, S, G (hard), K, D, T, and N. Still later there is difficulty in pronunciation of words requiring the aid of the lips, as P, B, F, V, O, A (long), and the sound of O in tool, while whispering becomes impossible.

Concurrently with these symptoms the *tongue and lips* are observed to *waste*, the tongue becomes thinner and narrower, the lips thin and compressed in appearance, the loss of power being commensurate with the degree of wasting. *Fibrillar tremors* are usually seen in the tongue, and the mucous membrane may be thrown into transverse folds. Finally, the *tongue cannot be protruded*, or can be brought only to the edge of the teeth, while the *mouth cannot be closed* because of complete paralysis of the orbicularis oris muscle. In more advanced stages other muscles of the face become involved, the labionasal fold is less distinct, and the face becomes expressionless.

Before this degree has been attained, however, the muscles of the *palate* have commenced to fail in their action, and thus a further difficulty in the articulation of words is added, while the *voice is nasal*. Fluid begins to pass through the nose when swallowing is attempted. The difficulty in swallowing is increased by growing *paralysis of the pharyngeal muscles*, and is further aggravated by the inability of the tongue to carry the bolus of food backward. Feeding the patient is a troublesome and disgusting process, the food being scattered all about and sometimes thrown to a considerable distance, by the act of coughing facilitated by absence of power in the lips to retain substances in the mouth. By this time, too, the *laryngeal muscles* are involved, and the patient's efforts to speak result in mere grunts.

Thus he cannot talk, he cannot swallow, he cannot close his mouth; he cannot expectorate, yet the saliva flows from his mouth because he can neither swallow nor close his lips, and the term "driveling idiot" well covers the impression caused by his appearance. Yet his mental powers are unimpaired, and may remain so until the last. The motor electrical phenomena in the muscles involved may be altered, and the *reaction of degeneration* may be present.

To these symptoms are to be added complications due to the paralysis. From the difficulty in swallowing, particles of food may enter the larynx, be insufflated to the deeper parts of the lungs, and there cause a pneumonia which may be fatal, or the fragment which enters the larynx may be so large as to cause death by suffocation.

In rare cases the lower distribution of both facial nerves is involved,

producing *diplegia facialis*; but the upper distribution usually escapes. Or there may be paralysis of the ocular nerves to which it may be confined (anterior bulbar paralysis or progressive *ophthalmoplegia* of von Graefe). Even the muscles supplied by the spinal accessory and the motor branch of the trifacial may be invaded. In all these instances the nuclei of the corresponding nerves are affected.

**Diagnosis.**—The diagnosis is generally easy, the symptoms are so characteristic and so evident. For a typical case they must be purely motor; they must be disassociated from other muscular involvements which would go to make them a part of *progressive spinal muscular paralysis* or *amyotrophic lateral sclerosis*. If there are disturbances of sensation, invasion of the upper division of the facial, of nerves of special sense, the disease is not true bulbar paralysis. There must be some general involvement of the medulla oblongata, thrombosis, or embolism, a tumor developing near it or diffuse sclerosis through it.

There is a *glossolabiopharyngeal paralysis* of cerebral origin known as "pseudobulbar paralysis," in which there is partial or complete paralysis of the tongue and lips, due to bilateral and possibly even unilateral cerebral lesions. Close examination will, however, detect, sooner or later, deviations from the typical course, which include absence of fibrillary tremor, and of atrophy, and of reaction of degeneration. The symptoms tend, too, to occur first with the involvement of the limbs of one side and later of those of the other side. Mentality is much affected, and the reflexes may be exaggerated. Bulbar tumors run a like chronic course, but almost always present unilateral symptoms.

**Prognosis.**— The disease is invariably sooner or later fatal, although it is said that its progress may be delayed by treatment; this, however, is questionable.

**Treatment.**—If there be any suspicion that syphilis is the cause, *iodid of potassium* should be used. *Galvanism* is recommended, electrodes being applied to the two mastoid processes daily for two or three minutes, the current often reversed. The sympathetic nerve and the affected muscles of the lips and the tongue may be similarly treated, faradization being also substituted for galvanism in the case of the muscles. Deglutition may even be excited by galvanism when it begins to be impaired. This is accomplished by placing the anode on the nape of the neck and the cathode on one side of the larynx. At every cathodal closure, or every time that the cathode is carried across the side of the larynx, there is a reflex act of deglutition. When deglutition becomes very difficult, the stomach-tube should be used and nutrient substances thus introduced. Great care should be exercised in feeding the patient without the tube, lest the food pass into the trachea and cause suffocation. Hence, too, the use of the tube should not be too long deferred.

In addition to *iodid of potassium*, *nitrate of silver* and ergot are also recommended. The first should be given in such doses as the stomach will tolerate, while salivation may be controlled by atropin— $\frac{1}{100}$  to  $\frac{1}{60}$  grain (0.00066 to 0.0011 gm.). Silver should be given in the usual doses of  $\frac{1}{6}$  to  $\frac{1}{4}$  gr. (0.0166 to 0.016 gm.); ergot in usual doses.

## ACUTE BULBAR PALSY.

**Etiology.**—Besides the chronic or progressive form of bulbar palsy, there is an acute variety which is caused by hemorrhage into the pons and medulla, or possibly by thrombosis or embolism of the vessels supplying these centers—viz., the anterior spinal, vertebral, and basilar. Inflammation of the medulla oblongata is also a cause. Thrombosis may occur in any of the vessels, and is commonly due to atheromatous or syphilitic endarteritis. Inflammation is a rare affection, but does occasionally occur.

Hemorrhage, thrombosis, and embolism are subject to the same causes here as elsewhere in the brain, but the cause of the inflammatory form of acute bulbar palsy is unknown. It is probably infection or intoxication.

**Symptoms.**—In any event the symptoms are sudden. They are those already detailed in connection with progressive bulbar paralysis, but others are added. There is usually no loss of consciousness, though there may be. There may also be deranged cardiac action and respiration, including irregular and frequent pulse, vasomotor derangements, and Cheyne-Stokes breathing. The temperature, normal at first, may rise to 105° to 107° F. (40.5° to 40.71° C.) and higher as a fatal termination is approached. Sensation is rarely affected. Most characteristic of all is the so-called *crossed paralysis*, described on page 932, which attends most hemorrhages into the pons, in which there is paralysis of the face on one side and of the extremities on the other; but the motor tract may not be involved, and in that case paralysis is not observed.

**Diagnosis.**—Suddenness of occurrence of the symptoms named indicates one of the accidents previously mentioned, while a crossed hemiplegia, provided it is of the limbs on one side and of the face on the other, is conclusive. When inflammation of the medulla oblongata is present, the phenomena of bulbar paralysis do not occur quite so suddenly. They may be several days or even a few weeks in developing, and may be preceded by prodromal symptoms, such as vertigo and painful sensations in the back of the neck.

**Treatment.**—The treatment is the same as for similar lesions elsewhere in the brain.

## MYASTHENIA GRAVIS.

**SYNONYMS.**—*Pseudoparalytic Myasthenia; Bulbar Palsy without Discernible Anatomical Changes; Asthenic Bulbar Paralysis; General Profound Myasthenia; Erb's Disease; Hoppe-Goldflam Symptom Complex.*

**Definition.**—A disease beginning usually with weakness of the muscles of the tongue, lips, larynx, and eyes, followed by rapid exhaustion and temporary paralysis of the muscles of the extremities; by temporary recovery of power after rest; occasionally terminating in persistent paralysis.

**History.**—The disease was first described by Wilkes in 1877 as "an unusual form of glosso-labio-laryngeal paralysis." In 1879 Erb reported three cases which he described as a new syndrome, probably of bulbar origin. It, however, attracted little

attention until the publication of Goldflam's paper in 1891. In 1891 and 1892 Jolly, and in 1892 Hoppe published reports of cases; also in 1892 Goldflam published his paper in which were collected all cases published up to that date with four new cases. In 1896 Strümpell collected twenty cases. In 1900 Harry Campbell and Edwin Bramwell made the most complete study of the cases so far as published—in all about 70. They give the details of 60. In a later paper<sup>1</sup> Edwin Bramwell says up to the present time only some 80 or possibly 90 cases have been reported. Other cases have, however, been reported since this date.

**Etiology and Pathology.**—The disease occurs usually in those from twenty to forty years of age, and in both sexes alike. It is believed to be due to an autogenetic toxin. Congenital defect or abnormality either in the construction or mode of functioning of the neuro-motor apparatus rather than in the muscles, has been suggested by E. Bramwell, and especially the lower motor-neuron. It has followed the infectious diseases, and in about one-fourth of the cases neurophathic heredity has been noted. At necropsy no lesion was found for a long time, which would account for the symptoms, but more recently several cases have been reported in which a cellular infiltration of muscles was observed.

**Symptoms.**—These include ptosis, paresis of the facial muscles, difficult mastication, and difficulty in swallowing and talking. They are due to fatigue of the muscles involved, and the patient can talk a few sentences quite glibly, but his speech soon grows indistinct and ultimately incomprehensible. So with chewing and swallowing so far as the first mouthfuls are concerned, but these acts soon become impossible. The muscles of the extremities and trunk, as well as those innervated by the cranial nerves are involved, the same rapid fatigue supervening on effort. Thus one of Strümpell's patients could ascend a flight of stairs very well once, but in making a second effort had to invoke the aid of a bannister, while the third and fourth efforts were ineffectual. Such a condition is known as the *myasthenic* state. At times the abnormal fatigue and consequent symptoms are limited to the lower extremities. A similar effect succeeds on continued faradization of the muscles, first detected by Jolly, and is called the *myasthenic reaction*. Almost equally characteristic is the disappearance of fatigue after the muscles have been put at rest for a time.

**Diagnosis.**—In well-marked cases this is easy, but when the symptoms are less pronounced, there may be difficulty. Cases are often met, especially in hysterical women, who complain of inability to hold up the head, which clearly do not belong to this class. But it is to be remembered that true myasthenia gravis is very different from hysteria. An ability to use the muscles at first, followed rapidly by an opposite state, must always be looked for, and these conditions may be applicable to the muscles of the lower extremities, as well as to those of the bulbar nerves. The absence of muscular atrophy is essential to myasthenia gravis; the ocular and upper face muscles are more likely to be paralyzed than in bulbar palsy. The myasthenic reaction should be sought. The muscles respond normally to galvanism.

**Prognosis.**—This is not always unfavorable, but one must not be misled by the apparent improvement succeeding rest, which is often temporary.

<sup>1</sup> "Scottish Med. and Sur. Journal," May, 1901.

**Treatment.**—It is evident from what has been said that rest is most important. Prolonged rest and the avoidance of mental excitement, and the use of massage and mild galvanization of muscles are recommended, and even central galvanization of the spinal cord and medulla oblongata. Galvanization of the respiratory muscles may produce unfavorable results. Since faradization excites the myasthenic state, it should not be used.

The nourishment, or mode of nourishment, is most important, in view of the fact that the muscles of mastication and deglutition are at fault. The food, therefore, should either be liquid or very finely minced, and unless deglutition is natural and easy, the stomach tube should be used, but great care should be exercised in its use for fear of producing exhaustion. Dark glasses may relieve the fatigue of the ocular muscles.

The drugs recommended are the usual ones: strychnin, arsenic, phosphorus, and other tonics, but no direct results have been traced to them.

## AMYOTROPHIC LATERAL SCLEROSIS.

SYNONYM.—*Charcot's Disease.*

Notwithstanding the similarity of the clinical phenomena, and, to a certain extent, of the morbid anatomy of amyotrophic lateral sclerosis to those of the so-called progressive spinal muscular atrophy, to be next considered, there appears to me sufficient difference to justify a separate consideration.

**Definition.**—Amyotrophic lateral sclerosis is a systemic degeneration of the pyramidal tracts of the spinal cord, with atrophy of motor cells in the anterior cornua and medulla oblongata, and consequent wasting of muscles, depending upon these cells for their trophic influence.

**History.**—The confusion which has long existed between this disease and progressive spinal muscular atrophy was first cleared up by Charcot and his pupil, Joffroy, who published a fairly accurate account of the disease in 1869 and a complete description in 1874. Such description became possible, however, only after Flechsig's studies of the paths of motor conduction in the spinal cord. That there are, however, certain common features in the two affections appears not only from the clinical history, but also from the morbid anatomy.

**Etiology.**—The causes of this condition are still essentially unknown. *Severe muscular exertion* has been assigned as a cause, as it has also of the allied affection, progressive spinal muscular atrophy. As in it, too, the *male* sex suffers most. It is a disease of *middle age*. It is probably due to the degeneration of an imperfectly formed central motor system.

**Morbid Anatomy.**—A *sclerosis of the crossed pyramidal tracts* in the two lateral columns and the *direct pyramidal tracts* in the anterior columns is essential to the morbid anatomy in a typical case. As important is *atrophy* of the corresponding *large ganglion* cells in the anterior cornua and medulla oblongata. The degeneration has been traced in the pyramidal tracts from the sacral cord upward to the pyramids in the medulla oblongata, some times even through the pons and crura into the internal capsule and central convolutions, in which, too, the large ganglion cells have been found atrophied. The nerve nuclei which are affected in the

medulla oblongata are especially those of the vagus and hypoglossal nerves. The motor cranial nerves are sometimes degenerated.

The changes in the motor ganglion cells of the cord and the nerve nuclei in the medulla oblongata are analogous and produce corresponding results in the *muscles* supplied by the motor nerves originating from them. These results are an atrophy present in various degrees, some fibers disappearing almost entirely, others partially. The process is by fatty metamorphosis and absorption of resulting fat, leaving a residue of connective tissue.

**Symptoms.**—The clinical phenomena are in strict accord with what would be expected from the pathological lesions, consisting in *muscular wasting* and *corresponding paresis*. Before the muscular wasting appears, a *sense of fatigue* succeeding slight effort may be manifested, followed by a positive weakness, primarily almost always in the *upper extremity*, first one and finally both. This is followed by *wasting* of the muscles of the *same* extremity, usually first seen in the thenar and hypothenar eminences, the interossei and the muscles of the extensor side of the forearm, while the flexors of the hand and fingers remain longer uninvaded. The atrophy is particularly well seen in the deltoid, and to a less degree in the triceps, still less in the biceps and shoulder muscles. Usually symptoms do not appear in the lower extremities, with the exception of exaggeration of the tendon reflexes, until some time after they have appeared in the upper, but occasionally the disease begins in the lower limbs.

When the lower limbs are affected, the patient tires easily in walking, the gait becomes unsteady and stiff, and rising from the chair becomes difficult. *Tremor* may appear in the legs. The paresis in both extremities is proportionate to the destruction of muscle, though first, at least, it is independent of the atrophy. Associated with muscular atrophy, sooner or later, is a *diminished electrical excitability*. Some excitability, however, remains as long as the muscles are intact, diminishing as their destruction spreads. A reaction of degeneration may also develop in the muscular fibers still intact. The excitability remains for the most part *intact* in the *nerve-trunk* because in any event a large number of fibers are preserved in their normal state.

A distinctive feature of amyotrophic lateral sclerosis is found in the *reflexes*, which, in strong contrast to progressive muscular atrophy, are *markedly increased*. Even in the early stages of the disease vigorous contractions are obtained by gently tapping the tendons of almost any of the muscles in the extremities. Always most conspicuous is the patellar reflex, while more rarely ankle clonus may be obtained. The same is true of the masseter reflex. In the arms the biceps and triceps and the flexors of the hands may be excited to strong contraction.

*Contractures* may take place in the later stages of the disease in the *arms and hands*, but not always. In the lower extremities, where the atrophic symptoms develop some months later and are less marked, *spastic* symptoms are a more prominent feature. The legs become rigid and some strength is required to flex them, though the muscles themselves are parietic. A typical spastic paraplegia may be produced, which is due

mainly to the increase of the tendon reflexes, and a spastic paretic gait is common—that is, at first.

Later on in the disease *bulbar symptoms* may present themselves, manifested first by defects of speech, difficulty in retaining the saliva and in swallowing; and later still the lips and tongue may be seen to be atrophied, and ultimately there is difficulty in taking food, whence nutrition is impaired, and the patient gradually sinks. In some cases the disease may begin without bulbar symptoms.

Throughout, *sensibility* remains *normal* in the upper and lower extremities, and the superficial reflexes are not much altered. The *sphincters* are, as a rule, *unaffected*, although micturition may be disturbed. There may be constipation, but no actual paralysis of the bowel. Sexual power may be lost.

The successive involvement of the upper extremities, the lower extremities, and the bulbar centers marks quite well-defined stages of the disease.

Death comes ultimately from exhaustion, or more frequently through an inspiration pneumonia, caused by entrance of foreign matter into the air-passages as a result of defective deglutition, or through bulbar palsy.

**Diagnosis.**—The disease is distinguished from *progressive spinal muscular atrophy* by the invariable increase in the tendon reflexes, even in the early stages, as contrasted with their absence in the latter disease.

**Prognosis and Treatment.**—The prognosis is very unfavorable and the disease cannot be arrested. By rest in bed, massage, electricity, and hot bathing we may be able to defer the end somewhat. (See, also, Treatment of Progressive Spinal Muscular Atrophy.)

## PROGRESSIVE SPINAL MUSCULAR ATROPHY.

**SYNONYMS.**—*Wasting Palsy; Progressive Muscular Atrophy, Type Duchenne-Aran; Duchenne-Aran's Disease; Cruveilhier's Atrophy; Chronic Anterior Poliomyelitis; Chronic Degeneration of the Motor Nuclei.*

**Definition.**—Progressive spinal muscular atrophy is a *progressive wasting* of more or less limited *groups of voluntary muscles*, associated with *degenerative atrophy of the corresponding portion of the motor nerve tract*, including the ganglion cells of the anterior cornua, but *unaccompanied by disease of the pyramidal tracts*. The existence of this condition has been disputed, but degeneration of the cells of the anterior horns without degeneration of the pyramidal tracts has been seen by most reliable investigators. It is well to include the word spinal in the description of this disease, as thereby the disease is distinguished from progressive muscular atrophy from other causes.

**Historical.**—The history of the development of our knowledge of this disease is very interesting. A few facts only can be given here. Although a number of isolated cases were described at an earlier date, Duchenne's memoir on "*Atrophie Musculaire avec Transformation Graisseuse*," published in 1840, and Aran's "*Recherches sur une Maladie non encore décidée du Système Musculaire*," published in the next year, contained the first accurate description of this malady. Cruveilhier's studies were commenced in 1832, but were not given out until 1853. All of these

observers believed at first—Cruveilhier reluctantly—that the disease was purely muscular. In his third case, however, Cruveilhier found atrophy of the anterior roots of the spinal nerves, and in his fourth, lesion of the gray matter of the cord, whence the anterior roots take their origin, and first asserted the belief that the disease of the gray matter in the spinal cord was the special anatomical lesion of the disease. The researches of Lockhart Clarke in 1866 and 1867 and of Charcot in 1869 may be said to have established the spinal nature of the disease; while Friedreich in 1873 still maintained its muscular nature, and Gowers and Leyden regard it as identical with amyotrophic lateral sclerosis. Strümpell also separates the two diseases of progressive spinal muscular paralysis and amyotrophic lateral sclerosis, and it appears to me there is quite enough reason for doing so. The close relation of these two diseases cannot be disputed, but most unquestionable proof has been furnished by Dejerine and others that they are not identical.

**Etiology.**—In the majority of instances we fail to find a sufficient cause. Heredity has been regarded as playing an important rôle in its causation, but Strümpell considers the cases thus originating as instances of the juvenile myopathic variety of atrophy—that in which no nervous lesion is traceable. On the other hand, *excessive muscular exertion* seems to be more than an accidental coincidence. Exposure to cold, especially to very cold water, and the *infectious diseases*—typhoid fever, influenza, diphtheria, and syphilis—have all been held accountable, but it is likely that some of the atrophies thus resulting include other forms than the true progressive spinal muscular atrophy.

It is a disease commonly of adult males, most supposed cases among those who are younger being probably, as held by Erb, instances of the juvenile form of muscular dystrophy, although a very rare family form of progressive spinal muscular atrophy has been observed in children.

**Morbid Anatomy.**—The *anterior horns of the gray matter* are wasted and reduced in size; their ganglion cells wholly or partially destroyed; the neuroglia is proliferated and is intercalated in places with spider cells. The *anterior nerve-roots* passing from the horns are *atrophied*, as are also the motor nerve filaments in the peripheral nerves. But the crossed pyramidal tracts in the lateral columns containing the crossed motor fibers descending from the brain to the cells in the anterior cornua are intact. A slight degeneration may be seen in some cases in the antero-lateral columns about the anterior horns. The *muscles* seen to be *wasted* before death are found converted into fat and connective tissue, a remnant of true muscular tissue remaining. At times also they are the seat of waxy change, at others still, narrowed but retaining their transverse striation.

As to the *relation of the nervous changes to the muscular atrophy*, the conspicuous symptoms of the disease, there is more than one possible explanation. As in bulbar palsy, according to one view, the atrophy of the anterior cornua is primary, the result of chronic poliomyelitis anterior, the degeneration of the peripheral nerves and muscles being secondary to it. According to another view, the muscular atrophy is primary, possibly due, as Friedreich sought to prove, to a myositis, followed by fatty metamorphosis of the sarcous substance and subsequent absorption of fat, or to a simple primary fatty metamorphosis. In such event it may be inferred that the nerves atrophy from want of use. According to a third, the degeneration begins in the last terminal branches of the motor nerves and extends upward along them to the spinal cord. Finally, it is held that there may be a simultaneous degeneration of the

whole motor system involved, including muscles and nerve, and nerve cell. It is more in accord with the office of the spinal cord as a nutritive center, as well as with its morbid anatomy, to suppose the disease is a chronic poliomyelitis anterior, the essential infantile paralysis of Rellet and Barthez being an acute form of the same disease. Very important is the anatomical fact that the pyramidal tracts are quite normal in a typical case.

**Symptoms.**—One of the most striking features of the disease is its *slow development*. Like its congener, amyotrophic lateral sclerosis, it begins most frequently in the *upper* extremities, seven out of nine times in Aran's cases. Of the upper extremities, the right was first invaded in 37 out

FIG. 115.—Position of Hands and Fingers in Ulnar Paralysis of Long Standing; Bird-claw Hand, "Main en Griffe"—(after Duchenne).

A, A. Wound of the ulnar nerve. B, B, B, B, B. Ends of the metacarpal bones. D. Tendons of the flexor sublimis digitorum. C. Muscles of the ball of the thumb.

of 62 of Sandahl's cases, the left 14 times, while the involvement was simultaneous in 11. The disease may begin in the *lower* extremities, as shown by Friedreich's statistics, according to which these were first invaded 27 times out of 146 the upper extremities 111, the lumbar muscles in eight.

The atrophy usually begins with the short muscles of the thumb, the abductor policis brevis first, then the opponens and the abductor. The consequent flattening of the ball of the thumb and its persistent approximation to the second metacarpal bone produces the so-called "ape-hand." Simultaneously, or almost simultaneously, the interossei begin to waste, producing conspicuous depressions between the metacarpal bones, associated with loss of power to extend completely the terminal phalanges of the fingers. Atrophy of the lumbricales follows, producing a flattening of the hollow of the hand. The ultimate result is the characteristic *main en griffe* of Duchenne, in which the extensor tendons on

the dorsum of the hand, and the flexors in the palm, may become as distinct as if dissected out.

From the hand the wasting creeps up the forearm and thence to the arm, or it may skip the forearm and pass into the arm, sparing usually the triceps extensor. In the forearm the muscles on the extensor (external) side are usually first affected, then the abductor pollicis and extensor longus pollicis, and later the supinators and flexors. It may come to a standstill at either of these stages, or may involve the muscles of the shoulder, especially the deltoid, in which, indeed, it may begin, preferably in the right, passing thence to the scapular and trapezius muscles, the pectorals, the rhomboidei and latissimus dorsi, while a grotesqueness of effect is often produced by reason of certain adjacent muscles retaining their natural size or being even seemingly hypertrophied. This is particularly the case with the inferior part of the trapezius and platysma myoides which are almost never involved. The disease may be arrested at almost any of these stages.

The lower extremities may escape altogether and the atrophy always develops late. The small muscles of the foot would naturally be the first affected. Very rarely there may be exceptions to this rule. The muscles of the face are invaded late or not at all, but ultimately even the intercostal and abdominal muscles may be involved. The result, then, is a veritable living skeleton, instances of which are sometimes exhibited. Deformities, including lordosis or anterior curvature of the spine may result.

With all this, *sensibility* is unaffected in the vast majority of cases, but the patient may complain of a numbness and coldness of the affected limbs. Very rarely *pains* precede the wasting in the muscles, when they are sometimes regarded as rheumatic. The *galvanic and faradic irritability* of the muscles progressively diminishes and disappears with the complete destruction of the muscle, the galvanic persisting longer. The *reaction of degeneration* may, however, be elicited late in the disease in certain muscles, more especially in the modified form known as "partial reaction" of degeneration. If the disease runs a rapid course, it may occur earlier and be more typical. *Fibrillary* muscular contractions may be present, and idiopathic muscular contractions, or myoid tumors brought out by a blow, may be thus produced. The bladder and rectum remain intact, but sexual function may be lost.

Sweating and other *vasomotor* disturbances may occur in the affected muscles, such as pemphigoid bullous eruptions, thickening and fissuring of the skin, and curving and grooving of the nails. In certain places there is an overaccumulation of fat, producing an appearance of hypertrophy when there is actual atrophy.

Along with wasting there is a corresponding *paresis*, the result of the atrophy and not its cause. The arms are flaccid and toneless and hang loosely at the sides. The patient can no longer dress himself, and various devices are resorted to in order to accomplish certain acts. Especially characteristic is one of these—when the shoulders, being first affected, the arm and forearm retain their usefulness. Under these circumstances the power of lifting the arm from the side, and especially of raising it above the head, is lost, while that of the forearm remains. Hence, if the

patient wishes to lay hold of anything, he swings the arm forward with a jerk until the object is brought within reach of his fingers, when it may often be caught by the pathologically hooked terminations of these. So long as the neck muscles remain active, objects may be grasped by the mouth.

In true progressive spinal muscular atrophy the *reflexes* are entirely absent, at least in the wasted extremities, a natural result of the atrophy of the ganglion cells in the anterior cornua and of the centrifugal motor fibers of the reflex arc. The *special senses* and the *sphincters* remain normal.

Toward the close of the disease sometimes, and then only after it has existed for a long time, the phenomena of *bulbar* paralysis may present themselves after invasion of the ganglia of the medulla oblongata. These have been detailed in the section on that subject. They are by no means always present, even in advanced cases.

**Diagnosis.**—Muscular atrophy is not confined to the disease under consideration. It occurs in diffuse myelitis, in tumors of the cord and when cavities are formed in its interior, in multiple neuritis, and especially in amyotrophic lateral sclerosis. From all these named, except the last, it is easily distinguished by strict attention to the conditions and order of development of the symptoms—viz., insidious and progressive atrophy of groups of muscles to the exclusion of others, beginning usually in the hand or more rarely in the shoulder and upper arm; accompanied by a corresponding loss of power in the affected muscles and partial or complete reaction of degeneration in the same, by diminished reflexes and fibrillar twitchings.

**Differential Diagnosis.**—From *amyotrophic lateral sclerosis* it is to be distinguished by its greatly *slower course* and *absence of the reflexes* and of *spastic symptoms*. It is also to be distinguished from *muscular dystrophy* in its various forms—the myopathic juvenile muscular atrophy of Erb, pseudohypertrophic muscular paralysis, and Duchenne's infantile type. In the *juvenile progressive muscular atrophy of Erb* there is also slow symmetrical, and intermittent wasting, with weakness in certain groups of muscles, especially those of the shoulder girdle and upper arm, and later possibly the pelvis, upper thigh, and back, associated at times with true or false *muscular hypertrophy*, but usually unassociated with *fibrillar contraction* or reaction of degeneration. The average age, also, in the juvenile form is much less, Erb's cases ranging from seven to 46  $\frac{1}{2}$  or an average of 26  $\frac{1}{2}$ , while in the spinal form or true progressive spinal muscular atrophy the average age is much greater. Of Roberts' cases, all of which seem to be true cases of progressive spinal muscular atrophy, the youngest was 20, while the ages of the remaining four were 38, 39, 47, and 67.

While in the *pseudohypertrophic* form there are also great weakness and wasting of muscles, though the latter may be obscured by the fatty deposit, there are *no alterations in the spinal cord*. It is a disease of childhood, and strikingly *hereditary*, beginning in the lower extremities, while progressive muscular atrophy is a disease of adults, is not hereditary, and begins usually in the upper extremities.

*Duchenne's infantile type* is characterized by onset at an *early age*,

infancy or adolescence, and by *beginning in the facial muscles*. It is often hereditary. The distribution of the atrophy is very similar to that of Erb's form, when the disease has involved the muscles of the shoulders, but it begins in the face and may be confined to the face. The muscles of the hands and fingers are spared in Duchenne's form; *fibrillar tremors* are not present, and there is no reaction of degeneration.

**Prognosis.**—Many years are required to develop these symptoms in their entirety, and there may be spontaneous arrest, during which the patient may die of other causes. Sooner or later, if the patient lives, they recur, and their march is irresistible.

**Treatment.**—It has already been said that cure is impossible, although well-authenticated cases of arrest are reported. *Mercurials* and *iodid of potassium* should be used in cases of suspected syphilitic origin. Cooke reports a case of arrest under a course of mercury, after the disease had progressed for five years, during which many remedies were tried. In the main the treatment must consist of measures intended to *maintain the health and strength* of the patient and to counteract the muscular wasting. To the former end an abundance of nutritious food, fresh air, and outdoor life should be supplied, while tonics, including, especially, cod-liver oil, iron, arsenic, and strychnin, are indicated. The muscular wasting may be combated by *electricity* and *judicious massage*. Both kinds of *electricity* may be used, the faradic with rapid interruption to stimulate the circulation, or with slow interruption to excite individual muscles to contraction. The current should be of moderate strength, not too frequently interrupted, and continued for a few minutes only. Duchenne recommended, particularly, treatment of important muscles, like the diaphragm through the phrenic nerve, or the intercostal muscles and the deltoids before they are actually invaded by the disease. In evidence of its usefulness he relates the case of a man who had lost many of his trunk muscles, and who was beginning to suffer from dyspnea, on whom faradization of the phrenic nerves, repeated three or four times a week, was of great service, enabling him to walk considerable distances and to go upstairs without fatigue. Another patient, whose arms were much wasted, was again able to support his family. The direct current—galvanism—is useful in advanced stages of the disease, when the strongest faradic currents fail to produce response. When galvanic currents fail to excite contractions, the treatment ought to be persevered in for a long time, using very strong currents at the onset, gradually reducing them as contractility returns. Remak, who especially advocated the use of the continuous current, advised placing the positive pole in the front of one mastoid process and the negative pole on the opposite side of the neck, near the spinous process of the vertebræ, not higher than the fifth cervical, by which he produced the contractions already described as diplegic in the fingers and other paralyzed parts. Galvanization of the sympathetic has been apparently useful in the hands of some, Erb reporting a case of complete cure.

Massage is especially important, and should be used in connection with electricity, but at a different time of day. Eulenberg refers to a case said to have been brought to a standstill by it.

Hypodermic injections of strychnin, from 1/100 to 1/40 grain (0.0005 to 0.002 gm.), are said to have arrested the disease on the authority of Gowers.

In families in which a hereditary tendency exists prophylactic treatment should be used. It should include hygienic measures of the kind already referred to and the avoidance of undue fatigue and exposure, and in the selection of an occupation these matters should be kept in view. On the supposition that the disease is a purely local one, gymnastics involving the exercise of the groups of muscles prone to attack are indicated, but assume less importance from the standpoint that it is a spinal cord disease. At the same time the patient should have the benefit of any doubt in the pathogeny, and as gymnastics are eminently calculated to improve the general health and thus indirectly to avert disease, their use is indicated on these grounds.

## DISEASES OF THE BRAIN.

### LOCALIZATION OF CEREBRAL DISEASE.

SYNONYMS.—*Cerebral Localization; Relation of Locality to Symptoms; Topical Diagnosis of Cerebral Lesions.*

**Physiology.**—The brain is the organ of consciousness and of perception of impressions and sensations—of memory, of thought, of origination of voluntary motion, and of speech. It is also the seat of the instinctive acts. It has been learned from clinical observation in connection with studies at the autopsy table and from experiment that certain parts of the cortex are concerned with corresponding offices, especially motion, speech, vision, and hearing, so that from the presence of given symptoms the involvement of corresponding localities may be inferred. Allusion has already been made to the subject of topical diagnosis, on page 930. Such diagnosis, it is important to remember, gives no information as to the nature of the lesion, the result being the same whether it be abscess, hemorrhage, or softening. We are simply informed that such and such area is involved.

**Historical.**—As early as 1825 Bouillaud asserted that derangements of speech are produced only by disease of the anterior lobes of the brain. In 1836 Marc Dax, also a French physician, pointed out that aphasia was caused only by lesions in the *left* half of the brain. In 1861 Broca announced that aphasia results from a lesion of the third left frontal convolution, which was accordingly called the convolution of Broca. Other observations show that it is the posterior part, or the *pars opercularis*—the part of the frontal lobe covering the island of Reil, which is the speech center, and, further, that lesions here are the cause of motor aphasia only. The publications of Marie are extremely radical. He denies the importance of Broca's center and advances views very different from those previously held regarding aphasia. In 1870 Fritsch and Hitzig published the results of their experiments in irritating the surface of the brain in animals, such irritation being followed by muscular contractions in definite portions of the opposite side of the body. These observations were rapidly confirmed and extended in further experiments by Meynert and Flechsig among anatomists Ferrier, Munk, Goltz, and others among physiologists, and Charcot, Nothnagel, Hughlings Jackson, Horsley, Marie, Grünbaum and Sherrington, among clinicians. Our knowledge in this department is, however still inexact, and is likely to be altered as well as increased by further studies.

## I. THE MOTOR AREAS OF THE CORTEX.

An examination of the following illustrations (Figs. 116 and 117) will convey an idea of the gyri and sulci of the surface of the brain.

**Functional Assignments.**—The motor region was formerly regarded as made up of the two central convolutions, anterior central and posterior central, also known as ascending frontal and ascending parietal; the posterior part of the three frontal convolutions; the upper part of the parietal lobe adjoining the ascending parietal convolution, and the paracentral lobule (Fig. 117) on the median surface of the hemisphere. The investigations of Grünbaum and Sherrington<sup>1</sup> on the gorilla seem to show that the

FIG. 116.—Lateral Aspect of the Brain—(after Ecker, modified).

motor cortex is entirely in front of the Rolandic fissure, and this view has been widely accepted (Fig. 116). All diseases which destroy any considerable portion of this cortical area invariably produce paralysis of the opposite half of the body, while no matter how extensive the destructive process elsewhere in the cortex, motion remains intact if this is not touched. An acute cortical lesion sufficient to involve all the motor centers of one side and cause total hemiplegia would be likely to be fatal, while a smaller lesion, extending into the white matter, involving fibers coming from uninjured portions of the cortex, might produce a more extensive palsy than a more superficial cortical lesion.

We can even point out separate regions which act as separate centers for various groups of muscles. The center for the movements of the facial muscles lies at the lower end of the precentral convolution (Figs. 116 and 117). Near

<sup>1</sup>Sherrington. The Integration Action of the Nervous System, London, 1906.

by and lower down is the center for movements of the tongue and vocal cords, while the center for the movements of the arm lies somewhat higher than that for the face—that is, about the middle of the anterior central convolution. From above downward the various segments are represented as follows: Shoulder, elbow, wrist, fingers—the index finger and, lowest of all, the thumb. The center for the leg lies in the uppermost part of the central convolutions, but mostly in the paracentral lobule. Most

FIG. 117.—Brain of a chimpanzee (*Troglodytes niger*)—(from Grünbaum and Sherrington).

Left hemisphere viewed from side and above so as to obtain as far as possible the configuration of the *sulcus centralis* area. The figure involves, nevertheless, considerable foreshortening about the top and bottom of *sulcus centralis*. The extent of the "motor" area on the free surface of the hemisphere is indicated by the black stippling, which extends back to the *sulcus centralis*. Much of the "motor" area is hidden in sulci; for instance, the area extends into the *sulcus centralis* and the *sulci precentrales*, also into occasional sulci which cross the precentral gyrus. The names printed large on the stippled area indicate the main regions of the "motor" area; the names printed small outside the brain, indicate broadly by their pointing lines the relative topography of some of the chief subdivisions of the main regions of the "motor" cortex. But there exists much overlapping of the areas and of their subdivisions which the diagram does not attempt to indicate.

The shaded regions, marked "eyes," indicate in the frontal and occipital regions, respectively, the portions of cortex which, under faradization, yield conjugate movements of the eye balls. But it is questionable whether these reactions sufficiently resemble those of the "motor" area to be included with them. They are therefore marked in vertical shading instead of stippling, as is the "motor" area. S. F., superior frontal sulcus. S. Pr., superior precentral sulcus. I. Pr., inferior precentral sulcus.

anterior is the hip, next the knee and ankle, next the great toe, the center for the movement of which surrounds the upper end of the fissure of Rolando; still further back are the centers for the small toes. The center for the trunk is situated in the precentral convolution between those for the upper and lower limbs. The different regions are not sharply defined, but merge into one another.

As to the so-called *muscular sense*, it has been believed that it resides also in the motor area, while there have been those who have claimed for

it also a separate and different localization. M. Allen Starr and A. J. McCosh<sup>1</sup> have reported a case of injury with symptoms which go to prove the latter view and to show that the seat of the muscular sense is "a spot in the brain about at the junction of the superior and inferior parietal convolutions, clearly posterior to the posterior central convolution." The so-called muscular sense is probably largely represented in the parietal lobe.

These *cortical motor areas are united with spinal centers by nerve-fibers which proceed from cell to cell in each, without connection with intervening cells. Their route is through the white matter of the hemispheres, where they form the corona radiata, the fibers of which converge to the internal capsule which lies between the optic thalamus and the caudate nucleus on the inside, and the lenticular nucleus on the outside.* (See

FIG. 118.—Aspect of the Median Surface of the Cerebrum as it appears when the Two Hemispheres are Separated—(after Ecker).

The gyri and fissures are indicated by the lettering.

Fig. 120.) The anterior portion of the capsule—the knee—is occupied by the fibers from the face, tongue, eye, and speech centers; behind these lie the fibers from the upper extremities, while those from the lower extremities occupy the middle of the posterior part. Thence the fibers of the motor path pass into the crus cerebri through its middle third, then through the pons, covered by the superficial transverse fibers of this body, into the medulla oblongata, of which they form the anterior pyramids. At the lower portion of the medulla oblongata a large portion of these pyramidal fibers cross over into the opposite half of the spinal cord, constituting the crossed pyramidal tract of the lateral column, while a small bundle of fibers descends into the anterior column of the same side, forming the direct pyramidal tract, or Türk's column; some fibers probably pass to the lateral column of the same side. Both pyramidal tracts diminish in bulk as they descend, because they give off fibers which pass into

<sup>1</sup> "Amer. Jour. of the Med. Sciences," November, 1894, p. 520.

gray matter, dividing and subdividing, to come into contact with the protoplasmic processes which are continuous with the large nerve-cells of the anterior cornua.

These motor fibers form the *upper or cerebrospinal segment* of the motor system. Between the motor nerve-cells in the anterior cornua and the muscles to which the motor nerve-fibers are distributed is the *lower or spino-muscular segment*. In response to the law already mentioned as to the nutritive independence of each neuron, each of these segments has a certain nutritional independence, depending for its integrity upon

FIG. 119.—Lateral Aspect of the Brain—(after v. Monakow).

Lateral aspect of the human cerebral hemisphere. Motor fields (principal foci) after Allen Starr, W. W. Keen, Charles K. Mills, Victor Horsley, and Monakow's observations. 3, Spot on the posterior central convolutions whose isolated irritation causes thumb movements, and whose destruction in a case of cranial injury caused continued defect of motion of the thumb and finger; also derangement of the stereognostic sense. The lines 9-9, 10-10, etc., 20-20 indicate certain planes of section in other figures in Monakow's monograph in Nothnagel's system.

the integrity of its neuron, the upper or cerebral depending upon the cortical cells and the lower upon the large cells in the anterior cornua.

*Lesions of the Upper Motor or Cerebrospinal Segment.*—If, therefore, the cortical cells of the motor area degenerate, the fibers attached to them will waste as far as the beginning of the lower segment, and if the cells in the latter degenerate or are cut off, not only do the nerve-fibers below them waste, but the muscles to which they are distributed as well. Accordingly, all the cases of paralysis due to *destructive* disease in the motor cortical region have been found associated with descending degeneration of the motor tract previously outlined, into the *direct* pyramidal tract in the anterior column of the cord on the same side, and the *crossed* pyramidal tract in the lateral column of the other side. At the same time

the paralysis is accompanied by a *spastic condition*, manifested by an exaggeration of the tendon reflexes and an increase in the tension of the muscles, ascribed to a loss of the inhibitory control exerted by the cells of the cortex in the normal state. This explanation, however, is not entirely satisfactory. In other respects the paralysis due to cortical lesion does not differ from that due to focal disease lower down in the upper tract, except that the latter is apt to involve more muscles because of the compactness of the tract at this point. Atrophy is usually not intense in muscles paralyzed by lesion of the upper segment, but occasionally is observed in muscles thus paralyzed, but the reaction of degeneration

FIG. 120.—The Motor Tract—(after Starr).

S, S, Fissure of Sylvius. NL, NL, Lenticular nucleus. OT, OT, Optic' thalamus. NC, NC., Caudate nucleus. C, Crus. P, Pons. M, Medulla. O, Olivary body. The tracts for the arm, leg, and face gather in the capsule and pass together to the lower pons, where the face fibers cross to the opposite seventh nerve nucleus, while the others pass to the lower medulla, where they partially decussate, to enter the lateral columns of the cord. The non-decussating fibers pass into the anterior median columns.

does not occur. Lesions of the motor cortex are sometimes limited, causing correspondingly limited paralysis and even monoplegias, never, however, affecting less than a whole limb or a segment of a limb. A lesion may involve two centers lying close to each other, producing paralysis of the face and arm or of the arm and leg, but rarely of the face and leg without involvement of the arm. It happens not infrequently that the whole motor cortex is involved, producing paralysis of one side—cortical hemiplegia. The lesion then is usually thrombosis of the middle cerebral artery.

Such is the effect of destructive lesion of the cortex. Quite different is that of *irritative* lesions. These produce convulsive seizures known

as Jacksonian or cortical epilepsy, characterized by convulsions beginning in a single muscle or group of muscles and proceeding in a definite order to the involvement of other muscles corresponding to portions of the cortex affected. Thus, the convulsions may begin in the face, and extend thence to the arm and thence to the leg. The convulsions may also be accompanied by sensory symptoms and followed by weakness of the muscles involved, as a result of exhaustion of the motor centers implicated.

In point of fact, most lesions of the cortex are both destructive and irritative, consisting in the destruction of nerve-cells in one center and increasing the activity of cells of neighboring centers.

Lesions of the upper segment include hemorrhages, tumors, abscesses, injuries, inflammations, and degenerations involving the brain and spinal cord.

*Lesions of the Lower or Spinomuscular Segment.*—Here, as in the upper segment, the *destructive* lesions produce motor paralysis. The added peculiarity is, however, a degeneration of the muscles as well as the nerve-fibers distributed to them from the motor cells of the anterior cornua, as evidenced by the wasting of the muscles, and further characterized by the presence of the reaction of degeneration described on page 946. In these lesions there is also a loss of reflex excitability in the areas supplied from the segments destroyed, the reflexes are lost, and there is reduced muscular tension. Lesions of the lower segment may also cause paralysis of limited groups of muscles when confined to limited areas of the cord.

*Irritative* lesions of the lower segment do not occur unless we regard as the result of such the slow atrophy of the ganglion cells of the anterior cornua in progressive spinal muscular atrophy, and consider the fibrillary contractions found in this affection as a result of the stimulation of these cells in their slow degeneration.

## II. SENSORY AREAS OF THE CORTEX AND SENSORY PATHS.

Our knowledge of the sensory areas is much less definite than that of the motor. Beginning at the periphery, we learn that sensory fibers emanating from tactile surfaces, like the skin, promptly and for the most part become associated with motor nerve filaments in the lower motor segment, the union of both constituting a mixed nerve. The two sets of fibers, however, separate again within the spinal canal, the motor filaments are continuous with the anterior roots, and the sensory enter the cord by the posterior, on which is a ganglion. The areas whence the posterior roots gather their nerves will be found in Starr's table on page 1078. The precise routes of sensory impressions to the brain are not determined, but experiment and clinical pathology show that probably a considerable number of sensory fibers cross at once and become associated with other fibers which ascend to the brain in the opposite half of the cord. The following seems to be the results of the latest histological studies:

The sensory nerve-fibers, entering the spinal cord from the spinal ganglion on the posterior root, pass to the posterior columns and divide dichotomously, one branch passing upward, the other downward. From

peripheral centripetal neuron); *F. c.*, axon of fasciculus cuneatus; *F. cls.*, axon of fasciculus cerebellospinalis (direct cerebellar tract); *F. vl. G.*, axon of fasciculus ventrolateralis [Gowers]; *St. i. l.*, axons of stratum interolivare lemnisci; 1, cell bodies of peripheral centripetal neurons (situated in the spinal ganglia); 1', ascending limb of bifurcated central axon of peripheral sensory neuron extending from the pars lumbalis of the spinal cord to the medulla oblongata, being situated first in the fasciculus cuneatus, in higher levels of the cord in the fasciculus gracilis, and finally terminating in the nucleus funiculi gracilis. 1'', ascending limb of bifurcated central axon of peripheral sensory neuron pertaining to the thoracic portion of the spinal cord. It enters the fasciculus cuneatus, and passing upward, approaches the medial border of this fasciculus without, however, entering the fasciculus gracilis. It is seen to terminate ultimately in the nucleus funiculi cuneati. 1''', ascending limb of bifurcated central axon of peripheral sensory neuron pertaining to the pars cervicalis of the spinal cord. It passes upward in the fasciculus cuneatus to terminate at a level higher than that indicated in the diagram. 1''', reflex collaterals extending from the central axons (or their subdivisions) of the peripheral sensory neurons to the ventral horns of the spinal cord, there coming into conduction relation with the cell bodies and dendrites of the lower motor neurons. 1, collaterals from the axons of the fasciculus cuneatus to the nucleus dorsalis [Clarkii]; 2, cell bodies in substantia grisea giving rise to axons of the fasciculus ventrolateralis [Gowers]; 2', axons of fasciculus ventrolateralis [Gowers]; 3, cell body in nucleus dorsalis [Clarkii] giving rise to axon of fasciculus cerebellospinalis; 3', axon of fasciculus cerebellospinalis (direct cerebellar tract); 4, cells of nucleus funiculi gracilis giving rise to axons of fibræ arcuatæ internæ which undergo decussation (decussatio lemniscorum) in the raphe; 4', continuation of axons of fibræ arcuatæ internæ after decussation. They run cerebralward in the stratum interolivare lemnisci. 5, cells of nucleus funiculi cuneati which give rise to axons of fibræ arcuatæ internæ which undergo decussation (decussatio lemniscorum) in the raphe. 5', continuation of axons of fibræ arcuatæ internæ after decussation. Having had their origin in the nucleus funiculi cuneati of the opposite side, they now run forward in the stratum interolivare lemnisci.

*Blue.*—The areas of white matter in the spinal cord and medulla oblongata indicated by parallel blue lines correspond to the position of the fasciculi cerebrospinales (pyramidales). The cell bodies and axons of the lower motor neurons are also printed in blue. *F. cs. l.*, fasciculus cerebrospinalis lateralis or lateral pyramidal tract; *F. cs. v.*, fasciculus cerebrospinalis ventralis or ventral pyramidal tract; *F. Py.*, fasciculi pyramidales in the medulla oblongata; *Py.*, pyramis medullæ oblongatæ, *v. r.*, radix ventralis, nervi spinalis; 1, cell bodies of lower motor neurons situated in the ventral horns of the gray matter of the spinal cord giving off axons which go to form the ventral roots of the spinal nerves; 3', axons of fasciculi pyramidales which undergo decussation in the decussatio pyramidum and pass down in the fasciculus cerebrospinalis lateralis of the opposite side of the spinal cord to terminate in the ventral horns of the cervical region. They throw the lower motor neurons which innervate the musculature of the upper extremity of one side under the influence of the pallium of the opposite side. 4', axons of fasciculi pyramidales which undergo decussation in the decussatio pyramidum and pass down in the fasciculus cerebrospinalis lateralis of the opposite side of the spinal cord to terminate in the ventral horns of the lumbosacral region. They throw the lower motor neurons which innervate the musculature of the lower extremity of one side of the body under the influence of the pallium of the opposite side. 4'', axon of fasciculi pyramidales which does not undergo decussation in the decussatio pyramidum, but passes down in the fasciculus cerebrospinalis lateralis of the same side (homolateral fiber). 4''', axon of fasciculi pyramidales which does not undergo decussation in the decussatio pyramidum, but passes down in the fasciculus cerebrospinalis ventralis to terminate in the ventral horn of the same side. It would throw the lower motor neurons governing a portion of the musculature of one side under the influence of the pallium of the same side. It is probable that in addition to these fibers of the fasciculus cerebrospinalis ventralis, which terminate in the ventral horn of the same side, there are other fibers (not shown in the diagram) which, passing through the ventral commissure, terminate in the ventral horn of the opposite side. (See text.)

*Yellow.*—Cell bodies, axons, collaterals, and terminals belonging to the fasciculi proprii of the ventral and lateral funiculi—(Barker).

ganglion cells in the anterior and posterior horns and in Clarke's column. From these ganglion cells other nerve-fibers are projected, the course of which is not clear except as to those which pass into the anterior roots, and those from Clarke's column which pass over to form the ascending cerebellar tract. Some pass up the anterolateral columns, some decussate through the gray commissure with fibers from the opposite side. Many fibers from the posterior roots ascend in the posterior columns of the same side and decussate in the medulla oblongata to form the fillet or lemniscus. Further confirmation of this course is found in the fact that if a posterior nerve-root is cut, the ascending Wallerian degeneration is

seen only in the posterior columns of the same side, and ceases in the nuclei of the *funiculus gracilis* or *funiculus cuneatus*, which are ganglionic bodies in the medulla oblongata beginning another stage of the sensory path. It is questionable whether there are separate strands of conduction for tactile, thermal, or painful impressions, but probably there are such fibers. The experiments of Gotch, Horsley, and Mott also go to show that tactile impressions pass up the same side in the posterior columns, while impressions made by pain, cold, and heat radiate into the gray matter of the cord, and through these probably again into the white conducting tracts of the lateral column. Hence pain and painful temperature sensations are only of different degrees, and excite a wider and more complex nervous mechanism than simple touch. Whence not only diseases involving extensively the gray matter, as syringomyelia, cause alteration in the temperature sense, but also diseases of peripheral parts, as pachymeningitis and neuritis. Many hold very different views from those just expressed and believe that different fibers exist for the conduction of the different forms of sensation.

Many investigators believe that all the sensory fibers of the opposite side of the body are collected in the posterior third of the posterior limb of the internal capsule, just behind the motor fibers of the upper segment. Dejerine utterly rejects this teaching, and holds that the sensory fibers are mingled with the motor in the posterior limbs of the internal capsule.

SENSORY AREAS IN THE CORTEX.—Much doubt exists as to the seat of the sensory areas in the cortex. Horsley suggested that the muscular and tactile senses are localized in the motor cortex, and that two of the three principal layers of cells in this region subserve these functions. The experimental studies of Munk lead to the same conclusions—that the so-called "sphere of sensation" lies in the same region as the motor centers of the cortex. Dana also has shown that many lesions of the motor area, especially in the hinder part, are associated with anesthesia, while Ferrier considers the *hippocampal convolution*, and Schäfer the *gyrus fornicatus*, as the sensory center in the cortex. Clinical evidence on this point is not uniform. In some cases of motor paralysis there is undoubted simultaneous disturbance of sensation, in others not. By some the parietal lobe is considered the important sensory area, and the weight of opinion is in favor of this view. The muscular sense is also sometimes impaired in paralyzed limbs, in consequence of which the patient cannot tell with his eyes closed the position of the affected limb.

Among the cortical areas representing sensation must be included those for sight, hearing, smell, and taste, which will be considered in connection with affections of the peripheral nerve. Suffice it to say, briefly, that the auditory center is located in the first temporal gyrus, the visual in the occipital lobe, the cortical visual center being on the mesial surface in the *cuneus*, especially about the calcarine ("calcar," a spur) fissure, where are represented the opposite half visual fields. Some authorities include more of the occipital lobe than this in the visual area.

LESIONS OF THE SENSORY TRACT.—These may also be *destructive* or *irritative*. *Destructive lesions* would, of course, destroy sensation in the part whence the nervous supply comes to the point of lesion. Most fre-

quently it is an injury to a peripheral nerve, though loss of sensation is rarely complete in the part to which such nerve is distributed, because that area may receive sensory nerves from another segment of the spinal cord. Complete transverse section of the spinal cord itself causes complete anesthesia in the parts supplied from the segment below the injury. The effects of a lesion invading one-half of the cord are detailed on page 988.

*Irritative* lesions of the sensory path cause paresthesias, including formication, tingling, numbness, and finally pain corresponding to the degree of irritation. The last is commonly due to irritation in the course of a peripheral nerve, though it may also be caused by irritation to the sensory path within the central nervous system.

## CORTICAL AREAS COVERING SPEECH.

### THE VARIOUS FORMS OF APHASIA AND THEIR ANATOMICAL LESIONS.

It has already been stated that almost our first accurate knowledge of cerebral localization was the discovery by Broca, in 1861, that derangements of speech result from lesions of the third or inferior left frontal convolution. The loss of power to comprehend words correctly and to use them properly is covered by the general term *aphasia*. Further derange-

FIG. 122.—Primitive Speech Apparatus of the Child in Mechanical Repetition of Words, according to Wernicke and Lichtheim.  
*a*, Sensory speech center. *b*, Motor speech center. *x*, Acoustic center of pure sense of hearing.  
*m-x*, Route to acoustic center. *b-n*, Motor speech tract.

ment consists in inability to articulate words, and is due to lesions of nuclei situated for the most part in the pons and medulla oblongata, regulating the action of the vocal cords, the tongue, and the lips, and is known as *anarthria* or *dysarthria*.

The study of the phenomena of aphasia will be facilitated by a brief review of the conditions of acquired language. Language is acquired

by the child gradually through imitation. Thus, when the mother teaches it to say "cat" or "bell" or "papa," she names the word, and its sound impresses the distribution of the auditory nerve, *m* (see diagram, p. 1071) whence it passes to the *acoustic center*, *x*, and thence to the sensory *speech* center, *a*, in the first or *upper temporal* convolution, where it is stored as a sound memory. From this it passes from behind forward along the association fibers to *b*, the motor speech center in the left inferior *frontal* convolution (Broca's center, propositionizing center of Broadbent),<sup>1</sup>

FIG. 123.—Wernicke's Schema, Showing the Association of the Various Partial Conceptions to Form the Whole Conception or Word Image of an Object.

For the sake of simplicity only three partial conceptions and three sensory areas are shown, instead of the many which go to make up our notions of complex objects. The letters *a*, *b*, *m*, and *n* have the same application as in the previous figure, but *x* may indicate the seat of any of the special senses—hearing, vision, smell, touch.

whence the muscles of articulation are put into operation and the word is spoken. Thus, the speech mechanism consists of *receptive*, *perceptive*, and *emissive* centers.

The development of *voluntary* speech in the child continues through the accumulation of associated ideas in the perceptive and emissive centers, *a* and *b*. The *word image* or picture which is the foundation of every word is made up of the sum of a number of partial conceptions of memory pictures acquired by experience and stored for further use in the different sensory areas of the cerebral cortex. Thus, the memory of the *sound* of a word as spoken, the memory of the *appearance* of a word as written or printed, as well as the *muscular movements* needed to speak the word

<sup>1</sup> That is, the center where thoughts are set in a framework of words, but through which utterance is not consummated; whence other cortical centers are necessary to motor speech, and these are found caudal of Broca's convolutions at the foot of the two central convolutions. This region Broadbent calls the *uttering center*.

or write it, are distinct from one another and yet associated. Loss of one of these memory pictures or derangement in their association impairs the integrity of the word image and produces such defects in the use of the word as are covered by the different varieties of aphasia. These derangements have been arranged in two divisions, according as the defect is in (1) the receptive and perceptive and (2) emissive function of the brain, the former constituting the *sensory* aphasias, the latter the *motor*.

#### THE PHYSICAL BASIS OF THOUGHT—APRAXIA.

A *word* is a means of expression of a thought. Thus, when we say the word "bell," with a full conception of its meaning, such conception or mental picture is made up of as many distinct partial conceptions or memory pictures as there are special senses, these conceptions being seated in the most diverse parts of the brain. Especially concerned in the case of the bell is the acoustic conception, *c*, derived from its sound; the optic, *c'*, from its appearance; the tactile, *c''*, from what is learned by touch, united to form one conception, as shown in Fig. 122, where the partial conceptions, *c*, *c'*, *c''*, among others, taken together, give us the idea of a bell. In the blind, of course, the sensory perceptions are smell, taste, touch, and hearing only. The schema of conscious voluntary speech may be still further simplified by combining the partial conceptions, *c*, *c'*, and *c''*, into one single point, *C* (Fig. 123), as the sum of intellectual concepts, *m* representing any of the special senses—hearing, vision, smell, etc.

Broadbent has gone a step further, and suggested the existence of a center on the sensory side of the nervous system, to which converge sensory fibers from all the receptive centers and in which is combined all the evidence respecting the nature of the object, which he called the *naming center*. He suggested a locality for this center in an unnamed lobule on the under surface of the temporal lobe near its junction with the occipital lobe. Charles K. Mills<sup>1</sup> has reported a case of glioma with autopsy which goes to confirm Broadbent's speculation and to locate the exact position of this center in the *third temporal convolution*. Its correlative center is the *propositionizing* center referred to on page 1071, in which names or nouns are set in a framework for outward expression or utterance.

The loss of these memory pictures is known as *apraxia*, which may be defined as a state in which there is impairment or loss of the power to recognize the nature and purpose of objects, and which is something apart from aphasia. In one form of it any object, such as a watch, a knife, or a spoon, may be taken up and handled by the patient, but all knowledge of its use or purpose is gone. Such a condition, when dependent on loss of the visual memories, was well named by Munk *mind-blindness*. A person formerly familiar with the tick of a watch or the sound of a bell no longer interprets such sounds aright; or is unable to follow melodies or appreciate music as he once did. Thus we have *mind-deafness*, or auditory amnesia, or in the case of music, *amusia*. Again, the odor of the

<sup>1</sup> Dercum, "Diseases of the Nervous System" by American authors, p. 427, 1895.

rose and violet no longer suggests these flowers, giving *mind anosmia*; or the taste of an orange, *mind agcusia*; or the soft feel of fur or velvet gives no notion of these substances, *mind atactilia*. For the sum of these defects the term *apraxia* is now used, but mind-blindness and mind-deafness are the most important subvarieties. Apraxia may occur alone, but it is usually associated with sensory or motor aphasia. In simple apraxia the patient may be able to read, but the words arouse no intelligent impression in his mind. Some observations go to show that the lesion in mind-blindness is in the *supramarginal and angular gyri*, or in the tracts interior to these in the white matter beneath them; and possibly mind-blindness only occurs when this area is injured, as pointed out by M. Allen Starr, in the left hemisphere in right-handed persons, and

FIG. 124.—Simplification of the Schema of Voluntary Speech by Uniting the Ideas into the Point, C, and Omitting the Acoustic Center, x.

The letters have the same meaning as in Figures 122 and 123.

in the right hemisphere in those left-handed. Mind-blindness is, however, at times functional and transitory, and as such is associated with many forms of mental disturbance. Starr also considers it probable from the association of psychical or *mind-deafness* with the form of aphasia known as *word-deafness*, to be considered presently, that mind-deafness may be due to lesion in the *upper temporal convolution*, though autopsies are wanting.

There are as many varieties of apraxia as there are organs of sense, but the most common appears to be psychical or mind-blindness, generally associated with the form of aphasia known as word-blindness. The seat of the lesion in mind-atactilia has been placed in the gyrus fornicatus, hippocampal gyrus, precuneus and postparietal gyrus. Mind anosmia in the uncinate and hippocampal gyri, and mind ageusia in the temporal gyrus.

## APHASIA, OR LOSS OF THE FACULTY OF SPEECH.

Aphasia is sensory or motor according as it is caused by a loss of memory of words, or by an inability to enunciate—according as it is the receptive or the emissive center which is at fault.

**Sensory Aphasia.** Including **Word-blindness**, **Word-deafness**, **Amnesic Aphasia**.—By *word-blindness* is meant loss of the memory of the appearance of a word. In this condition the patient does not recognize words which he sees on the written or printed page, and although he may be able to pronounce them after hearing them or write them at dictation or copy them, he does not understand what he reads or writes. On the other hand, *figures* are sometimes recalled when words are forgotten, and the patient may even be able to solve mathematical problems and to recognize playing-cards. Word-blindness may occur alone or with

FIG. 125.—Situations of Lesions Causing Aphasia—(after Starr).

*F*<sup>1</sup>, First frontal convolution. *F*<sup>2</sup>, Second frontal. *F*<sup>3</sup>, Third frontal. *T*<sup>1</sup>, First temporal. *T*<sup>2</sup>, Second temporal. *T*<sup>3</sup>, Third temporal. *P*<sup>1</sup>, First parietal. *P*<sup>2</sup>, Second parietal. 1, Lesion of word-deafness and deafness for musical sounds, or mind-deafness, according to M. Allen Starr. 2, Lesion of mind-blindness and word-blindness, according to Ferrier. 3, Lesion of motor aphasia. 4, Supposed lesion of agraphia.

*motor aphasia*. The lesion in most cases of word-blindness has been in the *angular* and *supramarginal* gyri on the left side, as located by Ferrier, but this area is not believed by all to be the center for word-seeing. *Alexia*, or inability to read, is a corollary growing out of this, as is also *agraphia*, or inability to write, so far as it depends on sight. It is often associated, as already stated, with *mind-blindness*, but may occur independently of it.

*Word-deafness* is a condition in which the patient has forgotten the significance of spoken words, although he hears them as sounds. The words of his own language are as a foreign tongue which he does not understand, while there is deafness also to musical sounds—*amusia*, the "*Tontaubheit*" of the Germans. Word-deafness is commonly associated with other forms of sensory aphasia in various degrees, but cases of pure word-deafness occur in which the patient has been able to read and to speak, but is unable to recognize the meaning of a word when spoken. It is a rare variety of deafness whose *lesion* is placed by most students of the subject in the first *temporal convolution* or its posterior part, but

Starr, basing his conclusion on 50 cases which he has collected with autopsies, places it, with Seppilli, in the *posterior half* of both the *first and second temporal* convolutions of the left side in right-handed persons, and of the right side in left-handed persons, as shown in the drawing. Recent investigations indicate that the posterior convolutions in the left island of Reil in right-handed persons is important in word hearing.

A simple variety of sensory aphasia is *amnesic aphasia*, in which the patient simply forgets words—just as we are all, at times, at loss for a word. Such a person sees a dog or another animal, knows perfectly well what it is, but cannot recall its name. The moment, however, the word “dog” is suggested, he knows all about it. In disease usually a

FIG. 126.—The Left Hemisphere, with the Fissure of Sylvius Drawn Apart in Order to Show the Convolutions in the Island of Reil or 5th Lobe. The Island of Reil is covered by the *pcrs opercularis* or posterior part of Broca's convolution, which is here drawn aside—(after Henle).

Sc. Sulcus centralis. Gca, Gcp. Gyrus centralis, anterior and posterior. Fop. Fissura parieto-occipitalis.

number of words are thus lost. Such aphasia is called *amnesic*, because it is really a loss of memory for words. It may be partial, as when a patient forgets nothing but his own name and remembers all other words, or when he is able to express himself in another tongue. If permanent, it is probably due to a *break in the association tract*, to be later considered, and should be so limited. Word-deafness may be distinguished from amnesic aphasia by asking the patient to do some act, such as to touch an object, when he will respond correctly if he has simple amnesic aphasia, but will not if he is the subject of word-deafness.

Allied to amnesic aphasia is sensory or *amnesic agraphia*, in which a word cannot be written because it cannot be called to mind. A person thus affected may be unable to write voluntarily, but may be able to

write at dictation if he is one who writes much. As already mentioned, agraphia also occurs as a part of word-blindness so far as it depends on sight.

**MOTOR OR ATAXIC APHASIA OR APHEMIA—ALALIA.**—In this condition the memory of the muscular action necessary to transfer the word image into speech is lost. There is disturbance of the emissive center, *b*, in which this transfer takes place. The patient knows perfectly well what he wishes to say, but cannot say it, though he may make the greatest effort to do so. Nor can he repeat a word after hearing it. The degree varies greatly. In complete cases he may be able to read, though not aloud, and understand what is said, but cannot say a word himself. More commonly, he can say one or two words, such as "no," "yes," while in mild cases he may simply misplace or omit letters, say "widow" instead of "window," or "wrelsters" instead of "wrestles." Singularly, too, when in a passion he may be able to say the right word or to swear. This is because such words are uttered, to a certain degree, involuntarily. A man acquainted with the French and German languages may lose the power of expressing his thoughts in them while retaining his mother tongue, and if completely aphasic, he may recover one language before the other. This is the form of aphasia long ago recognized by Broca and localized by him in the third left frontal convolution, and since this is in contact with the center for the face and arm, there is not infrequently partial or complete *right-sided hemiplegia*. *Alexia*, or inability to read aloud, is a necessary corollary to motor aphasia so far as it depends on the power to speak.

*Paraphasia*, or *mixed aphasia*, and *monophasia* are allied to motor or ataxic aphasia. Paraphasia is a confounding of words, the wrong word being used instead of the right one, because of a confusion between the idea and the proper word. All degrees of this also occur, only a single word being sometimes erroneously used, while in others whole sentences are wrong. The patient may also use a wrong word which has a certain resemblance to the correct one, beginning, for example, with the same syllable, as "between" for "bewitch"; or the idea usurps the situation, as in the case of one of Strümpell's patients, who called a white handkerchief "snow." In these cases the *association* or *conduction tract* between the *perceptive* center and the *emissive* center is broken whence it was called by Wernicke *aphasia of conduction*. The lesion in paraphasia is usually in the island of Reil and in the convolutions which unite the frontal and temporal lobes. But any disturbance in the association processes of language, no matter where the break lies, may cause it. In *monophasia* the patient can command but one syllable or one word or a short phrase, which he repeats over and over again.

*Motor agraphia* must also be distinguished from sensory. Sensory agraphia is sometimes amnesic—that is, the patient cannot write the word because he cannot call it to mind; at others it is a part of word-blindness. Motor agraphia is quite independent of ability to read aloud—that is, of effort memories necessary to speech, the difficulty being connected with the movements of the hand; but when motor aphasia exists, motor agraphia is usually also present. In sensory agraphia the patient may

still be able to write by dictation, in the latter not. Agraphia also varies greatly in degree. The patient may write one or two letters, or he may be totally unable to write voluntarily or from dictation. The seat of the *lesion* of motor agraphia is still unsettled. It was located by Charcot in the neighborhood of the middle of the anterior central *convolution*, but studies by Victor Horsley furnish some ground for locating it in the *posterior central* (*ascending parietal*) convolution. According to some authorities the graphic center is located in the *second frontal* convolution of the left side, near the ascending frontal convolution. Starr locates it in the middle of the convolution (Fig. 125). *Paragraphia* is a condition in which one word is written when another is intended. It is a corollary to paraphasia.

*Amimia* is the loss or impairment of the power of expression by signs when caused by cerebral disease. *Paramimia*, the misuse of signs in the attempt to express thought, is comparable to paraphasia for speech and paralexia for reading, and is dependent on a like cause—the *destruction or impairment of commissural or association tracts between sensory and motor centers*. It is not correct to suppose that the aphasic can substitute signs for words and thus express himself, for the two defects go hand in hand, even though he retain the power of moving his hands. A patient may, however, regain pantomimic power before he regains speech. Loss of pantomimic power is found often associated with *destruction of the third left frontal convolution*, or destruction of the receptive speech centers or their connecting tracts. It may accompany verbal amnesia due to disease of these areas or disturbance of the association tracts. Just as the aphasic may say "yes" when he means "no," so he may use a sign which will be affirmative when he intends to be negative.

The following table may aid somewhat a review of the previous text, while Fig. 125, from Starr's book of "Familiar Forms of Nervous Disease," shows the situation of the lesions causing aphasia:

APRAXIA, inability to recognize the nature and purpose of an object.

	<i>Seat of Lesion.</i>	
<i>Mind-blindness.</i>	Supramarginal and angular gyri, or the white matter beneath, in the left hemisphere in the right-handed and right hemisphere in the left-handed.	
<i>Mind-deafness, including amusia, or auditory amnesia.</i>	Upper temporal gyrus of left hemisphere in the right-handed.	
<i>Mind atactilia.</i>	Gyrus fornicatus, hippocampal gyrus, precuneus, and post-parietal (Mills).	
<i>Mind anosmia.</i>	Uncinate gyrus (Ferrier) and hippocampal gyrus.	
<i>Mind ageusia.</i>	Temporal gyrus (Ferrier).	

APHASIA, inability to comprehend words correctly and to use them properly.

<i>Sensory aphasia</i> , inability to recognize word pictures and word sounds, loss of memory of word pictures and word sounds.	<i>Word-blindness</i> , in which memory of the appearance of a word is lost.	Angular and supramarginal gyrus.
	<i>Word-deafness</i> , in which memory of the sound of a word is lost.	Posterior part of first and second temporal gyri (Seppilli and Starr).
	<i>Amnesia</i> , inability to recall a word.	Disturbance of association tract.

*Motor aphasia*, inability to utter words, though knowing well what to say.

Including *alexia*, or inability to read aloud.

Posterior part of third left frontal (Broca's convolution).

*Paraphasia.*

A confounding of words in speaking, in which the wrong word is used instead of the right one.

Island of Reil and any disturbance of the association tracts.

*Animia.*

Loss of power of expression by signs.

Third left frontal convolution, receiving or concept center. Disturbance of association tracts.

*Paramimia.*

Misuse of signs to express thought.

AGRAPHIA, inability to write.

*Sensory Agraphia.*

Inability to write because (a) of want of idea as to what a word is or (b) looks like.

(a) Amnesic agraphia.  
(b) A part of word-blindness.

*Scat.*

Association tract.  
Angular and supramarginal gyrus.

*Motor Agraphia.*

Inability to write because of want of motor power of writing, although the other movements of the hand may be excellent.

Not settled, but possibly middle of the ascending frontal convolution or ascending parietal—i. e., in the arm center. Possibly posterior part of second left frontal convolution.

Availing ourselves of Wernicke's condensed schema (Fig. 124), most aphasic derangements met in practice are easily explained by it by supposing lesion and interruption of conduction in certain places. According as the centripetal conduction, *m*, *a*, *C*, or the centrifugal conduction, *C*, *b*, *n*, is interrupted we have sensory or motor aphasia, while the interruption of the line, *a*, *b*, produces the conduction aphasia of Wernicke. Lesions between *a* and *b* on the one hand and *C* on the other are called *transcortical* aphasias; between *a* and *b*, *cortical*, and between *a* and *b* on the one hand and the periphery on the other, *subcortical*. These distinctions are schematic.

### DERANGEMENTS OF SPEECH OF IRRITATIVE ORIGIN.

In addition to those due to direct lesion of the speech centers there are also derangements of speech due to irritation. Such are the different kinds of stuttering, the labiochoreic and gutturotetanic stuttering and choreic speech. The first two probably reside in the cortical speech centers, but the choreic spasms not necessarily, since the function of muscles concerned in their production may be disturbed from lesions in other centers as well.

**Diagnosis.**—The study of derangements of speech is by no means an easy matter, but it may be facilitated by pursuing a systematic method like the following, which is that of M. Allen Starr, slightly modified:

- |  |   |  |
|--|---|--|
| <p>A. To determine whether apraxia is present.</p> <p>B. To test integrity of the auditory speech area and association tracts between other sensory areas and the temporal convolutions.</p> | { | <p>(1) Test the power of recognizing the nature, uses, and relations of objects.</p> <p>(1) The power to recall the spoken name of objects seen, heard, handled.</p> <p>(2) The power to understand speech and musical sounds.</p> <p>(3) The power to call to mind objects named.</p> |
|--|---|--|

C. To test the condition of the visual word memories in the angular gyrus and of the connections between this area and the surrounding sensory and motor areas.

D. To test the integrity of Broca's center and its association tracts.

- (1) The power to understand printed or written words.
- (2) The power to read aloud and understand what is read.
- (3) The power to recall objects whose names are seen.
- (4) The power to write spontaneously and to write the names of objects seen, heard, etc.
- (5) The power to copy and write at dictation.
- (6) The power to read understandingly what has been written.
- (1) The power to speak voluntarily; and if it is lost, the character of its defects.
- (2) The power of repeating words one after another.

When aphasia is associated, as is so often the case, with paralysis of the right arm, the writing test may be made with the left hand, when the patient may produce the so-called aphasic mirror writing, which can only be read by the use of a mirror; or if he cannot write with the left hand, as also happens, he may be asked to form words by letters cut out of printed pages or with the letter blocks of children.

FIG. 127.—Simplification of the Schema of Conscious Speech by Reduction of the Ideas to the Point, C, and Omission of the Acoustic Center, *x*.

The letters have the same application as in previous figures.

Recently Marie has announced some iconoclastic views as regards aphasia. He believes hearing is not localized in the first temporal convolution, and denies that impairment of hearing has ever been observed as a result of a lesion of the right first temporal convolution. In aphasia there is more or less difficulty in understanding spoken words due to defect of

intellect, and not to a lesion of the left third frontal convolution, since Broca's area has been destroyed without causing aphasia, and motor aphasia has occurred without a lesion in Broca's area. He declares that the left third frontal convolution plays no part in the function of language, and when a lesion occurs in this convolution the occurrence of aphasia is a mere coincidence. In motor aphasia which Marie calls the aphasia of Broca, the patient cannot read or write and understands imperfectly what is said to him. It is similar to sensory aphasia which he calls the aphasia of Wernicke, from which it differs solely in that the patient cannot speak. In what Marie calls anarthria the patient cannot speak, but understands what is said to him and can read and write. It is the condition described as subcortical motor aphasia. Everyone, says Marie, places the lesion of anarthria in or near the lenticular nucleus, it may be in the right hemisphere. When the lesion is limited to one hemisphere the anarthria tends to disappear, but is persistent when the lesion is within or near each lenticular nucleus and is usually a part of a pseudobulbar symptom-complex.

He also says aphasia is a unit and that the aphasia of Broca is only aphasia complicated by anarthria. According to Marie, the only region capable of causing aphasia when damaged is the zone of Wernicke, i.e., the supramarginal and angular gyri and foot of the first two temporal convolutions. The aphasia of Broca is caused by a lesion of Wernicke's zone, or of the fibers coming from it, associated with a lesion in or near the lenticular nucleus. The speech zone should not be divided into separate centers. The intensity of aphasia corresponds with the extent of the lesion. Dejerine denies most of Marie's assertions.

**Prognosis and Treatment.**—Aphasia is a symptom of a disease and not a disease itself. Yet it is a symptom which in its various phases informs us so precisely of the seat of the lesion that it sometimes suggests a point of operative interference comparatively easy of access. Where the symptoms of diffuse cerebral disease are wanting, and where the continuation of the symptoms and the addition of others suggest the presence of a possible circumscribed cause, such as abscess or tumor, operation is justified, and by it not only cortical, but also subcortical lesions and abscesses have been relieved. In cases of *sensory* aphasia the trephine should be applied over the upper part of the *temporoparietal* region, in *word-deafness* over the posterior part of the first *temporal*, in *word-blindness* over the *angular gyrus*, in word-deafness and word-blindness combined over the *inferior parietal* and *first temporal gyrus*, especially if verbal amnesia be present. In purely *motor aphasia*, in which the understanding of language is preserved but the power of talking lost, the trephine should be applied over the posterior part of the *third frontal convolution*, or Broca's center. The lesion of simple *agraphia* is not sufficiently determined to warrant surgical interference.

When urgent symptoms do not exist, attempt should be made to re-educate the patient, and much may be accomplished in this way by perseverance, especially in the young. With adults, the prognosis is more unfavorable, especially in cases of complete motor aphasia associated with right hemiplegia. In them the patient may be taught to write with his left hand: Sensory aphasia, if it exist alone, is commonly transient.

## CORTICAL AREAS WHOSE FUNCTION IS UNKNOWN OR UNCERTAIN.

After subtracting the motor, visual, and speech areas of the two hemispheres there remain extensive cortical areas, the function of which is more or less uncertain, and which are unexcitable. They include:

1. *The Frontal Region, Including all the Frontal Convolution except the Posterior Half of the Third Frontal on the Left Side, and if Starr be correct, the Middle of the Second Frontal Convolution on the Left Side where he Locates the Graphic Center.*—Of this area the most that can be said is that, if injured, mental symptoms are quite likely to be prominent—symptoms ascribable to a loss of self-control. It is to the greater development of the region of the frontal lobes in man as compared with the lower animals that his higher mental qualities are ascribed. Various forms and degrees of dementia have been observed after such lesions, and when such mental symptoms are present, it may with reason be inferred that there is lesion of the frontal lobes, especially of the left frontal lobe according to some investigators, more particularly when the lesion elsewhere can be excluded. It should never be forgotten, however, that the intellectual development depends on the integrity of the entire brain.

2. *The Region of the Cortex Lying between the Rolandic Fissure and the Occipital Convolution, Including all the Parietal Convolution except the Left Inferior Parietal Lobule.*—Recent investigations seem to show that this is the chief sensory region of the brain. The recognition of objects by contact when the eyes are closed, the sense of position, and general sensibility have all been found affected in extensive lesions of the parietal lobe.

3. *The Region Covering the Entire Temporosphenoïdal Lobe on the Right Side except the First Temporal, which probably has to do with hearing of ordinary sounds, and the temporosphenoïdal on the left side, excluding the parts not concerned in hearing of words, as well as ordinary sounds.* To the first temporal gyrus the function of hearing is assigned, but the remainder, so far as the cortex is concerned, appears unexcitable. Abscesses are common here after otitis media, and are sometimes reached with the trephine, the diagnosis being based on the presence of otitis with symptoms of brain disease.

4. *The Apex of the Temporosphenoïdal Lobe, including the uncinate convolution.* To this the olfactory sense has been ascribed with some show of reason.

5. *Of the Entire Median Surface of the Hemispheres, except the paracentral lobule, which is motor, and the cuneus, which is visual, and including the gyrus fornicatus and the hippocampal cortex, the function is unknown, although the hippocampal is probably a part of the olfactory area.*

TRACTS WITHIN THE BRAIN—CENTRUM OVALE, INTERNAL CAPSULE,  
CENTRAL GANGLIA, CORPORA QUADRIGEMINA.

CENTRUM OVALE.—In the centrum ovale, constituting the mass of white fibrous substance beneath the cortex and above the level of the basal ganglia, the fibers of the motor paths are more or less closely associated with other systems of fibers. They include three sets—*projection, com-*

*missural*, and *association* systems; the first connecting the cortex with nervous structures lying below it, the second joining the two hemispheres, while the third, or *association fibers*, join different parts of the same hemisphere. By these fibers adjacent convolutions, alternate convolutions, and more distant regions are connected, and through these as a physical basis the activities of the various cortical areas are harmonized and the different memories united.

The *diagnosis* of lesions involving this mass is exceedingly difficult. We can only surmise in cases of *disturbance of association*, such as occur with aphasia and kindred disorders, that the *association fibers* have been destroyed. A break in the continuity of the fibers of the corona radiata

FIG. 128.—Transverse Section through the Crura Cerebri in Secondary Degeneration of the Right Pyramidal Tract (after Churcol).

*sn.* Substantia nigra. *p.* The degenerated, and therefore translucent, pyramidal tract. *III.* Oculomotor nerves. *AS.* Aqueduct of Sylvius.

must produce the same symptoms as if the corresponding center were destroyed. Thus disease of the white substance of the *occipital lobe* may cause *hemianopsia*; of the *left temporal lobe*, *word-deafness*. If the coronal fibers which proceed from the *third left frontal convolution* are injured, *motor* or *ataxic aphasia* occurs; yet quite extensive disease of the white substance of the frontal lobe has been found postmortem without any symptoms having been present during life.

**INTERNAL CAPSULE.**—Since in the comparatively narrow space in the posterior limb of the internal capsule is centered the pyramidal tract on its way from the cerebral convolutions to the crus cerebri, a very limited focal disease in this locality will lead to hemiplegia on the opposite side, while clinical experience shows that almost all cases of persistent hemiplegia are occasioned by disease in this spot.

According to the views of many neurologists, a purely motor hemiplegia, unattended by impairment of sensation, implies a lesion that does not involve the most posterior portion of the internal capsule, while such involvement is probable when there is sensory disturbance as well as motor paralysis. Dejerine, on the other hand, believes that disturbance of sensation in hemiplegia indicates involvement of the optic thalamus, and that there is no distinct sensory tract in the posterior part of the posterior limb of the internal capsule.

CENTRAL GANGLIA—*i. e.*, *Caudate Nucleus*, *Lenticular Nucleus*, and *Optic Thalamus*.—In the writer's student days the corpus striatum was regarded as the great motor ganglion and the optic thalamus as sensory, while most hemiplegias were ascribed to lesions of the former, and hemianesthesia was ascribed to lesion of the optic thalamus. From what is said above it is evident that there is a tendency to return to these older views of the function of the thalamus. It is conceded, also, to-day that the optic thalamus may have to do with the movements of mimetic or emotional expression, such as laughing and crying, which are lost in lesion of the thalamus, but which remain when the thalamus is intact, even though the half of the face is paralyzed and cannot be moved voluntarily. It is also likely that some of the fibers of the optic tract terminate in the posterior portion of the thalamus known as the pulvinar, while most of the fibers go to the corpus geniculatum externum, and possibly some to the anterior colliculus of the corpora quadrigemina. Hence destruction of the hinder part of the thalamus produces complete hemianopsia of the opposite side, usually by destruction of the optic radiations. Focal disease of the thalamus has been supposed to cause posthemiplegic chorea and other posthemiplegic symptoms of irritation.

It would appear from recent experiments that the lenticular nucleus contains centers for regulating heat, which would explain certain temperature changes in cerebral affections.

Beyond this, little definite is known of the effect of lesions strictly limited to the central ganglia, while disorganization of these ganglia has been found unattended by any symptoms during life.

CORPORA QUADRIGEMINA AND CRURA CEREBRI.—Lesions of the *corpora quadrigemina* are rare. Not much, therefore, is known of their function. The anterior tubercles are connected with fibers of the optic tract, but the extent of the connection in man is uncertain. Unilateral, or even bilateral, *paralysis of the oculomotor nerve* has been observed in connection with lesions of the quadrigeminal bodies, as have also *nystagmus* and *immobility of the pupil*. But this is because the nuclei of the motor nerves of the eyeball, except the sixth, lie very close to the tubercles, and may, therefore, be involved in such a lesion. According to Nothnagel, a staggering gait with oculomotor paralysis, associated with general symptoms of a tumor, points to the corpora quadrigemina as its site. The oculomotor paralysis is apt to be of irregular distribution, involving upward and downward movements of the eye, and should be an early symptom. Tumor of the corpora quadrigemina causes early optic neuritis.

If a *crus of the cerebrum* is diseased, there often result characteristic symptoms—*viz.*, *paralysis of one side of the body* (arm, leg, and face), and on the side *opposite* the hemiplegia a *paralysis of the motor oculi*, or *third nerve*—crossed paralysis. An examination of Fig. 128, from Charcot, will explain this. A lesion on the right side at *p* in the right pyramidal tract, might involve the oculomotor nerve, III, on that side, but would produce a hemiplegia on the left side. Since the crus contains sensory fibers from the opposite side, a lesion in one crus may also produce hemianesthesia of the opposite side of the body. Tegmental lesions should also produce sensory paralysis.

## CEREBELLAR DISEASE.

The cerebellar lateral lobes may occasionally be the seat of extensive lesions which do not produce symptoms. The trunk and lower extremities are chiefly affected in cerebellar ataxia. The patient may be able to lie abed and move his legs much better than when standing, but as soon as he arises he begins to sway back and forth with his whole body. This tendency is increased if he brings his feet together, but is diminished while the legs are widely separated. In this respect cerebellar ataxia does not differ from the ataxia of posterior sclerosis. Closing the eyes may occasionally increase the ataxia, but usually does not do so markedly, because the cutaneous and muscular sensibility of the lower limbs remains normal. So, too, when the patient tries to walk, he totters, but there is none of the stamping gait of *tabes dorsalis*. It is more the true drunkard's reel, at one time forward, rolling now to one side and now to the other, but often with a distinct tendency toward one side or backward. Unfortunately, this gait is not so peculiar to cerebellar disease as to be pathognomonic of it, and we can only suggest that the cerebellum or its peduncles may be involved. The upper extremities are usually less affected than the lower, but Hughlings Jackson has called attention to a paresis of the trunk muscles as the result of which the movements of bending, erection, and lateral flexion of the trunk cannot be performed. The head is sometimes carried much inclined toward one side, but it is impossible to use this sign to determine with certainty the side on which the lesion is situated.

The *vertigo* of cerebellar disease, if severe, is one of the most distressing symptoms with which one can be afflicted. It varies greatly and is not constant, while it may be the only symptom. It occurs, however, under the same circumstances as the ataxia—that is, when the patient stands or moves about, disappearing when he lies down. The vertigo and ataxia are not necessarily associated, and either may be present and the other absent.

*Headache* is a frequent symptom in cerebellar disease, having been present in 83 out of 100 cases collected by W. C. Krauss. Most frequently it is occipital; more rarely there may be pain in the side of the head or in the forehead. *Vomiting* is also a result of chronic disorders of the cerebellum, being present in 69 of Krauss' cases. So is *visual disturbance* due to optic neuritis, which was found in 66 cases. None of these symptoms is pathognomonic, and each one may be a symptom of disease elsewhere in the brain. The most valuable, perhaps, is persistent *occipital headache*, especially if associated with the cerebellar gait. It might be expected that retained reflexes would be a distinctive sign as contrasted with their absence in *tabes dorsalis*; but, in fact, they are sometimes absent, this being the case no less than 12 times in Krauss' 100 cases.

Other symptoms which suggest cerebellar disease, but are not distinctive, are *neuralgic pains* in the region of the neck and occiput; blocking of the venæ Galeni and dilatation of the lateral ventricles producing *hydrocephalus* in children; pressure on the medulla oblongata, causing *paralysis of the cranial nerves*, *glycosuria*, or even *sudden death*, if the vital spot is impinged upon; finally, *bilateral rigidity* from pressure on the motor paths.

On the other hand, there may be cerebellar disease without any symptoms whatever, especially as long as the middle lobe is not involved.

*Form of Lesion.*—By far the most frequent cerebellar lesion is *tumor*—in fact, some sort of tumor was found by W. C. Krauss in 88 out of 100 cases, of which ten were *abscess*, and there was one each of *softening* and *hemorrhage*. The remainder were: sarcoma and tubercle, each, 22; glioma, 18; nature of tumor unspecified, 13; cyst, seven; and one case each of endo-thelioma, cyst and sarcoma, cancer, gumma, and fibroma. The tumor occupied one or the other hemisphere 32 times; the middle lobe, 17 times.

*Disease of the middle cerebellar peduncles* may be accompanied by the so-called *forced positions* and *forced movements*. As a result of the former, the subject may lie in bed upon a particular side, whether conscious or unconscious; and if put on the other side, may reassume his former position involuntarily. Sometimes this is accompanied by a corresponding forced position of the head and eyeballs, the extremities being seldom affected. The *forced movements* are less frequent. They consist either in oft-repeated rotations of the body on its longitudinal axis or, if the patient can walk, in involuntary circular movements. There is no guide by which to determine which of the two peduncles is affected under these circumstances, while in a few cases of brain disease the same symptoms have been observed without involvement of the cerebellum.

The following very convenient summary from Strümpell's "Text-book," slightly altered American edition of 1901, contains the most important facts bearing on the localization of cerebral disease, and will be found useful for reference:

"1. The most frequent cause of ordinary hemiplegia is a lesion of the *pyramidal tract* in the posterior limb of the internal capsule. If the hemiplegia be persistent, then this tract is actually destroyed; if temporary, the tract has been functionally deranged for a time by focal disease in neighboring parts of the brain.

"2. Monoplegic cerebral paralysis is usually due to affections of the *cortex* of the brain—that is, the anterior central convolution and the paracentral lobule. Monoplegia of the face and tongue is the result of lesions in the lower extremity of the anterior central convolution. Monoplegia of the arm is referable principally to some lesion of the middle third of the anterior central convolution. Monoplegia of the lower extremity implies some affection of the upper portion of the anterior central convolution and the paracentral lobule.

"3. Hemiplegia or monoplegia, if associated with epileptiform convulsions affecting either one-half or one particular portion of the body, is almost always caused by cortical lesions. These same symptoms of motor irritation without accompanying paralysis are likewise to be ascribed to some irritation of the above-mentioned regions of the cortex.

"4. Hemiplegia with crossed paralysis of the oculomotor nerve developing at the same time indicates a lesion of a *crus cerebri*. Co-existing tactile hemianesthesia implies that the tegmentum is involved.

"5. Hemiplegia with crossed facial paralysis implies, provided that the paralysis of the limbs and opposite side of the face occurred at the same time, that the lesion is situated in the pons.

"6. Posthemiplegic chorea (*vide infra*) seems to occur especially when there is focal disease in the neighborhood of the posterior part of the internal capsule. It is a rare phenomenon.

"7. Hemianesthesia of the skin and of the organs of special sense, associated with hemianopsia, is due chiefly to lesions of the most posterior portion of the internal capsule.

"8. Hemianopsia may be due to a lesion of the cuneus and neighboring parts in the occipital lobe. Probably, also, a lesion of the posterior extremity of the internal capsule may cause it, in which case it is usually associated with hemianesthesia. Finally, it may be produced by affections of the pulvinar of the optic thalamus, of the lateral geniculate body, or of one of the optic tracts.

"9. Genuine motor aphasia indicates disease of the foot of the third left frontal convolution. Unless we accept the teaching of Marie.

"10. Word-deafness (loss of understanding of speech) is due to disease of the first left temporal convolution or of the posterior convolutions in the island of Reil; word-blindness (loss of understanding of writing) is due to disease of the left lower parietal lobe (angular gyrus)—supramarginal gyrus also, according to Ferrier.

"11. Difficulty in articulation implies disease of the medulla oblongata, as does also dysphagia.

"12. Staggering gait and vertigo are the most constant symptoms of cerebellar disease, but they may also occur in diseases of the corpora quadrigemina and of the frontal lobe (*vide supra*). Forced positions and forced movements perhaps indicate lesions of the crura cerebelli ad pontem or of the optic thalamus.

"13. Staggering gait and ocular paralysis implicating the third and fourth nerves are indicative of lesions of the corpora quadrigemina."

## DISEASES OF THE CRANIAL NERVES.

### OLFACTORY NERVE.

The olfactory fibers may be affected in their intracerebral course in the rhinencephalon or in their distribution to the olfactory region of the nose. There are probably nerve cells in the frontal lobe belonging to the rhinencephalon, and nerve tracts belonging to the rhinencephalon pass through the frontal lobe.

**Morbid Anatomy.**—The lesions may be *tumors of the brain*, instances of which have been found in the hippocampal gyri, or disease in the hemispheres. There may be *congenital defect* of the olfactory center or atrophy of the nerve, which may explain the occasional anosmia in tabes dorsalis. There may be *inappreciable changes*, caused by injuries to the head or by concurrent disease, such as epilepsy, the aura of which is sometimes manifested by parosmia. The area of distribution of the olfactory nerve in the nose may be destroyed by *chronic nasal catarrh* or by *polypus*. *Hysterical neuroses* of the olfactory nerve are not infrequent. The sense of smell is sometimes impaired in cases of tumor situated in portions of the brain

remote from the olfactory area. This possibly may be caused by increased intra-cranial pressure.

**Symptoms.**—Lesions in any of these localities may produce subjective sensations of smell, or *parosmia*, of which various foul odors are illustrations; hypersensitiveness of the normal sense, or hyperosmia, in certain highly developed degrees of which the patient, generally a highly sensitive woman, can distinguish one person from another by the sense of smell; or loss of the sense of smell, *anosmia*.

**Diagnosis.**—The nasal region should be carefully explored by the rhinoscope and the sense of smell should be tested. For this purpose the essential oils, such as anise-seed, cloves, or peppermint, in various degrees of dilution are employed. Cologne water, musk, or asafetida may be used for the same purpose. Pungent substances should be avoided, as they stimulate the fifth nerve in the nasal mucous membrane, and thus the subject perceives what he does not smell. By such agents the fifth nerve is tested. No conclusion can be drawn as to anatomical differences on the two sides without a rhinoscope examination.

**Treatment** is useless, unless the condition be due to curable or removable polypos.

## OPTIC NERVE AND TRACT.

There may be derangement of the retina, of the optic nerve, of the chiasm, and of the optic tract.

### I. AFFECTIONS OF THE RETINA.

These may be *organic* or *functional*.

#### (a) *Organic Diseases of the Retina.*

The organic affections include hemorrhage and inflammation, or both.

HEMORRHAGE into the retina (arterial sclerosis) occurs as a cause or result of Bright's disease, most commonly chronic interstitial nephritis, in gout profoundly affecting the system, in leukocythemia, anemia, syphilis, purpura, ulcerative endocarditis, and other forms of septicemia. The hemorrhages are in the layer of the nerve-fibers. At first bright red, and then becoming darker and eventually lighter in color, they ultimately assume a diffuse cloudiness, owing to serous infiltration. The hemorrhages vary in extent, and often follow the course of the vessels. In septicemia they are due to capillary septic embolism, and often have white spots in the center, owing to the massing of leukocytes. Other white spots are due to fibrinous exudate, fatty degeneration of the retinal elements, or localized sclerosis of the same. Similar hemorrhages sometimes occur in the pia mater in the same cases.

RETINITIS occurs under the same circumstances as hemorrhage, especially in chronic nephritis, syphilis, anemia, leukemia, and also malaria; and in diabetes mellitus and chronic lead-poisoning.

*Albuminuric retinitis* may occur in all forms of chronic nephritis, more frequently in the interstitial variety, of which disease it may be the earliest

symptom recognized. It is characterized in general by the presence of white spots of various extent and distribution, as seen by the ophthalmoscope. They are caused by degenerative processes and hemorrhages. Gowers recognizes three forms:

1. A degenerative form, which is the most common, in which there is retinal changes, but scarcely any alteration of the optic disk.
2. An inflammatory form, in which there is much swelling of the retina with obscuration of the optic disk.
3. A hemorrhagic form, in which there are many hemorrhages, but little evidence of inflammation.

In some instances of the second type the inflammatory changes in the optic nerve predominate over those of the retina, producing an *optoneuritic* form, in which the appearances are more closely allied to those of papillitis or choked disk, such as is caused by intracranial disease.

*Syphilitic retinitis* is a rare affection in acquired and congenital disease. In the latter it is called *retinitis pigmentosa*. *Syphilitic choroiditis* is less rare. Retinitis is not uncommon in *chronic anemia*, especially in the pernicious form. After excessive loss of blood the patient often becomes blind, either suddenly or in the course of one or two days. In such cases a neuroretinitis has been found quite sufficient to explain the blindness, which, in rare instances, may be permanent and complete. A rare variety of anemic retinitis is *malarial retinitis*, first described by Stephen MacKenzie. It may be associated with hemorrhage. In *leukemic retinitis* the retinal veins are large, and hemorrhage may also occur, with white and yellow areas. Tumor of the brain, especially of the cerebellum, has been found in some instances to cause a condition of the retina like that of albuminuric retinitis.

#### (b) *Functional Disturbance of the Retina, or Amaurosis.*

This may be *toxic*. Of this, the most striking and best known variety is *uremic amaurosis*.<sup>1</sup> Its suddenness is its most striking feature, and it is very frequently the forerunner of uremic convulsions, although it may occur without them. It, too, may be the first symptom noted in Bright's disease. The retina is free from any changes visible by the ophthalmoscope, and the condition is probably due to the action of the poison on the nerve centers. It generally disappears, not quite so suddenly as it comes on, but comparatively quickly, while the impaired vision of retinitis albuminurica is a more or less permanent condition. Similar are the amauroses from *lead-poisoning* and from massive doses of *quinin*. *Hysterical amaurosis* is more frequently a dimness of vision—*amblyopia*—but true blindness may occur in one or both eyes. *Tobacco amblyopia* is usually gradual in its appearance, and affects more especially the center of the field of vision. There may be congestion of the optic disk, and if the use of tobacco is persisted in, there may be a permanent organic change, with atrophy of the disks. A scotoma for red and green is invariably present.

In *nyctalopia*, or night-blindness, objects are clearly seen by the day or

<sup>1</sup> Amaurosis is a vague term usually defined as partial or total loss of vision. For partial loss of vision amblyopia is now commonly applied, while the less obscure term blindness is best used for total loss of vision.

by strong artificial light, but are visible in the shade or at twilight. In *hemeralopia* the reverse state of affairs exists, objects being seen with discomfort in bright daylight or by strong artificial light, but being easily seen in deep shade or at twilight. *Retinal hyperesthesia* is sometimes met in hysterical women.

## 2. AFFECTIONS OF THE OPTIC NERVE.

Those which are of medical significance are *optic neuritis*, or choked disk, and *optic atrophy*.

### (a) *Intracranial Trunk.*

The intracranial trunk of the nerve is rarely affected, by reason of its shortness. It may, however, be compressed by a *tumor* in adjacent parts, as of the pituitary body or of the bone; by *aneurysm of the ophthalmic artery* within the orbit, or of the *internal carotid* within the skull. The trunk may also be the seat of inflammation, which may extend from carious bone or meningitis, or may be rheumatic.

### (b) *Optic Neuritis, Papillitis, Papillo-edema, or Choked Disk.*

**Definition.**—Inflammation of the intra-ocular end of the optic nerve.

**Anatomical.**—It will be remembered that the optic nerve pierces the sclerotic and choroid coats about  $1/10$  inch (2.5 mm.) to the nasal side of the center of the retina, which is occupied by the yellow spot of Sömmering. In this spot the sense of vision is most nearly perfect, while the optic papilla or disk is the only part of the retina from which the power of vision is absent. A central depression, or "cup," is due to the separation of the nerve-fibers, pale because of the absence of blood-vessels, while the periphery of the disk has a rosy tint from the presence of the minute blood-vessels that lie among the nerve-fibers. The "cup" varies in size, and may be absent, the vascular portion of the disk at times extending over it. The tint of the vascular portion of the disk also varies, and differences are of significance only when noted at successive examinations of the same case.

**Morbid Anatomy.**—It is by swelling and diminished transparency rather than by recognizable signs of congestion that the *first stage* of optic neuritis is characterized. Then there follows lessening of the sharpness of the edge of the disk, and finally its total obscuration, as seen in the right half of Fig. 129 as contrasted with the left half. It is to be remembered that the normal contrast is sometimes diminished within the limits of health, with this difference: that the pathological indistinctness is better seen with the direct method of examination, while the indistinctness sometimes normally present is more evident to the indirect. The abnormal change is earlier recognized on the nasal side, because there are more nerve-fibers there than at the temporal edge. In the *second stage* the swelling rapidly increases and the whole circumference of the disk disappears, though the cup is still represented by a slight depression. The swelling extends even beyond the normal disk, becoming two or three times as wide. The swollen disk assumes a red or grayish-red color to the indirect examination, but

by the direct a fine striated appearance is noted, the striae radiating from the center of the disk in the direction of the fibers. White spots may appear on its surface, due to degeneration of the nerve-fibers, and may be seen in the illustration. As the swelling increases the retinal vessels, at first unaffected, become affected by the compression, the veins becoming wider and more tortuous, the arteries being narrowed or remaining normal, while hemorrhages may occur. The retina may also be invaded, producing a neuro-retinitis.

In very slight degrees of inflammation the swelling subsides and recovery takes place. In high degrees it remains for a long time, owing to the presence of inflammatory products, which gradually, however, undergo

FIG. 129.—Commencing Optic Neuritis from a Case of Caries of the Sphenoid Bone with Secondary Meningitis—(after Gowers).

The left-hand figure shows the normal right optic disk with clear outline and deep central cup. The right-hand figure of the left papilla shows well-marked neuritis; the edge of the disk is concealed by a swelling which extends beyond the normal limits of the disk. The central cup is encroached upon, but not yet quite obliterated. Some of the vessels are partly concealed at their points of emergence, and the veins lose their central reflection.

the usual contraction of cicatricial tissue, a condition of "consecutive atrophy" resulting, in which the disk is white and atrophied.

**Etiology.**—Most commonly optic neuritis is caused by intracranial disease; especially in nine-tenths of all cases tumor is said to be present. It gives no information as to the seat of the tumor. It is ascribed by some to a descending neuritis; by others, to intracranial pressure. In over 90 per cent. of cases the neuritis is bilateral, though often unequal in the two eyes. Unilateral neuritis is generally due to disease within the orbit or at the optic foramen, but may also be due to intracranial tumor. *Meningitis*, either tuberculous or simple, is the next most frequent cause. It is said to be rather more common in meningitis of the base than of the convexity. Such optic neuritis is less severe than that caused by tumor. *Cerebral abscess* may cause it; so may *diffuse cerebritis*. In *thrombotic softening* and *hemorrhage* optic neuritis is rare, but in *embolic softening* it is more common.

Optic neuritis may result from *Bright's disease*, *chlorosis*, *anemia*, or *lead-poisoning*, and may occur after *acute fevers*, especially scarlet and typhoid. In the latter it may be associated with brain symptoms, especially headache. About six per cent. of all cases of *multiple sclerosis* are accom-

panied by optic neuritis, due to inflammatory or sclerotic patches in the nerve, usually slight and of short duration, often one-sided in consequence of unilateral involvement of the nerve by a sclerotic patch.

**Symptoms.**—Mild degrees of optic neuritis may be without symptoms, except such as are revealed by the ophthalmoscope. With higher degrees, acuity of vision, color vision, and the visual field all become affected and may be lost. Its severest effect on vision may not appear until contraction sets in, because it is at this period that the nerve elements suffer most in integrity. The defective sight is not, however, necessarily due to changes in the disk or retina; it may be due to intense inflammation in the nerve behind the eye or to intracranial disease.

**Prognosis.**—Even in severe cases there may be some improvement of vision with subsidence of the inflammation. On the other hand, vision may be permanently lost.

### (c) *Optic Atrophy.*

There are three varieties of atrophy of the optic nerve:

(1) Primary; (2) secondary; (3) consecutive.

1. *Primary or simple atrophy* is that form which is not preceded by any recognizable inflammatory change in the papilla or surrounding structures. It occurs in degenerative diseases of the brain and spinal cord, more frequently in multiple or disseminated sclerosis and tabes dorsalis. It is present in about 40 per cent. of all cases of multiple sclerosis, and, in various degrees, in at least 15 per cent. of those of tabes. In dementia paralytica it is present in about five per cent. Primary atrophy is sometimes hereditary, occurring in the males of a family after puberty. Other causes to which the condition has been ascribed are cold, alcoholism, lead-poisoning, sexual excesses, diabetes, and the specific fevers.

2. *Secondary atrophy* is the result of damage to the optic nerve behind the eye or at the chiasm. It is characteristic of it that demonstrable signs of atrophy follow, instead of accompany, the deranged vision; of which, too, hemianopsia may be a form.

3. *Consecutive atrophy* is that form of atrophy which succeeds neuritis or papillary neuritis. It has the same causes and the same significance. Only secondary and consecutive atrophy are the result of uncomplicated intracranial diseases; for although primary atrophy accompanies disseminated sclerosis, tabes dorsalis, and general paralysis of the insane, it is not caused by the associated brain disease, but is the result of the same widespread tendency to degeneration.

The ophthalmoscopic appearances in primary atrophy differ somewhat from those of the consecutive and secondary forms, the disk being gray-tinted—whence the name *gray atrophy*—with its edges well defined, while the arteries appear almost normal. In secondary and consecutive atrophy the disk has an opaque, white appearance, with irregular outline, and the arteries are small.

The **symptoms** of optic atrophy are the defects of vision already detailed when treating of optic neuritis.

As to **prognosis**, in primary atrophy the ultimate result is usually

blindness, but in secondary consecutive atrophy some vision remains, even in severe cases, while in mild cases recovery is not impossible.

### 3. LESIONS OF THE CHIASM AND TRACT.

**Anatomical.**—The decussation of the optic tracts at the chiasm is peculiar. As it reaches the chiasm each tract divides and sends a portion—the smaller—of its fibers to the temporal half of the corresponding retina, and the remaining portion to the nasal half of the opposite retina. Thus the right tract supplies the right or temporal half of the right retina and the right or nasal half of the left retina; the left tract supplies the left or temporal half of the left retina and the left or nasal half of the right retina. The decussating fibers occupy the middle of the chiasm, and the direct fibers the corresponding side. (See p. 1094.)

*Effect of Lesion of the Chiasm: Hemianopsia.*—(a) If the central portion of the chiasm, composed of decussating fibers only, is involved (lesions *b* and *c*, Fig. 130), the result will be anesthesia of the inner half of each retina and blindness of the outer half of each field of vision, it being remembered, of course, that the half field which is blind is the reverse of the half of the retina which is anesthetic, since the picture formed on each half of the retina is projected from the opposite half of the field of vision. Such half blindness is known as *hemianopsia*, and the form just described, in which outer or temporal half of each field is blind, is known as *bi-temporal hemianopsia*.

(b) If the whole chiasm is involved, as is not infrequently the case as the result of pressure by tumor, there will, of course, be total blindness.

(c) If the lesion is intermediate, involving the direct fibers on one side of the chiasm as well as the central fibers, there will then be blindness in one eye and temporal hemianopsia in the other.

(d) The rarest of all forms of hemianopsia is *bi-nasal hemianopsia*, due to a symmetrical lesion involving only the direct fibers passing to the temporal half of each retina, whence results blindness in the nasal field only. It is found sometimes in tumors involving the outer part of each tract, or of each optic nerve.

*Effect of Unilateral Lesion of the Tract.*—If there be a lesion involving the left tract at *d* (Fig. 130), the left or temporal half of the left retina and the nasal half of the right retina become anesthetic and useless, the right half of each field of vision is blotted out, and there results a right *lateral hemianopsia* which is called *homonymous hemianopsia*. The reverse is the case if the lesion is in the right tract. The number of cases involving the right side is about equal to the number involving the left. When the left half of one field and the right half of another is blind, or the reverse, the condition is known as *heteronymous hemianopsia*.

In the usual forms of bi-temporal hemianopsia the obscure fields are by no means always exact demi-fields, which would be the case if the dividing line passed exactly through the fixing point, or macula lutea. It may diverge to temporal side so as to leave a small area around this within the seeing half. These differences are due to peculiarities in the decussation rather than to the lesion. The half fields which remain, though com-

monly natural, are sometimes contracted. This is usually due to an inflammatory affection of the peripheral fibers of the optic nerves in front of the chiasm.

There are other differences in the dividing-line, such as obliquity, want of sharpness, etc., due to the same cause, but minute description

FIG. 130.—Diagram of Course of Optic Nerve-fibers from the Cortex to the Retina—(after Sahli, Modified and Extended).

of these belongs to special works on nervous diseases. Since vision remains intact in the central region, equally in right and left-sided hemianopsia, it follows that there must be a passage of fibers from the macular region to the optic tract of each hemisphere, else this region would be blinded by disease of one or the other tract. There is usually the same loss of vision

for color in the half field, but half vision for color may be lost in central disease without any change in the field for white. This is known as *hemichromatopsia*.

#### 4. LESION OF THE TRACT AND CORTICAL CENTERS.

The optic tract on each side crosses the crus cerebri backward and sends fibers to the external geniculate body, to the pulvinar of the optic thalamus, and to the anterior colliculus of the quadrigeminal body. From these so-called primary optic centers fibers pass backward through the posterior part of the internal capsule, forming the fibers of the optic radiation in the white substance of the occipital lobe, into the visual area of the cortex, of which the area about the calcarine fissure is the chief cortical center, though other parts of the occipital cortex possibly also receive and store up visual impressions.

Whence it is plain that vision may be influenced by lesions in any of the following situations:

1. In the tract itself.
2. In the external geniculate body.
3. In the pulvinar of the optic thalamus and in the anterior colliculus of the corpora quadrigemina.
4. In the fibers passing from the primary optic centers to the occipital lobe, as at *e* (Fig. 130), in the hinder part of the optic radiation.
5. In the area about the calcarine fissure.

The effect of lesion in any one of these situations is to produce anesthesia of that half of the retina corresponding to the affected side and a homonymous hemianopsia of the opposite half of the visual field.

**Morbid States Affecting the Optic Nerve, Chiasm, Tract, and Centers.**—Outside of the affections of the retina, which concern the ophthalmologist chiefly, and outside of optic neuritis or papillitis as a result of intracranial disease, already considered, the affections of the *optic nerve* which concern the physician are tumors springing from the pituitary body or the bone, aneurysm of the ophthalmic artery within the orbit or of the carotid within the skull, and interstitial inflammation from an adjacent focus, or rarely from rheumatism and injury.

The *optic chiasm* is encroached upon by tumors in the neighborhood, especially of the pituitary body; by tuberculous or syphilitic growths in its substance, or by inflammation invading it from the adjacent dura mater or from carious bone; by internal hydrocephalus, the distended infundibulum of the third ventricle pressing on the middle of the chiasm; by interstitial inflammation of a possible gouty origin or associated with *tabes dorsalis*; and, finally, by interstitial hemorrhage.

The *optic tract* may be invaded or compressed by tumors springing from the inner part of the temporosphenoidal lobe, by softening after thrombosis of the internal carotid, or by disseminated sclerosis. Primary softening in the tract is rare, as is also hemorrhage.

The *cortical visual centers* may be invaded by hemorrhage, softening, tumors, pressure by depressed bone in fracture, and other traumatic causes.

**Symptoms of Lesions of the Optic Nerve, Chiasm, Tract, and Cortex:**

1. *Visual Effects.*—(a) Lesions of the optic nerve cause defects of vision on the same side, with lessening of the reflex action of the pupil proportionate to interference with vision. The impairment of vision includes extent of field of vision as well as degree. There may be concentric limitation of the visual field because the peripheral layer of nerve-fibers near the optic foramen is damaged by processes external to it. In other cases there is irregular defect, and in others still the loss of sight is total and lasting.

To the ophthalmoscope there may be at first no change, but if the lesion is considerable, the atrophic condition soon makes its appearance "secondary" to changes in the nerve as distinguished from "consecutive" atrophy, which succeeds papillitis. There may be slowly supervening atrophy without recognizable papillitis. Central loss of vision, due to axial neuritis, is less common, but occurs sometimes in tobacco amblyopia.

(b) In lesions of the chiasm the characteristic symptom is bitemporal hemianopsia, or loss of the outer half of each field of vision; this is because the lesions mainly affect the chiasm at its central portion, where the fibers, after decussating, pass to the nasal half of each retina. Usually, however, the process, be it tumor or inflammation, which causes temporal hemianopsia extends laterally, involving the non-decussating fibers of one side of the chiasm, causing total blindness of the corresponding eye; or, if extending to both sides, blindness of both eyes. The different stages may often be traced in a single case as the disease progresses. The term "oscillating bitemporal hemianopsia" is applied to a rapid and frequent variation of the dark fields, and is regarded as more or less clearly diagnostic of basal syphilis, such as gumma or syphilitic meningitis. More rarely we have the binasal hemianopsia already described. Slight variations in the extent of the dark fields have been referred to as the result of peculiarities in decussation rather than of lesion or seat of lesion.

(c) In lesions of the optic tract between the chiasm and the external geniculate body there is bilateral hemianopsia.

(d) Bilateral hemianopsia is also a result of lesion of the central fibers of the nerve between the primary visual centers and the cerebral cortex.

(e) Lesions of the cuneus cause bilateral hemianopsia. A lesion in each hemisphere, destroying the visual paths back of the chiasm, will cause a double hemianopsia, with total loss of vision in both eyes. Such a result has followed successive lesions in the two occipital lobes.

(f) Hemianopsia may be due to functional disease. Transient hemianopsia is sometimes a symptom of migraine, either as an isolated symptom apart from headache and gastric disturbances or associated with them. It may affect now one half of the field and now another.

Hemianopsia has been reported as a symptom of hysteria, but the occurrence of true hemianopsia in hysteria is questioned.

2. *Other Symptoms Associated with Hemianopsia.*—In about one-half the cases of hemianopsia there is transient or permanent hemiplegia, the result of the same lesion, the hemiplegia being on the side of the loss of vision, so that the patient cannot see on the paralyzied side. Hemianesthesia

may also be associated, and defects in speech are sometimes found when the paralysis is on the right side.

Hemichromatopsia has been mentioned. (See p. 1096.) In this condition there is no change in the field for ordinary objects, but all colors appear gray as soon as the vertical line is passed. The symptoms, according to Gowers, probably depends on disease of one part of the occipital lobe, and is proof of a separate center for color not yet precisely located, perhaps in some part of the occipital cortex in front of the apical region.

The limitation of the remaining functionally active half field and the isolated loss for colors are the only known differences in the features of hemianopsia due to variations in the seat of the lesion in the optic path behind the chiasm; the limitation of the active half field indicating a lesion in the optic radiation near the thalamus, the isolated loss for colors pointing to a lesion in the occipital lobe.

3. *Amblyopia*.—Amblyopia is another form of sight defect due to brain disease. The term is used to indicate a *partial loss or blurring of vision*. There is concentric limitation of the visual field, different in different cases, and along with it the color fields are also reduced.

Similar eye defects, associated with hemianesthesia, occur sometimes in hysteria, with which it may be confounded. Since a simple functional loss of vision may rarely result as a reflex from irritation of the fifth nerve or from hysteria, so a functional amblyopia, affecting both eyes, may also result from such causes—indeed, is more common than the organic form. A carious tooth may act in this way. Amblyopia from errors of refraction must not be confounded with the amblyopia due to brain disease.

**Diagnosis.**—How shall we interpret these phenomena of vision concerned with the optic nerve and tract? Some conclusions are easy; others are difficult, because of our limited knowledge. Accurate investigation of fields of vision, with a view to the study of hemianopsia and other defects in the visual fields variously caused, is made by means of the perimeter, for directions concerning the use of which instrument the student is referred to works on ophthalmology. Herman Sahlbi suggests an easy, rough method, quite sufficient for recognizing marked difference in the field of vision, performed as follows: The physician seats himself opposite the patient, whose right eye—supposing this to be the one to be tested—is opposite the physician's left, the other eye of each being closed. The two open eyes being thus fixed opposed, the physician passes his finger to and fro across the field of vision exactly midway between the two eyes. In this way he can compare his own field of vision with that of the patient, noting at what moment the finger is seen approaching from the periphery of each. Care must be taken that the finger is kept exactly midway between the physician and patient, and in order to do this, the examiner may from time to time open his closed eye.

Defective sight in one eye with diminished reflex action of pupil proportionate to the defect, the function of the remaining eye being intact, usually means disease of one optic nerve. In some rare cases of functional disease in which the sight of one eye only is involved, the perfect responsiveness of the pupil distinguishes it from organic disease of the nerve. Total loss of sight in both eyes may mean chronic atrophy, damage to the

chiasm, or disease of both tracts or in both hemispheres. In these cases the symptoms are at first partial, and in this way the diagnosis is aided.

Central scotoma means damage to nerve-fibers in the center of the trunk of the optic nerve, either inflammatory or the result of hemorrhage. Peripheral limitation of vision means damage to fibers running in the periphery of the nerve. Sectorial blindness in one eye means disease of the nerve, decided in degree but limited in extent.

Bitemporal hemianopsia means disease of the chiasm, while the combination of complete blindness of one eye with temporal hemianopsia in the other means disease of the chiasm which has extended to the outer fibers, and even to the optic tract or optic nerve, on the side on which blindness is complete.

Bilateral hemianopsia may be due to disease back of the chiasm, and the determination of the spot involved in the tract between the chiasm and the occipital area which is the cortical center of vision, stimulates diagnostic acumen. The most that can be attempted is the settling of the question as to whether the disease is in the tract between the chiasm and the external geniculate body or in the fibers beyond in the visual center of the hemisphere. To this end the *hemianopsic pupillary* reaction of Wernicke is sought. A perfect pupil reflex requires the integrity of the retina, of the fibers of the optic nerve and tract, of the nuclei and fibers of the third nerve, and of the iris. When the light is thrown on the blind half of the retina the pupil contracts as much as if it is thrown on the seeing half, if the disease is in the hemisphere; but if the disease is in the tract, it does not contract because the path to the third nucleus below the corpora quadrigemina is interrupted. The employment of the test requires much care and experience. Seguin directs that the patient, being in a darkened room with a light behind his head in the usual position, be directed to look to the other side of the room, so as to eliminate accommodation movements. Then a faint light is thrown upon the eye from a plane or large concave mirror, held well out of focus, and the size of the pupil is noted. With the other hand a beam of light, focused by an ophthalmoscope mirror, is then thrown directly into the optical center of the eye, then laterally in various positions and from above and below the equator of the eye, noting the reaction at all angles of incidence. According or not as a response is obtained in the pupil the inference is drawn.

Amblyopia with concentric reduction of the field, decided in one eye and slight in the other, may be due to atrophy of the nerve, to disease of the distal visual center in one hemisphere, or to hysteria. If atrophy, the ophthalmoscope recognizes the lesion and the responsiveness of the pupil is diminished. If disease of one hemisphere, the nerve is normal to the ophthalmoscope, the pupil contracts perfectly under the action of light, and the onset is sudden or accompanied with other signs of organic brain disease. Mind-blindness, described on page 1074, may also be a result of lesion in this locality. In hysteria the symptoms are the same as in disease of the higher visual center, and the diagnosis depends on the presence or absence of signs of organic or functional disease. In hysterical blindness the loss of sight is rarely complete. In hysterical and neurotic defects of vision there may be a derangement of the natural relation in color fields.

Thus, while normally the blue field is most conspicuous in the last-named conditions, it is often overshadowed by other colors.

## LESIONS OF THE MOTOR NERVES OF THE EYEBALL.

**Anatomical.**—The third cranial nerve (oculomotor) supplies the levator palpebræ superioris, the superior, inferior and internal recti, the obliquus inferior, the sphincter of the iris, and the ciliary muscle. The fourth cranial nerve (the trochlear) supplies the superior oblique; the sixth cranial nerve (the abducens), the rectus externus. The functions of the muscles to which these nerves are distributed are sufficiently indicated by their names.

**THIRD NERVE.**—Lesions may involve the nerve at its nuclear origin or in its course. Lesion of the third nerve *at its origin* involves also usually the origin of the other motor nerves of the eye, except the sixth, producing general ophthalmoplegia, as a result of which the eyeball is motionless, and an object moved about in front of it can be followed only by moving the entire head. The nerve may be invaded *in its course* by traumatic causes, meningitis, gummata, aneurysm, or neuritis, frequently rheumatic, and may also be affected in diphtheria, tabes dorsalis, and diabetes mellitus. The effect may be spasm or paralysis.

The results of *spasm* of the muscles supplied by the third nerve are manifested in *nystagmus*. This consists in an involuntary, clonic, rhythmic, oscillatory movement of the eyeball, usually horizontal, but sometimes rotary, more rarely vertical. It is seen in congenital or acquired brain lesions, and is often a striking feature in albinism. In meningitis and hysteria there is also sometimes spasm of the muscles supplied by the third nerve, especially the internal rectus and the levator palpebræ, the antagonist of the orbicularis.<sup>1</sup>

*Paralysis* of those muscles supplied by the third nerve, which include all the eye muscles except the external rectus and the superior oblique, results in outward squint; ptosis, or drooping of the upper eyelid; the absence of contracting power in the pupil, which remains of medium size; loss of accommodation; double vision, or diplopia. Such paralysis, involving all the branches of the nerve, may be recurrent, especially in women, often at the menstrual period, or at wider intervals.

It is sometimes associated with pain in the head and at other times with migraine. The individual attack lasts a few days, or as many weeks. Partial involvement of the third nerve may include the levator palpebræ, the superior rectus, the ciliary muscle, and the iris, while the external muscles—that is, the internal and inferior recti and the inferior oblique—may escape.

*Ptosis* only, due to paralysis of the levator palpebræ, complete or partial may occur under various conditions. It may be congenital and incurable, or due to cerebral lesion; or it may be hysterical, when it is apt to affect both eyes and is associated with other symptoms of hysteria. It may be caused by disease of the sympathetic nerve (pseudoptosis), and may be

<sup>1</sup> Blepharospasm is a spasm of the orbicularis muscle, which is supplied by the facial nerve. It amounts usually only to twitching of the eyelids, but may be so severe as to close them completely, so that it is not in the power of the patient to open them.

associated with symptoms of vasomotor palsy—viz., elevation of temperature on the affected side, redness or edema of the skin, and contraction of the pupil on the same side. Finally, it is seen in weak, delicate women as a transient event, especially in the morning. When ptosis is the result of a definite lesion of the third nerve, at its nucleus or in its course, it may also be associated with a paralysis of the superior rectus alone, or of the internal and inferior recti in addition.

*Condition of the Pupil.*—The condition of the pupil should be studied with light of moderate intensity, and in doubtful states the pupil under examination should be compared with that of the eye of a healthy individual about the same age.

*Miosis*, or contraction of the pupil, is found physiologically during sleep, especially in elderly persons; pathologically, as an early symptom in tabes dorsalis, in progressive paralysis of the insane, and as an effect of eserin, pilocarpin, morphin, and in complete chloroform narcosis.

*Mydriasis*, or dilatation of the pupil, occurs in deep unconsciousness, during extreme pain, in dyspnea, in peripheral blindness, especially from optic atrophy, in oculomotor paralysis, rarely in tabes dorsalis and progressive paralysis of the insane. It is also an effect of atropin, duboisin, and cocain, and of the early stage of chloroform narcosis.

The pupil may be unduly large from palsy of the sphincter (third pair) fibers or from spasm of the radiating (sympathetic) fibers; or the pupil may be abnormally small from the opposite conditions.

Other limited paralyses due to third nerve disease are cycloplegia and iridoplegia. *Cycloplegia* is paralysis of the ciliary muscle, producing loss of the power of accommodation. In this state of affairs distant vision is good, but near objects cannot be seen distinctly. It may occur in one or both eyes, being in the latter event more usually due to disease of the nuclear origin of the third nerve. It is one of the earliest manifestations of diphtheritic paralysis, and is a symptom also of tabes dorsalis. It may be corrected by the use of eye-glasses.

*Iridoplegia* is paralysis of the iris, and its three forms are thus classified by Gowers, one associated and two reflex:

1. *Accommodative iridoplegia* is a form in which the pupil does not diminish in size during accommodation. It is tested by having the patient look at a distant object and then at a near one in the same line of vision, so as to avoid any change in the amount of light entering the eye. It is usually associated with paralysis of accommodation, but the ciliary muscle may be efficient and yet the associated action of the iris be lost, or the reverse. This loss is less common than that of reflex action. It is the result of the same cause as cycloplegia.

2. *Reflex Iridoplegia, or Argyll Robertson Pupil.*—The path for the optic reflex is along the optic nerve and tract to the nucleus of the third nerve; thence to the ciliary ganglion, and through the ciliary nerves to the eye. In testing for this condition each eye should be tried separately, the other being covered, but not closed. The patient is asked to look toward a dark part of the room, when a bright light is thrown suddenly in front of the eye at a distance of three or four feet, so as to avoid the effect of accommodation. If the patient looks at a nearer light, he will accom-

**FOURTH NERVE.**—The fourth cranial nerve (trochlear), as it passes around the outer surface of the crus into the orbit, is liable to be compressed by tumors, by aneurysm, or by the exudation of basal meningitis. Its nucleus below the aqueduct of Sylvius may be involved in tumors or may undergo degeneration with other ocular nuclei. As the superior oblique muscle, supplied by it, acts in such a way as to direct the eyeball downward and rotate it slightly, paralysis causes retardation of downward and inward movement, often so slight as not to be noticeable. The head is inclined somewhat forward and toward the sound side, and there is double vision when the patient looks down, as in descending stairs. Paralysis of this nerve is seldom met with alone, except in nuclear disease.

**SIXTH NERVE.**—The sixth nerve (abducens), emerging at the junction of the pons and medulla oblongata, passing forward and entering the orbit, is liable to be affected by meningitis at the base, or by tumors, especially fibromata, or by cold. The external rectus being alone supplied by it, the effect of its paralysis is to produce *internal squint*, and the eye cannot be turned outward. There is diplopia when looking toward the paralyzed side. It is a frequent ocular palsy, because the nerve has so long and exposed a course.

If the nucleus of the sixth nerve is affected, a very interesting condition results, which was first studied by Beever. In consequence of paralysis of the external rectus the eye of that side is turned inward, while at the same time the internal rectus of the eye of the opposite side has lost the power to turn its eye inward. Consequently, both eyes are turned to the side opposite and away from that of the injury. Thus, if the nucleus of the right sixth nerve is involved, both the right and the left eye are turned toward the left. Such opposite deviation away from the side of lesion is known as "conjugate deviation." It is due to the fact that the nucleus of the third nerve, supplying the internal rectus, is connected by fibers with nucleus of the sixth; whence in lesion of the nucleus of the sixth nerve there is paralysis of the internal rectus nerve, in associated movements, even though the nucleus of the third nerve is not involved while the power of convergence is not affected.

In consequence of the proximity of the nucleus of the sixth nerve to that of the seventh or facial, disease of the former is likely to involve the latter. Whence, say if there is lesion of the left nerve, there follows conjugate deviation of both eyes to the right, with a complete paralysis of the left half of the face.

Diabetes insipidus is sometimes associated with paralysis of the sixth nerve. Such a case I saw at the Philadelphia Hospital with J. Hendrie Lloyd. The paralysis of the sixth nerve was subsequently substituted by paralysis of the third, the polyuria remaining. A similar condition may be caused by syphilitic meningitis. Basal meningitis, involving the vascular supply to the floor of the fourth ventricle, may be suspected. Other cases of polyuria associated with paralysis of the sixth nerve are reported, notably Maguire's.

**Phenomena in General of Paralysis of Motor Nerves of the Eye.**—These include, first, limitation of movement and strabismus, referred to. In

addition to these certain derangements of vision, known as *secondary deviation*, *erroneus projection*, *double vision*, occur.

*Secondary deviations* are thus demonstrated: After covering the sound eye, let the paretic eye fix itself upon a point which it cannot reach at all, or can reach only after extreme exertion. Then remove the covering hand from the sound eye, and it will be found that the latter has been moved much too far in the same direction, the abnormal attempt at innervation of the affected eye passing over to the associated ciliary muscle of the healthy eye and causing in it too great a contraction.

*Erroneus projection* furnishes the idea that an object at which we are looking is further on one side than it really is or that the movement of the eye in following it, when moving, is greater than it is. Under these circumstances, in an attempt to touch the object with the fingers the latter may go beyond it. This grows out of the fact that when the eyes are at rest in the mid position, an object at which we are looking appears directly opposite the face. Turning the eye to one side, the object appears to the side of its former position; and if the object moves, we estimate the extent of its motion by the amount of movement of the eyeball following it. Now, when one muscle is weak, the increased innervation required to contract it gives the impression of a degree of movement greater than actually takes place. This is erroneous projection. Now, as the equilibrium of the body is largely maintained by a knowledge of the relation of external objects to it, obtained by the action of the eye muscles, the erroneous projection due to paralysis disturbs the harmony of visual impressions and may produce dizziness known as ocular vertigo.

*Double vision* results from the fact that if one eye is paralyzed the axis of the two eyes do not coincide, nor do the images in the two retinæ. The image produced in the sound eye is called the true image; that in the affected eye, the false image. In simple or homonymous diplopia the false image is on the same side as the paralyzed eye; in crossed diplopia it is on the other side. It is one of the most annoying symptoms of paralysis of the eye muscles.

**OPHTHALMOPLÉGIA.**—Ophthalmoplegia or nuclear palsy, is a term applied to a chronic progressive paralysis of the ocular muscles, *due to disease of the ocular nuclei*. It is called *internal* when the internal muscles only are involved—*i.e.*, the iris and ciliary muscles; *external*, when the external muscles are affected more or less completely. When both internal and external muscles are involved, it is known as *total ophthalmoplegia*.

**Historical.**—The term was first used by Brunner, in 1850. The nature of the cases was pointed out by v. Graefe in 1856, and in 1868 compared by him with bulbar palsy. Foster localized the lesion in 1878 for external palsy, including all the muscles except the iris and ciliary muscles. Internal ophthalmoplegia was described by Hutchinson in the same year, and the external form, with postmortem proof of its nature, in 1879.

**Symptoms.**—These vary according to the position and character of the lesion, which may be degenerative, hemorrhagic, or the result of pressure by tumors or the product of basilar meningitis. They are bilateral, except in the instance of the sixth nerve, with resulting conjugate paralysis. Gowers describes three modes of onset—chronic, sudden, and acute.

The *chronic* form is the most common, due to nuclear degeneration, or more rarely to tumor and embolic obstruction, and still more rarely to hemorrhage. In this form there is a great variety of combination and degree. Thus, there may be internal ophthalmoplegia only, or external, or both. In the internal form there may be loss of the iris-reflex only or of the ciliary muscle action only. In the external variety the levator and superior recti are commonly first involved, the other muscles gradually. There may be loss of the upward and downward movement of the eye, ptosis, and conjugate lateral palsy. There may be double vision, generally of short duration. In the total form the eye is fixed and immovable. Each variety may be associated with tabes dorsalis, general paralysis of the insane, progressive muscular atrophy, and bulbar palsy, often with syphilis. It is more common in males, and occurs occasionally in the young. There is a form occurring in children, known as infantile oculo-facial palsy, which may be congenital or acquired; rarely, it occurs as a sequel of diphtheria, late and permanent.

The disease may be very slow in developing, and may require years. Sometimes one eye is more affected than the other. If the internal muscles are unaffected, the disease is quite certain to be nuclear, because these muscles can scarcely escape bilateral disease of the nerve trunks. Indeed, v. Graefe thought this absence of involvement of the internal muscles characteristic. Palsy of the external ocular muscles is likely to be accompanied by facial palsy.

In *sudden nuclear palsy*, the second in frequency, the onset may take but a few minutes or an hour or two. The causes in such cases are commonly obstruction to the basilar arterial branches, rarely embolic obstruction, and still more rarely hemorrhage. The obstruction is usually bilateral. The lesions are irregular, and the symptoms are correspondingly irregular and unsymmetrical; the tendency is to recover. In these respects it differs from the chronic form also in that hemiplegia is a frequent accompaniment, generally on the side opposite the greater eye palsy. When hemorrhage is a cause, the resulting ocular palsy lasts usually but a few hours, provided the hemorrhage acts on the ocular centers only by pressure, while the other phenomena of pressure by effused blood, which is apt to spread, make their appearance.

*Acute nuclear palsy* is rare. It develops in a few days or weeks, and is possibly of inflammatory or toxic origin whence called by Wernicke *poliomyelitis superior*; but toxic cases may occur without inflammation. This form, according to Gowers, may be due to peripheral neuritis and not to nuclear disease. Alcohol may be a toxic cause. The eye muscles are invaded irregularly, and it is common for the internal muscles to escape. In fatal cases the causal influence extends to the centers of other nerves and possibly to the cortex. In cases that survive there is improvement, various in degree.

**Treatment of Ocular Palsies.**—The cause should be sought and if found, treated. Although syphilis is thought to be one cause of this disease and of tabes dorsalis, with which it is so frequently associated, disappointment follows the syphilitic treatment in the majority of cases. Yet mercury perhaps accomplishes more than any other single

remedy. Arsenic, strychnin, and iron are sometimes used, strychnin hypodermically.

In acute cases, when there is pain, hot fomentations, leeches, and counterirritation may be used. In chronic forms electricity has been extensively used, galvanism being preferred. Benedikt recommended placing the anode, or positive pole, on the forehead, and the cathode, or negative pole, on the margin of the orbit near the affected muscle. If the faradic current is used, the orbital pole is held still; if the voltaic, it is kept moving over the skin, or the current is broken by the commutator. To overcome the ptosis, electric stimulus is applied to the third nerve, as the muscle is not accessible.

The diplopia is removed by a prism not strong enough to fuse the two images completely, but of sufficient force to approximate them, so that the fusion may be completed by muscular action. Such action may be practiced for an hour each day. The dizziness due to erroneous projection can be removed only by throwing the eye out of use by an opaque glass. Operative treatment is not recommended.

PERIODICAL OCULOMOTOR PARALYSIS.—Up to June, 1890, according to A. Niden,<sup>1</sup> 21 cases of periodical oculomotor paralysis had been published. The organic lesion at the bottom of these paralyses is not yet settled upon. Möbius,<sup>2</sup> who was one of those who has contributed largely to the subject, claimed a *nuclear degeneration* as the cause, while Mauthner<sup>3</sup> another contributor, considers that the majority of cases have a basal cause, by which it is presumed he means a *basal meningitis* or other cause compressing the trunk of the nerve at the base of the cranium. The most recent paper on this subject is "Migraine ophthalmoplégique," Bornstein, *Monatsschrift für Psychiatric und Neurologie*, vol. xxv, No. 3, March, 1909.

In the paper referred to, Niden reports a case of periodical combined facial and abducens paralysis occurring in a woman 36 years of age, who had seven attacks involving the sixth and seventh nerves, separately or jointly, at intervals of from a few days to several months. Between these attacks she was free from symptoms. At other times there was derangement of other cranial nerves, especially of the auditory on the same side, manifested by tinnitus, which considerably interfered with the sense of hearing for the time. Again, in the fourth attack there was a paralysis of the left half of the tongue, which made speech stammering and unintelligible. All the attacks were accompanied by severe headache, which is more or less characteristic of oculomotor paralysis.

**Morbid Anatomy.**—From these conditions Niden infers an involvement of the nuclear region of the sixth and seventh cranial nerves affecting first the nucleus of the latter on the left side, and after a short interval the former of the same side and a part also of the nucleus of the hypoglossal. He thinks that there may have been an exudation in the region of the floor of the fourth ventricle deep enough to involve the nuclei of these nerves as well as the trunks of some of them

**Treatment.**—Because of syphilitic origin, in many of these cases mer-

curial treatment proved promptly efficient, while at times the symptoms subsided spontaneously.

### LESIONS OF THE TRIFACIAL OR FIFTH NERVE (TRIGEMINUS).

**Anatomical.**—This important mixed nerve of the face supplies by its motor trunk the muscles of mastication; by its sensory portion, the skin of the face, the mucous membrane of the mouth and nasal cavity, the conjunctiva, and the cornea; also, according to some physiologists, the anterior part of the tongue with gustatory fibers. The gustatory fibers are supposed to reach the lingual fibers of the fifth nerve by the chorda tympani nerve. Recent studies of Harvey Cushing make this doubtful.

**Lesions.**—1. There may be lesions of the pons, especially hemorrhage, or areas of sclerosis invading the trigeminus nucleus.

2. Injury or disease at the base of the skull, especially acute and chronic meningitis and caries of the bone, tumors, syphilis, new formations compressing the trunk or the Gasserian ganglion. Fracture of the base rarely affects this nerve.

3. Tumors or aneurysms pressing on the first division (ophthalmic) of the nerve through the cavernous sinus, on the second division (superior maxillary) and on the third division (inferior maxillary) by invasion of the sphenomaxillary fossa.

4. There may be inflammation of the nerve, which is rare.

5. The sensory division may also be affected in hysteria.

6. The gustatory fibers of the trigeminus may be influenced by peripheral lesions of the facial, whence the chorda tympani is derived.

**Symptoms.**—*Paralysis of the Sensory Portion.*—The distribution of the anesthesia varies according as the whole trigeminus or only a part is involved. In total anesthesia there is loss of sensation in half the corresponding side of the head, including the conjunctiva and cornea, mucosa of the lips, tongue, hard palate, and nose of the same side. Hence on the tongue or mucous membrane there are often ulcers which come from unconscious lacerations by the teeth. There is, according to the views of many, loss of the senses of taste and smell. The loss of the sense of smell is probably due to drying of the mucous membrane, as it is not probable that the fifth nerve contains olfactory fibers. The so-called trophic phenomena are also observed, and among them the much-discussed *neuroparalytic ophthalmia*, an ulcerative keratitis, beginning, also, always in the lower segment of the cornea, and passing over into purulent inflammation of the whole eyeball. It seems, on the whole, more likely that the inflammation is primarily due to the action of irritants which in health are excluded by the proper closure of the eyelids, though the inflammatory process itself may be trophically influenced. The salivary, lacrymal, and buccal secretions may be diminished and the teeth may become loose. Herpes is a trophic result which may develop in the course of the nerve, is painful, and may last a long time. So, too, the anesthesia may be preceded by tingling. The skin of the face is sometimes swollen.

*Paralysis of the motor portion*, which supplies especially the muscles of

mastication, the masseters, temporals, and pterygoids, is not common. It is most frequent in diseases of the base of the skull, compressing this branch. Difficulty in chewing is the result. If on one side, the patient can chew only on the other; if on both sides, he cannot chew at all. The lower jaw hangs down and cannot be moved from side to side because of the paralysis of the pterygoids. If on one side, the external pterygoid cannot push the jaw toward the sound side, and when depressed, the jaw is pushed by the muscle of the sound side toward the paralyzed side. Cases have occurred associated with cortical lesion; from one such Hirt inferred that the motor center for the trigeminus is in the neighborhood of the lower third of the ascending frontal convolution.

*Spasm* of muscles of mastication is found in connection with muscular cramp, the muscular contraction of tetanus (trismus), sometimes in tetany and meningitis, and reflexly through painful affections of the jaw or teeth, or from irritation near the motor nucleus. It is also sometimes hysterical. Clonic spasm occurs in muscles supplied by the fifth nerve, constituting "chattering teeth." It occurs generally in connection with general conditions, such as paralysis agitans, but it may happen as a local symptom in women late in life.

**Diagnosis.**—This is not difficult. Sensibility is tested in the ordinary way. The preliminary pain must not be mistaken for *neuralgia*. Gustatory sense is tested in the anterior end of the tongue by applying weak acid or salt solutions and comparing the effect on the two halves. The motor power is tested by biting on a piece of wood or cork or by moving the jaws against resistance.

**Treatment.**—This must depend upon the cause, which should be carefully sought. Syphilitic new formations are the lesions most commonly amenable to treatment. In the absence of such causes the treatment must be symptomatic. Stimulating liniments and faradization through the electric brush are often useful. Galvanism may also be used, brushing the part with the cathode. The anesthetic part should be carefully protected against irritants.

In the absence of tangible cause, systemic treatment is not indicated, except to build up the general health of the patient.

## LESIONS OF THE FACIAL NERVE, OR SEVENTH PAIR.

The seventh pair (portio dura of the seventh, old classification) is the motor nerve of the face, and is subject to paralysis of motion and to spasm.

### PARALYSIS OF THE FACIAL NERVE.

**SYNONYMS.**—*Mimetic Facial Paralysis; Bell's Palsy; Monoplegia facialis.*

*Monoplegia facialis* may be caused by lesions in the *cortical center* of the nerve, in the brain between the cortex and the nucleus, in the *nucleus itself*, and in the *nerve trunk*.

*Supranuclear Paralysis.*—The cortical center resides in the foot of the central convolution, probably the anterior central, from which pass out

fibers along with the pyramidal fibers through the internal capsule to the facial nucleus in the tegmentum of the pons on the opposite side. Accordingly, the nerve is commonly involved in hemiplegias—in fact, facial paralysis forms a part of most hemiplegias. Such a paralysis, due to lesion above the facial nucleus, is known as *supranuclear*.

In such a palsy the voluntary muscles of the lower half of the face are paralyzed, while the secretory and gustatory functions of the facial are not affected; nor are the orbicularis and forehead muscles, except in some cases in the beginning of the hemiplegia, these being innervated by the upper branch of the facial. These features, together with the normal electrical excitability of both nerve and muscle, the intact reflexes and taste sense, all point to a *central* facial paralysis as distinguished from a peripheral. The limitation of the paralysis to the lower half of the face is due to the fact that the lower portion only of the face receives exclusively crossed innervation, while the upper part, like the ocular muscles and the motor trigeminus, is innervated more from both hemispheres, so that a lesion in one may be overbalanced by the other. This will be understood by an examination of the schematic drawing (Fig. 132), from which it is plain that a one-sided brain lesion at *a* paralyzes only the inferior and not the upper facial, because the upper facial is also innervated from the sound side. Recent investigations show that the upper and lower branches of the facial nerve have not separate nuclei, although they may be represented in different parts of the same nucleus. That they are *functionally* distinct is further shown by the fact that in bulbar paralysis, also a disease of the nerve nuclei of the medulla oblongata, only the inferior facial is involved. That the upper face muscles are totally uninvolved in central facial paralysis is not quite true, for careful examination will show that the function is not quite so perfect as in health; the patient cannot close the eye of the paralyzed side by itself, as in the normal state; whence it follows that the upper half of the face is innervated from both hemispheres, as is also shown in Fig. 132. The crossed influence is, however, the larger.

Cortical facial paralysis, *monoplegia facialis*, has been found associated with lesions in the center for face muscles in the lower Rolandic region, but isolated facial paralysis due to involvement of the nerve-fibers in their path from the cortex to the nucleus is extremely rare. Cortical or capsular facial paralysis, as already explained, is on the same side as that of the arm and leg.

*Nuclear Paralysis.*—Paralysis may also be caused by lesions of the nucleus, but is not common. The symptoms are essentially the same as those of paralysis of the trunk of the nerve, or peripheral facial palsy, although there is no loss of taste in the nuclear palsy.

*Infranuclear Paralysis, or Peripheral Facial Paralysis.*—This includes all cases due to involvement of the nerve trunk. The distinctive features of this, as compared with cortical paralysis, have already been stated. It still remains, however, to determine the precise segment of the nerve involved, to be again referred to when treating of diagnosis.

*Etiology.*—*Cortical paralyses* are usually due to compression or destruction of the cortical center, as by traumatism, hemorrhage, tumor, meningitis, or embolism. *Nuclear paralysis* may be caused by tumors, chronic

softening, hemorrhage, or the diphtheritic toxin, while rarely anterior poliomyelitis may involve the facial nucleus.

The most frequent cause of *peripheral paralysis* is exposure to cold, as to a cold wind or draft from an open window. Such cases include so-called rheumatic paralysis, and may be due to neuritis. Disease of the middle ear and caries of the petrous portion of the temporal bone are relatively frequent causes, which have evident explanation in the course of the facial through the Fallopian canal adjacent to the tympanic cavity, whence it may be invaded. At the base of the brain, tumors, syphilitic new formations and inflammatory processes also involve the facial. Rarely swelling

FIG. 132.—Schema and Central Innervation of the Facial Nerve—(after Sahli).

The nucleus of the upper branch is innervated from both hemispheres, though mostly from the opposite side, while the nucleus of the lower branch is innervated almost totally from the opposite side.

of the parotid gland is a cause of pressure. John H. W. Rhein reports a case of right-sided Bell's palsy in a child of eight months succeeding the opening of an abscess under the chin on the right side.<sup>1</sup>

**Symptoms.**—The symptoms vary with the exact seat at which the nerve is invaded. Paralysis of the facial muscles of expression produces the most striking change of physiognomy. The homely description, understood by everyone, is that the face is drawn to one side; and so it is to some degree—to the sound side, except in old cases after contracture has occurred. The appearance of the face being drawn to the sound side is largely deceptive, and is caused by the flattening of the face on the paralyzed side and the contrast afforded by the two sides. Exami-

<sup>1</sup> "Archives of Pediatrics," January, 1906.

nation discloses that on the opposite and paralyzed side there is a remarkable smoothness of face, the wrinkles have disappeared from the forehead, the labionasal fold is gone, and this half of the face is quite expressionless. The corner of the mouth on the paralyzed side is lowered, while saliva frequently flows from it; the eye is wider open than natural, and can be only partly closed, even during sleep—*lagophthalmos*—and the eye waters. These symptoms are rendered still more striking on effort at smiling, talking, or whistling, at turning up the nose, wrinkling the forehead, inflating the cheeks, or closing the eyes. On attempting the latter the upper lid drops as though heavy, the eye is turned upward, the pupil covered, but quite a space remains “uncovered.” The so-called “corneal” and “optical” reflexes, by which, through closure of the lid, the eye protects itself from the entrance of foreign bodies seen approaching, are lost, and a tendency to conjunctivitis results.

In complete facial paralysis winking is impossible. Whistling is also impossible, and speech may be interfered with, owing to the difficulty in forming labial sounds. The proper muscles of mastication are not paralyzed, but, owing to paralysis of the buccinator muscle, food collects between the teeth and cheek on the paralyzed side, and an attempt to sniff reveals paralysis of the nasal muscles. The upper teeth cannot be uncovered, and an attempt to drink is only partly successful, because the lips cannot be kept close to the glass. The tongue is sometimes described as protruding toward the paralyzed side, but this appears to have been an error. The organ is really central, when examined in its relation to the incisors, and the erroneous impression arises from the fact that the lips are drawn to the sound side. Many authorities speak of a paralysis of the soft palate on the affected side, since facial fibers pass through the superficial petrosal nerve to the sphenopalatine ganglion. It is described as drooping, while effort at phonation raises the soft palate obliquely to the sound side. Both Gowers and Hughlings Jackson, however, deny this symptom in most cases, and are sustained by the discovery of Horsley and Beever, that the soft palate is innervated by the spinal accessory nerve. The innervation of the soft palate, however, is not definitely known.

*Derangement of taste* also occurs in the anterior two-thirds of the tongue on the paralyzed side in cases where the facial is involved in that part of its course in which it contains the chorda tympani nerve—that is, in the Fallopian canal between the genu and the union of the chorda tympani with the facial. When the nerve is affected outside of the skull, the sense of taste is intact. Tactile sense in the tongue is also sometimes lessened; salivary secretion is diminished, producing dryness of the mouth. Hearing may be more acute, especially for low notes, because of paralysis of the stapedius muscle, antagonized by the tensor tympani, which is innervated from the trigeminus. Hence results a greater sensitiveness of the membrana tympani. Other disturbances of hearing are also present, but they are generally due to associated aural trouble. Herpes is also an occasional symptom, and is ascribed to the presence of trigeminal filaments among those of the facial.

Facial paralysis usually sets in suddenly, rarely gradually. Sometimes there are prodromata, consisting in abnormal sensations of taste,

pain in the ear and face, and ringing in the former, all from inflammation of the nerve. With this exception, pain is not common.

**Diagnosis.**—The recognition of the presence of paralysis of the facial is for the most part easy. More difficult, and proportionately important, is it to ascertain the modifications due to lesions in different parts of its course. This is rendered easy by the appended schematic drawing of the distribution of the facial nerve, after Sahli. (Fig. 133.)

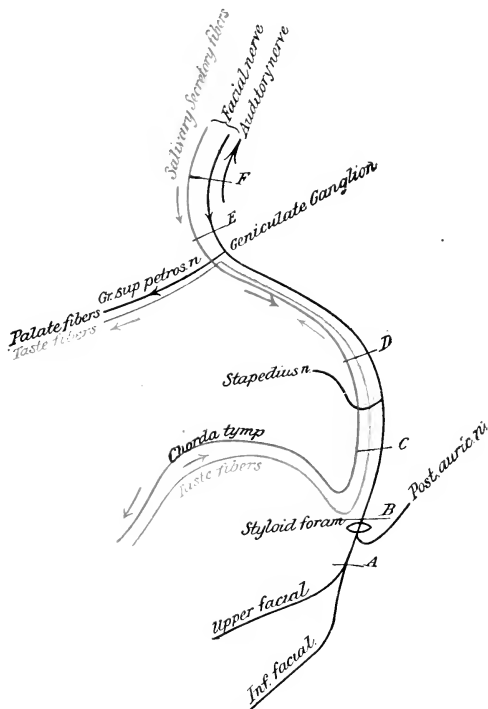

FIG. 133.—Simplified Drawing of the Peripheral Distribution of the Facial Nerve—(after Sahlb).

The phenomena vary in accordance with the following:

- (a) Lesion at *A*, trunk of the facial, affecting only the mimetic branches. Paralysis of all the facial muscles; taste, secretion of saliva, hearing, and palate normal.
- (b) Lesion at *B*, within the styloid foramen. Paralysis of facial muscles, and occipital muscles innervated by the posterior auricular nerve.<sup>1</sup> Taste, secretion of saliva, hearing, and soft palate normal.
- (c) Lesion at *C*. Paralysis of the facial muscles, derangement of taste, diminished secretion of saliva; hearing and soft palate normal.
- (d) Lesion at *D*. Paralysis of the facial muscles, derangement of

<sup>1</sup> Since the occipital muscle is in most men not under control of the will, its paralysis can be ascertained only by the electrical test (reaction of degeneration).

taste, diminished secretion of saliva, abnormal acuteness of hearing, and paresis of soft palate.

(c) Lesion at *E*, above geniculate ganglion. Paralysis of the facial muscles, diminished secretion of saliva, abnormal acuteness of hearing, paresis of soft palate, but no disturbance of taste.

(f) Lesions at *F*, in Fallopian canal, often associated with a lesion of the auditory nerve in consequence of its proximity to it. Paralysis of facial, diminished secretion of saliva; hearing may be influenced by common lesions to auditory; palate normal, taste normal.

The student is referred to what has previously been said as to the modification rendered necessary by the observations of Gowers and others on the non-involvement of the soft palate in facial palsy.

We are aided also in recognizing precise forms by the causes, if known, like the presence of ear disease, or a history of exposure to cold or of traumatism. Coexisting symptoms of brain or bulbar disease must also be considered. Reaction of degeneration cannot occur in true cerebral facial palsy, only in peripheral palsy or in such bulbar paralysis as affects the facial in or below the nucleus itself. In the cortical facial paralysis the frontal distribution of the facial nerve and the ocular muscles are not seriously affected except in the early stages; in the peripheral paralysis they usually are.

The existence of bilateral facial paralysis—*diplegia facialis*—points almost invariably to a central lesion, and more especially to a bulbar affection, since it must be a rare event to have a simultaneous involvement of both nerves in their peripheral distribution, though its possibility cannot be denied. Syphilitic meningitis is a common cause of facial diplegia.

**Prognosis and Course.**—The prognosis varies with the etiology and with the degree of severity. Some cases get well rapidly; others partly recover; many are permanent. The following division of forms with their probabilities, according to Erb, will be helpful:

1. *The Mild Form of Facial Paralysis.*—To this many rheumatic cases belong. The affection is usually one of facial muscles only. Electrical excitability in the paralyzed muscles remains normal, and there are no severe and deep-seated changes in nerves or muscles. Recovery is rapid, usually taking place in two or three weeks.

2. *Middle Form.*—There is partial reaction of degeneration, the excitability of nerve being diminished but not lost; in the muscles, however, in two or three weeks, there is decided increase of galvanic excitability to direct excitement, the anodal closure contraction being greater than the cathodal while contractions are slow. Recovery may still be quite rapid, usually in from four to six weeks.

3. *Severe Form.*—Complete reaction of degeneration in nerve and muscles—*i. e.*, loss of faradic and galvanic excitability of nerve, loss of faradic excitability of muscle, and quantitative and qualitative changes in galvanic excitability of muscle. In this form there is always degeneration of nerve and muscle, so that, if recovery takes place at all, it is only after two or six months or longer.

In these cases there often intervene symptoms of motor irritation, consisting:

1. In a marked tonic contraction of the paralyzed muscle, sometimes very striking.

2. Single spasmodic contraction of muscles.

3. Special associated movements. Thus, if the patient closes his eyes or winks, there always follows a marked distortion of the corner of the mouth, which cannot be restrained.

4. An increased reflex irritability, as the result of which, on pricking or blowing on the skin, vigorous muscular contractions follow.

These symptoms last for a long time—for years in incurable or imperfectly cured cases.

Further points bearing on prognosis have reference to the nature of the primary disease. Paralysis caused by tumors of the base of the brain and caries of the petrous bone is almost always incurable. If the paralysis is due to middle-ear disease, the prognosis depends on the curability of the ear disease. The electrical examination affords helpful data. If at the end of one or two weeks electrical excitability still remains normal, a rapidly favorable termination may be predicted. If, on the other hand, the reaction of degeneration is present, a much longer course and delayed recovery, if any, may be expected. Relapses may occur.

**Treatment.**—The treatment is, of course, that of the lesion which lies at the bottom of the paralysis. If it is a syphilitic, inflammatory product, the iodids should be administered in the usual ascending doses. Middle-ear disease should receive the promptest and closest attention, as some of the most unfortunate cases are thus caused. Any possible cause of pressure should be sought and removed.

When cold is the cause, and the case comes early under observation, warmth, either dry or moist, should be applied to the distribution of the nerve in the face, while mild counterirritation at the *pes anserinus* is useful. Decided blistering is of questionable utility, but it is harmless and probably does good.

For the paralysis remaining after the removal of the cause electricity is indicated, and more especially the constant current. A weak current should be used for from three to five minutes at a time, interrupting from four to six times a minute, placing first the anode and then the cathode in the auriculo-mastoid fossa, the other pole in front of the ear. Galvanism and faradization may be applied to the muscles themselves, including the orbicularis, the direct effect of the electricity on which is shown by an increased power to close the eye immediately after the application of the current. Massage of the muscles may be used.

Sulphate of strychnin is a drug which has some reputation in facial paralysis, although it is difficult to trace the results of its use. Its administration by subcutaneous injection, daily or on alternate days, is recommended. The salicylate may be used with advantage in some cases. Massage of the facial muscles is advisable.

#### FACIAL SPASM.

**Definition.**—By facial spasm is meant a real spasm confined to the mechanism of motor innervation of the face as contrasted with mimetic facial tic or convulsive tic, all usually unilateral, sometimes bilateral.

**Etiology.**—No cause can be found for most cases. Possible causes are exposure to cold, lesions at the base of the skull, or irritation of the facial center in the cerebral cortex. Other cases may be explained by reflex causes, such as irritation by ocular disease, carious teeth, intestinal worms, or disease of the sexual organs. Others have been ascribed to violent mental excitement.

**Symptoms.**—Hugh T. Patrick<sup>1</sup> thus contrasts facial spasm with facial tic, *tic convulsif*, or habit spasm. First, as to points of resemblance: Both facial tic and facial spasm are hyperkinesias. Both present intermittent painless twitching and contraction of facial muscles, both tend to become chronic and both cease during sleep with rare exceptions in case of spasm. Here resemblances cease.

On the other hand, tic is much more common than spasm, and invariably develops in a nervous or neuropathic person. Temperament has nothing to do with spasm. Second, facial spasm is a real spasm confined to the mechanism of motor innervation of the face. Tic is not a spasm, but a movement of volition.

3. Spasm is totally beyond voluntary or involuntary control, while tic is always to some extent under voluntary control and always to involuntary control as by strong emotional or mental preoccupation.

4. Spasm, according to Patrick, is an "anatomical, tic a physiological disorder." A good idea of facial spasm may be obtained by faradizing the facial nerve, and no one would mistake such resulting contraction for a voluntary movement. Tic is a reproduction of a perfectly natural and normal, though it may be unusual movement. Voluntary imitation of facial spasm is impossible, but the patient or even another person may imitate the tic movements.

5. In its incipency spasm is confined to a part of a muscle and ultimately extends to the entire distribution of the facial nerve, no less, no more, and is, moreover, strictly unilateral. Tic never affects a part of a muscle, because voluntary fascicular contractions are impossible. On the other hand, all the facial muscles are rarely included in one movement. In tic one physiologically associated group of muscles may contract one moment, and another group the next. Tic is apt to be bilateral either simultaneously or alternately, and it is peculiarly liable to be associated with tic of adjacent or remote muscle groups.

6. The contraction of facial spasm is very like that produced by faradism when the vibrator is not running smoothly. While the general effect is tonic, there is also a flickering or quivering, or rapid slight irregular twitching such as never occurs in voluntary movement or tic and cannot be imitated. Each spasm begins with this flickering contraction, generally of a part of a muscle and most frequently in the *orbicularis palpebrarum*. The preliminary quiver may be very brief or may last several seconds, and even in a fully developed case one may see abortive spasms. This never occurs in facial tic.

7. Facial spasm may not look worse than facial tic, but is more uncomfortable and much more disabling. The subject of tic may talk and sing as he pleases, and though his talk may be interspersed with grimaces his

<sup>1</sup>Patrick, "Journal of Nervous and Mental Diseases," January, 1909.

sentences are not interrupted by them. The speech of a person with spasm may be cut short at any time.

*Blepharospasm.*—A variety of the partial form is *blepharospasm*, a tonic or clonic spasm of the orbicularis muscle. In the clonic form it is apt to be associated with spasm of the lateral facial muscles, and there is constant twitching of the side of the face, with partial closure of the eye. In another clonic variety there is constant contraction of the eyelids and consequent winking.

The tonic form is usually reflex in origin, bilateral, and may last for days or weeks, with occasional interruptions. The reflex cause is commonly some affection of the eye, producing photophobia, or it may reside in some other point in the distribution of the trigeminus. The clonic form may also sometimes be traced to a reflex act as a cause.

Very interesting in connection with blepharospasm is the discovery by v. Graefe of certain so-called "pressure points." These are points at which pressure causes the spasm to cease, so that the eyelids "fly up as if by a spring." These are commonly found at points of exit of the trigeminus, but have also been found on the vertebral column and elsewhere.

For other forms of spasm of the facial nerve see Choreiform Affections, page 1210.

**Prognosis.**—This in all forms is, as a rule, unfavorable. There are intervals of suspension, sometimes of considerable length, but the spasm recurs, and the disease generally remains incurable.

**Treatment.**—The treatment by drugs is correspondingly unsatisfactory, but a number of things may be done. Causes of reflex irritation should be sought and removed, such as carious teeth and ophthalmia. Paquelin's cautery may be applied to the trunk of the nerve, or to pressure points, if they exist. Nerve section of the supra-orbital nerve has been practiced in blepharospasm. Nerve stretching has been followed by relief, at least as long as the paralysis continues, which is commonly a welcome substitute for the twitching. The constant current may be used, seeking also for pressure points, to which the anode is to be applied. If there are none, this pole should be applied to the trunk of the nerve and to the different branches of the pes anserinus. In cases of reflex origin Berger reports that satisfactory results were obtained by applying the anode to the occiput just under the protuberance, while the cathode was held in the hand—an attempt at galvanization of the medulla oblongata. The single sitting should last from five to ten minutes. Weir Mitchell recommends the freezing of the cheek every day or every other day with the rhigolene spray; at least transient relief follows. The injection of a small amount of alcohol into and about the nerve is a new and promising method of treatment. It has been successful in a number of cases. Paralysis of the facial distribution occurs, and after it has disappeared the spasm may not reappear.

As to medicines, those usual in nervous affections should be tried—bromid of potassium, strychnin by hypodermic injection, arsenic, iron, oxid of zinc, atropin, curare.

The treatment of convulsive tic is that of hysteria.

## LESIONS OF THE AUDITORY OR EIGHTH NERVE.

The eighth pair (portio mollis of the seventh in the older classification of Willis) with its central connections may be affected anywhere in its course from its cortical center in the upper part of the first temporo-sphenoidal convolution, thence in the internal capsule across to its nucleus at the junction of the pons with the medulla oblongata, or at the base of the brain after it passes out of the pons into the internal auditory meatus to its distribution in the cochlea and vestibule. The proximity of this nerve to the facial at the base of the brain and in the internal auditory meatus is to be remembered. As indicated by its name, it is softer and more vulnerable than the facial, so that equally acting causes may affect it and leave the facial intact.

The auditory nerve should be regarded as two nerves—the cochlear and the vestibular; the former having to do with hearing and the latter with co-ordination.

**Symptoms**—Directly due to disease of the auditory nerve are limited to some derangement of hearing, and it is their association with others which widens their significance in the study of nervous diseases. The derangements of hearing resulting from such lesion are six:

1. Loss of hearing, or deafness.
2. Increased sensitiveness, auditory hyperesthesia, or hyperacusis.
3. Symptoms of irritation, causing subjective aural sensations—tinnitus aurium and allied symptoms.
4. Disturbances of equilibrium or sensation of such, due to irritation of the fibers in the semicircular canals—Ménière's disease.
5. Certain rare instances of involuntary movements, due to disease of the nerve within the ear, as oscillatory motions of the head.
6. Purely functional derangements of hearing, occurring especially in connection with hysteria and with anemia following large hemorrhage.

## I. LOSS OF FUNCTION; NERVOUS DEAFNESS.

**Etiology.**—Deafness may be congenital when it is due to labyrinthine defect. According to Gowers, 80 per cent. of deaf mutes are congenitally deaf. The remaining 20 per cent. become so from disease in early life. Of congenital cases it is said that the intermarriage of relations having similar defects is responsible for some, while such intermarriage, even where there is no such defect, is held responsible for a smaller number. Partial as well as total deafness may be congenital.

Of the cases of acquired nervous deafness, disease of the labyrinth, either primary or secondary to that of the middle ear, causes most. The labyrinth is subject to inflammation, acute or chronic, to syphilitic disease, to degeneration, and to hemorrhage. It may be invaded by meningitis, cerebrospinal or tuberculous. Its membrane may undergo degeneration, due to gout or simply to old age. The product of all these may be fibrous or calcareous new formation. The deafness caused by certain drugs, as quinin, has been ascribed to congestion of the internal ear, and that by loud noise, as the explosion of artillery, to hemorrhage.

Lesions of the nerve trunks are less common causes. They may be of the same character as those of the labyrinth, except primary inflammation, although even this is said to be a cause. Primary degeneration may occur in *tabes dorsalis*. The nerve may be compressed by thickening of the cranial bones, calcareous nodules, tumors, or extravasated blood.

The nuclei within the pons may be damaged by hemorrhagic extravasations and tumors. Above the nuclei there may be a lesion encroaching on the superficial layer of the tegmentum, a lesion in the internal capsule, or in the cortical center.

**Symptoms.**—Since, as already stated, derangement of hearing constitutes the only essential symptom of nervous deafness, any enlargement of the subject can be made only by considering the modifications and conditions of this system, and by reviewing such methods of determining the precise seat of the lesion as exist.

The ability to hear through the bone while the air conduction is impaired implies that the function of the labyrinth is intact, and that deafness is due to obstruction of the meatus or to disease of the middle ear and not to nerve deafness. This is further confirmed if the bone conduction is intensified by closing the meatus, since in this way the vibrations, which ordinarily pass out by the meatus, are retained. On the other hand, if there is diminished bone conduction, it does not necessarily follow that the labyrinth is diseased, because there may be ankylosis of the stapes, which will diminish bone conduction, although no amount of disease of the middle ear will extinguish it if the labyrinth be intact. Further, in health air conduction is heard after bone conduction ceases. This is the basis of Rinne's test, in which the vibrating tuning-fork is first placed upon the mastoid process and allowed to remain until the sound dies away to the patient, when the fork is suddenly transferred to the external auditory meatus of the same ear. If the air-conducting apparatus is normal, the vibration of the fork should again be heard. Again, there may be a moderate impairment of hearing and maintenance of the relative delicacy of the air conduction. Absence of bone conduction is, however, the characteristic symptom of nervous deafness. So, to a less degree, is deafness to short and high-pitched sounds, whence the high-pitched, short sounds of the ticking of a watch is a delicate test of the ability to hear through the bone. Simple senile labyrinthine degeneration may be responsible for inability to hear the ticking through bone in persons sixty years old or more.

Can we distinguish between labyrinthine disease and disease of the nerve before its terminal distribution? Given the absence of bone conduction, if the facial nerve is paralyzed, and there is also disease of the middle ear or of the bone, we may conclude that the nerves (facial and auditory) are affected at the base of the brain or in the internal meatus. If there is disease of the middle ear along with deafness and paralysis of the facial, it is probable that the facial nerve and labyrinth are affected by extension of the disease from the tympanum, but this is not certain. An involvement of the trunk of the nerve at the base is also probable if some other nerve near it, as the sixth, is involved. The fact that the auditory nerve is more sensitive to pressure than the facial has already been mentioned, whence

an agency, such as an inflammatory product, pressing on both nerves may affect the auditory and leave the facial intact.

No distinctive symptoms have been found associated with lesion of the auditory nuclei in the medulla oblongata. Such lesion is very rare, but has been found associated with deafness on the same side, while it has also been found when the hearing has been unaffected. Sudden deafness, associated with other symptoms of a lesion of the pons or medulla oblongata, should excite suspicion of nuclear lesion, especially if paresis of limbs on the opposite side be one of those symptoms.

The auditory fibers between the cortex and the auditory nucleus in the pons, in their passage through the tegmentum, may also be affected and may produce deafness. Such a lesion is a tumor of the corpora quadrigemina.

Lesions of the cortical center are very rare, though they have been sufficiently frequent to confirm the results of experiment on the monkey, which go to show that the first temporo-sphenoidal gyrus represents the center for hearing, since the destruction of this gyrus on the left side in man has been attended by word-deafness. It is possible that the first temporal gyrus in each hemisphere in man must be damaged in order to produce cortical deafness for sound. Hemorrhages, softening, and pressure by fractures or tumors may be causative lesions in this situation.

**Treatment.**—This is for the most part unsatisfactory, at least from the physician's standpoint. Careful otoscopic examination should be made with a view to discovering the existence of disease of the external and middle ear, and the aural surgeon should invariably be consulted in derangements of hearing of more than brief duration, with a view to obtaining certainty of diagnosis between nerve deafness and disease of the middle or external ear. Suspected syphilitic tumors should be treated by iodids. A blister in front of or behind the ear may be useful, especially in acute cases; but deep blistering should be avoided in front lest it cause facial neuritis. Electricity has been employed with partly satisfactory results.

## 2. AUDITORY HYPERESTHESIA.

True hyperesthesia, or hyperacusis, is a condition in which ordinary sounds are heard with more than normal acuteness, and in which sounds inaudible become audible. In dysesthesia, or dysacusis, ordinary sounds, although not intensified, produce discomfort. There is generally present some pre-existing symptom, as a headache, during which sounds usually without effect intensify the headache. Both these conditions occur in functional as well as in organic brain disease. Of the former, hysteria is an instance; of the latter, meningitis.

**Treatment.**—The treatment, outside of the removal of the cause, is by nerve sedatives, as the bromids, preparations of valerian, and asafetida.

## 3. IRRITATION OF THE AUDITORY NERVE—TINNITUS AURIUM.

**Definition.**—The term tinnitus includes almost every conceivable form of auditory subjective sensation, of which the most common is ringing, roaring, or hissing. The tinnitus may include humming, ticking, the sound

of rushing steam, the roaring of machinery and the like, the sound of a bell, and even articulate speech, music, or the sound of voices. It may be persistent or intermittent, with rhythmical intermissions—these commonly corresponding with the beating of the pulse. The sounds may be so slight as to be forgotten when the attention is directed to something else, or they may be heard through everything, causing the sorest distress and misery. In fact, their victims have even been impelled to self-destruction. The clicking symptom, sometimes audible to those standing near, is often very annoying, and may be due to clonic spasm of the muscles connected with the Eustachian tube or levator palati. The so-called premonitory “aura” of epileptic seizures may be a variety of tinnitus.

**Etiology.**—Beyond what is conveyed by the word “irritation,” it is exceedingly difficult to discover the cause of tinnitus. Changes in the labyrinth appear to be the most common, and Gowers tells us that “evidence of nervous deafness, mostly due to changes in the internal ear, is distinct in four-fifths of the cases which come under the physician’s notice. Disease of the middle and external ear, including inflammation and wax accumulation, is also a fruitful cause, while in a few cases the process may be wholly in the auditory centers, in the nucleus of the nerve, or in the cortical area. Blood movement, not usually audible, may become so. Internal aneurysm is a possible cause. Tinnitus is a very frequent symptom in gouty cases, in my experience, especially when associated with the nervous temperament. So it is in anemia and neurasthenia. An epileptic aura is often a tinnitus. A systolic brain murmur is sometimes heard over the ear in children, and even in adults.

**Treatment.**—This is generally most unsatisfactory. The ear should be explored and its surgical diseases treated.

The gouty diathesis must be treated by the administration of the salicylates, colchicum, and purgatives, and by regulation of the diet; anemia and neurasthenia by iron, arsenic, nutritious food, and rest. Large doses of salicylic acid and quinin, it is known, produce ringing in the ears—a fact to be remembered always.

The bromids are sometimes beneficial, and a few drops of tincture of belladonna are sometimes added. Nitro-glycerin has been highly commended. Beginning with doses of  $\frac{1}{100}$  grain (0.00066 gm.), they should be rapidly increased until the physiological effect is produced. My experience with nitro-glycerin is that the physiological effect is often not attained in adults even by doses of  $\frac{1}{100}$  grain (0.00066 gm.).

Counterirritation is undoubtedly useful at times. It should be applied behind the ear, and actual vesication is the most efficient form. The temporary effect is sometimes striking, while permanent results may be produced by repeated blistering.

#### 4. DISTURBANCE OF EQUILIBRIUM ASSOCIATED WITH DEFECT OF HEARING—LABYRINTHINE VERTIGO. MENIERE’S DISEASE.

**Definition.**—The term Ménière’s disease is applied to a vertigo, usually sudden, associated with deafness and noises in the ear.

**Pathology and Etiology.**—In 1861 Ménière described some cases in

which vertigo was produced by a sudden lesion of the labyrinth. Since then the term Ménière's disease has come to be applied to all cases of sudden vertigo associated with labyrinthine disease. Gowers says that "in nine cases out of ten in which there is definite giddiness, not epileptic in nature or obviously due to organic brain disease, it is due to a morbid state of the labyrinth or auditory nerve endings." Thus the vertigo becomes the result of the irritation of the nerve.

In addition to clinical sources for the confirmation of this view there is the fact that experimentally induced lesions in the semicircular canals of animals result in vertiginous movements. In point of fact, aural vertigo results from almost any one of the morbid processes possible to the labyrinth and the nerve endings it contains, but not from disease of the middle ear. The precise nature of the morbid change can only be conjectured. It is twice as frequent in men as in women, and four-fifths of all cases occur between the ages of 30 and 60. Cold, gout, and syphilis have been followed by it, probably through inflammation, and possibly resulting hemorrhage. The slower forms may be due to degenerative processes, like those of tabes or such as are due to age. Vasomotor neuroses of the vessels of the labyrinth have been held responsible.

**Symptoms.**—The vertigo is usually sudden and paroxysmal, though there may be light continuous dizziness between paroxysms, which occur at intervals of from a few days to as many weeks. Occasionally they occur daily. They may be spontaneous or an exciting cause of trifling character may bring them on, such as turning, coughing, or sneezing. Gastric disturbances may excite them—a fact to be remembered in the differential diagnosis from gastric vertigo. There may be brief unconsciousness. The attacks generally pass off in a few minutes, leaving the patient pale, faint and nauseated, often in a cold, clammy sweat. Vertigo may or may not be accompanied by a tendency to fall forward, backward, or to one side, and the victim may have to grasp something to save himself from falling. External objects may appear to circle about him. The seeming movements of person and external objects are usually in the same direction.

The auditory symptoms—deafness and tinnitus—may be in one or both ears, and more marked in one side than in the other. In the latter case the sense of movement may be toward or from the ear most affected; but when the subjective and objective movements coincide in direction, they are more often toward the affected side.

The deafness is nervous and always partial. The tinnitus is usually roaring or throbbing. There may be ocular symptoms; these are secondary, and include nystagmus and diplopia. Pressure on the drum or on the meatus may bring on the nystagmus, and sometimes an apparent jerky movement of objects. Diplopia, nystagmus, and jerky movements may occur together.

**Diagnosis.**—The essential symptoms of Ménière's disease are dizziness, tinnitus, and deafness. Gastric disturbance is not peculiar to it. The deafness must be proved to be nervous and not the result of defective air conduction. True *gastric vertigo* is not associated with deafness, while other symptoms of dyspepsia are present with it.

While the aura of *epilepsy* is sometimes accompanied by giddiness,

there is no impairment of hearing. Moreover, in Ménierè's disease slight vertigo is more or less constant, the tinnitus is persistent, and loss of consciousness, if present, is very brief. It is the *petit mal*, with its brief unconsciousness, with which the confusion may occur.

The vertigo of *cardiac valvular disease*, especially aortic insufficiency, of *arteriocalillary fibrosis*, and of *chronic interstitial nephritis* is unaccompanied by any of the other distinctive signs of Ménierè's disease. *Gelier's vertigo*, characterized by attacks of parietic weakness of the extremities, ptosis, and profound depression, but without loss of consciousness, occurring especially among laborers in the canton of Geneva, should be mentioned as a source of possible error.

**Prognosis.**—This depends upon the durability of the lesion causing the malady. In cases resulting from remedial causes—such as gout and even syphilis—recovery is possible, while palliation is not infrequently attained. Other cases are obstinate and incurable. Relief, however, comes to the dizziness when the deafness becomes total.

**Treatment.**—When traceable to gout and syphilis, the remedies appropriate to these diseases should be prescribed. The salicylates and iodids are most frequently useful, but the lithium salts and colchicum are to be remembered. The salicylates should be given in moderate doses rather than large ones, which produce the ringing in the ears. In the absence of knowledge of a definite cause the bromids are the remedies to be most relied upon. From 20 to 30 grains (1.3 to 2 gm.) should be given at a dose, and Gowers recommends the addition of a few minims of the tincture of belladonna. Nitro-glycerin has been recommended. Suprarenal extract may be beneficial in some cases. Where the tinnitus is intense and not amenable to drugs, intracranial division of the auditory nerve may be advisable. The general health should be looked after.

Counterirritation by blistering behind the ear is sometimes promptly followed by favorable results.

## LESIONS OF THE NINTH OR GLOSSOPHARYNGEAL NERVE.

**Anatomical.**—This triply mixed nerve supplies sensibility to the soft palate, the tonsils, the upper part of the pharynx, the Eustachian tube, and the tympanic cavity; motor impulses to the stylopharyngeus and to the middle constrictor of the pharynx; and the sense of taste to the posterior third of the tongue and to the palate.

The study of the precise pathology of this nerve is rendered difficult by its numerous communications with other nerves, notably with the fifth, the facial, and the pneumogastric, and by the fact that it is rarely involved alone. Experimental inquiry with it also is difficult.

The nerve may be invaded by meningitis, tumors, or degenerations.

**Symptoms.**—Symptoms of such lesion would be *difficult deglutition* and *perversion of the sense of taste—parageusia—or complete gustatory anesthesia.*

Modifications of the sense of taste are tested by means of sapid substances in solution, applied to the anterior and posterior parts of the tongue by a glass rod or a brush, suitable substances being used for each taste.

Thus, for bitter a solution of quinin may be used; for sweet, a solution of sugar; dilute acetic acid or vinegar for acid, and common salt for the saline taste.

Ageusia may result not only from lesions of the glossopharyngeal nerve, but also from those of the gustatory or lingual branch of the fifth, and possibly of the fifth itself within the cranial cavity; from affections of the chorda tympani in disease of the middle ear, of the facial between the entrance of the chorda tympani and the geniculate ganglion, and in lesions of the peripheral organs of the nerves of taste. Disturbance of taste may possibly result from cerebral lesions, but the cortical area for taste is not known. It is probably in the region of the uncinate gyrus.

Perversion of the sense of taste is known as "parageusia." It is a rare phenomenon, found in patients with facial palsy, in the hysterical, and in the insane, in whom, also, subjective sensations of taste may be present. The latter also occurs as an aura in epilepsy. Hyperesthesia of taste is even more rare, and is purely a hysterical symptom.

#### LESIONS OF THE PNEUMOGASTRIC OR VAGUS NERVE— THE TENTH PAIR.

**Anatomical.**—This nerve has by far the widest distribution of any of the cranial set, supplying the pharynx, larynx, lungs, heart, esophagus, and stomach, and in part also the intestines and spleen. The symptoms of its involvement are, therefore, numerous and varied.

It is a *mixed nerve* of motion and sensation, some of its most important motor functions being derived from the spinal accessory nerve. It is the chief sensory nerve for the respiratory center in the medulla oblongata, but contains, also, accelerating and inhibitory fibers from this center. The former office preponderates, so that section of the nerve renders respirations less frequent, though deeper, while stimulation of the divided central end accelerates them, and acceleration may proceed to tetanic arrest. The inhibitory fibers are contained chiefly in the superior laryngeal nerve, stimulation of which arrests breathing with the muscles in a state of relaxation.

It is also the inhibitory nerve of the heart, slight stimulation increasing the length of diastole, while stronger stimulation arrests its action. On dividing the nerve cardiac contractions become more frequent. It is also inhibitory for the vasomotor center, and its stimulation produces relaxation of the arteries throughout the body. It is the motor and sensory nerve for the esophagus, sensory nerve for the stomach, and partly the motor nerve for the stomach and intestines.

#### LESIONS INVOLVING THE NUCLEUS AND TRUNK OF THE PNEUMOGASTRIC AND BRANCHES.

The *nucleus* in the medulla oblongata may be involved in softening, hemorrhage, or slow degeneration, but adjacent nuclei are also affected at the same time, whence resulting effects are associated and are especially seen in bulbar palsy.

The *trunk* of the nerve near its origin may be compressed by thickened meningitis, tumors, or aneurysm of the vertebral artery. In its course it has been implicated in incised wounds, and tied in ligation of the carotid. Neuritis and neuromata are possible. The results of such lesion are commonly paralytic, rarely irritative. The former, if total, are diminished breathing-rate, "suffocation," frequent pulse-rate, and death. According to Traumann and others unilateral division of the vagus in experiments on animals caused few pulmonary symptoms. One vagus seems to be sufficient for the function of both lungs. The results of partial paralysis are better considered in connection with lesions of the separate branches of the pneumogastric, some of which are also invaded separately.

**LESIONS OF THE PHARYNGEAL BRANCHES.**—These branches of the pneumogastric, together with branches of the glossopharyngeal, form the pharyngeal plexus, from which the muscles and mucous membrane of the pharynx are innervated.

**Etiology.**—Nuclear disease is a most common cause of paralysis of the pharynx. It shares with disease involving adjacent nuclei, constituting bulbar palsy, already considered; but it may also be caused by meningitis or bone disease at the base of the skull, or it may form part of the lesion of diphtheritic paralysis.

**Symptoms.**—The results are mainly paralytic, occasionally irritative, producing spasm. The symptoms of *paralysis* are difficulty in swallowing, food lodging in instead of descending into the esophagus. A most frequent consequence is the entrance of food into the larynx, causing spasm and even choking. Pulpy food is better swallowed than liquids, the latter passing easily into the posterior nares when there is paralysis of the soft palate, and even when the paralysis is limited to the superior constrictor of the pharynx owing to contraction of the middle constrictor. When the nerves on one side only are involved, the difficulty is much diminished. Should there be a doubt in diagnosis between paralysis of the pharynx and obstruction or morbid growth, the passage of a bougie will clear it up.

*Spasm* of the pharynx is always functional in origin, chiefly hysterical. The so-called "globus hystericus," or sensation as of a ball in the throat which has to be swallowed but immediately arises again, is one of its manifestations; so is eminently the spasm in hydrophobia. Extreme degrees are those in which persons cannot swallow their food in the presence of others.

**LESIONS OF THE LARYNGEAL BRANCHES.**—The laryngeal branches are two, the superior and inferior or recurrent laryngeal. The former supplies the mucous membrane above the vocal cords, the cricothyroid, and the depressors of the epiglottis. The inferior or recurrent laryngeal on the left side winds around the arch of the aorta; on the right, around the subclavian. The nerves then pass up to the larynx between the trachea and the esophagus, supplying all the laryngeal muscles except the cricothyroid and epiglottic, and the mucous membrane below the cords; also that of the trachea. It has been supposed that the motor fibers in these nerves come from the spinal accessory nerve, but this is now doubted. The

sensory filaments of the laryngeal branches pass to the medulla oblongata in the roots of the pneumogastric.

In order to appreciate the phenomena of paralysis of the larynx it should be remembered that the glottis is opened or closed only by the movement of the posterior extremity of the cords, the anterior remaining fixed, and that this movement is effected chiefly by the arytenoid cartilages attached to the cricoid cartilage by an articulation which permits free movement. Each arytenoid is shaped like an irregular pyramid prolonged at the base into two processes—an anterior or vocal, from which the cord passes to the thyroid cartilage, and an external or muscular, to which the muscles are attached. When the latter, which is at right angles to the vocal process, is moved back, this process moves outward from its fellow, the cord is abducted, and the glottis opened. If the muscular process is moved forward, the vocal process is moved inward toward its fellow, the cord adducted, and the glottis closed. These movements are further aided by movements of the arytenoids away from or toward each other.

**Symptoms.**—These are phonic and respiratory, together with altered position of the cords, as recognized by the laryngeal mirror. The voice may be changed or lost, the entrance of air in breathing impeded, while the closure of the glottis, necessary to coughing, is usually imperfect. The voice and respiratory functions of the larynx are regulated by the same muscles and nerves, but by centers that differ in anatomical connection, if not in position.

In breathing the cords are abducted or separated during inspiration, the extent being proportionate to the force of inspiration. During expiration they are a little nearer than in inspiration. In phonation they are made tense and brought together, the degree of adduction and tension varying with the note produced. After death the vocal cords assume a position of slight abduction from the middle line, a little nearer than during ordinary breathing, known as the cadaveric position. The position is one of partial relaxation, complete relaxation being never fully attained during life.

The symptoms of deranged function of the laryngeal nerves admit of classification into those of *paralysis* and *spasm*.

1. *Total Paralysis of Both Cords or of One.*—In what is known as *complete paralysis* of the laryngeal muscles—which does not, however, usually include the cricothyroid—the vocal cords assume the cadaveric position previously mentioned, from which they cannot be moved. Hence vocal sounds cannot be produced. In deep inspiration the current of air may bring them a little closer, and there may be slight stridor, and instead of the natural explosive cough, there is only a sudden rush of air through the glottis. If *one cord is paralyzed*, it alone is motionless in the cadaveric position. Phonation may still be possible, because the unaffected cord may be overadducted beyond the middle line, but the voice is low-pitched and often hoarse. During inspiration the abduction of the healthy cord prevents stridor, while an explosive cough is impossible because the glottis is not closed with sufficient firmness to produce it, unless the paralysis is very slight.

The *causes* of complete paralysis are central disease and disease of the trunk of the vagus or of the recurrent laryngeal.

2. *Bilateral Abductor Paralysis*.—In abductor paralysis involving the posterior crico-arytenoids the cords are near together—in the position of phonation—and cannot be abducted even as far as the cadaveric position. They can, however, be brought together in phonation and in coughing, at the cessation of which they recede a little, but the normal wide abduction of inspiration does not take place. This slight recession is due to the elasticity of the attachment of the cords. The abductors, unopposed, undergo secondary contracture, so that if the paralysis is of long duration, the chink of the glottis becomes permanently narrower. The tensors are still active, as well as the abductors, hence the voice is little affected. The chief difficulty is in breathing, since the normal recession of the cords essential to inspiration does not take place, while they are even brought closer together by the pressure of the entering air. Hence inspiration is accomplished with stridor, and the obstruction to the entrance of air brings into play the extraordinary muscles of respiration, the effect of which is to prolong the inspiratory act. Expiration is unimpeded, the current of outward air tending to open the cords. The absence of voice involvement and of cough may cause the obstruction to be referred to the trachea, but the absence of the expiratory stridor excludes this, while the movement of the larynx up and down during breathing is greater than in tracheal stenosis. The added urgent dyspnea, the loud inspiratory stridor, livid features, and cold extremities furnish an unmistakable picture; so that a laryngoscopic examination is therefore not necessary to complete the diagnosis. In bilateral palsy there is even great danger, as a slight catarrhal swelling may close the larynx and tracheotomy may be necessary to save life.

The *causes* of abductor paralysis are central disease and local influence such as laryngeal catarrh and degeneration of the posterior cricothyroids, possibly of toxic origin. Disease of the recurrent laryngeal has produced such paralysis, although this nerve supplies fibers to the adductors as well as abductors. On the other hand, the abductors have been found degenerated when the other muscles were found normal. Paralysis of both cords is generally due to disease of both nerves, and may be produced by pressure on both vagi and both recurrent laryngeal nerves. Central causes are tabes dorsalis and bulbar palsy. Abductor paralysis is also a rare symptom in hysteria, when it is bilateral, with characteristic symptoms, and has caused death.

3. *Unilateral Abductor Paralysis*.—In this the affected cord is near the middle line, and it does not move in inspiration. There are hoarseness and roughness of voice and sometimes dyspnea, but the mobility of the other cord permits the function of the larynx to be carried on with tolerable comfort. If the adductors become involved, as is sometimes the case, phonation is still more impaired.

The most frequent cause is *aneurysm*, and the *left cord* is most frequently involved—though other tumors may cause it—and on the right side the nerve may be involved in a thickened pleura.

4. *Adductor Paralysis (Phonic Paralysis; Hysterical Paralysis)*.—In adductor paralysis due to involvement of the lateral crico-arytenoid and the arytenoid muscles the cords are apart and cannot be approximated. In true adductor paralysis there is still the power of separating the cords

on deep inspiration, but no power to bring the cords nearer than in the cadaveric position.

The *causes* of adductor paralysis are rarely organic diseases of the nerves or centers. It is the condition causing the oft-quoted *hysterical aphonia*, and may be brought on by overuse of voice and catarrhal laryngitis. The patient with hysterical aphonia can sometimes sing, though she can only talk in a whisper. It is most common as a partial paralysis. While the cords cannot be approximated for phonation, they can be in coughing. Hence it was called by Türk "phonic paralysis." Another partial adductor paralysis is due to the loss of power in the arytenoid muscle, resulting in defective closure of the posterior part of the glottis and hoarseness or loss of voice.

5. *Tensor Paralysis*.—Little is known of this except that palsy of the internal fibers of the thyro-arytenoideus causes the edge of the cord to be concave.

**Diagnosis.**—The laryngoscope is necessary to a proper diagnosis of laryngeal palsies, but symptoms are also useful. The inability to produce explosive cough is of great value in pointing to palsy of organic origin, if there is no local lesion to prevent it.

(a) Absence of cough with entire loss of voice points to bilateral palsy of organic origin.

(b) No cough, voice low-pitched and hoarse, paralysis of one cord.

(c) Loud inspiratory stridor without loss of voice, total abductor paralysis.

(d) Little change of voice or cough, unilateral abductor paralysis.

(e) Perfect cough, no voice, no stridor, unimportant adductor palsy.

The following table from Gowers contains in separate columns the symptoms, laryngoscopic picture, and lesions:

SYMPTOMS.	SIGNS.	LESION.
(a) No voice; no cough; stridor only on deep inspiration.	Both cords moderately abducted and motionless.	Total bilateral palsy.
(b) Voice low-pitched and hoarse; no cough; stridor absent or slight on breathing.	One cord moderately abducted and motionless, the other moving freely and even beyond the middle line in phonation.	Total unilateral palsy.
(c) Voice little changed; cough normal; inspiration difficult and long, with loud stridor.	Both cords near together and during inspiration not separated, but even drawn nearer together.	Total abductor palsy.
(d) Symptoms inconclusive; little affection of the voice or cough.	One cord near the middle line, not moving during inspiration; the other normal.	Unilateral abductor palsy.
(e) No voice; perfect cough; no stridor or dyspnea.	Cord normal in position and moving normally in respiration, but not brought together on an attempt at phonation.	Adductor palsy.

*Spasm of the Larynx*.—In spasm of the larynx the adductors are alone concerned. The closers of the glottis are stronger than the openers, while reflex mechanism is connected chiefly with those muscles because of the importance in guarding against the entrance of foreign bodies into the larynx. Spasm is quite common in children, especially in the rickety, and is not rare in adults under the name of laryngismus stridulus. It is generally reflex, although the reflex cause is not always discoverable. The patient com-

monly wakes up at night in an attack of intense dyspnea; but it may occur at any time. The symptoms are like those of ordinary croup.

The paroxysm differs from that of abductor paralysis in that stridor accompanies expiration as well as inspiration. The attacks occur in the so-called laryngeal crises of *tabes dorsalis*, in tetany, in the paroxysms of hydrophobia, sometimes in alternation with attacks of migraine, and in hysteria.

Spasm is also sometimes excited by attempts to speak, when aphonia results. The condition is the reverse of phonic paralysis, in which the cords cannot be brought together in speaking, while in spastic aphonia they come together too forcibly.

Disturbances of the sensory innervation of the larynx are chiefly confined to the irritation which causes cough and spasm.

**LESIONS OF CARDIAC BRANCHES.**—The cardiac plexus is made up of fibers derived in part from the pneumogastric and in part from the sympathetic. The vagus fibers are motor, sensory, and probably trophic.

The *motor fibers* include those which inhibit, control, and regulate the cardiac action. Their *irritation* inhibits the heart's action and causes slowness of the pulse, or bradycardia. In *complete paralysis* of the vagi the inhibitory action is abolished and the accelerator influence is unhampered, producing rapid pulse, or tachycardia. Yet it sometimes happens that complete paralysis of the vagus is followed by no cardiac symptoms.

The causes of these effects are, unfortunately, not always discoverable. Pressure of a tumor, accidental ligation of one vagus, irritation of its nuclei, anginal attacks, in one instance associated with a small tumor of the vagus, have all been followed by bradycardia. Toxic blood states are also held responsible for it. Some persons are able to control the action of their own hearts, notably a Colonel Townsend, who could control the action of his heart at will. The heart may sometimes be slowed by pressure against the pneumogastric in the neck.

The opposite condition, tachycardia, has been produced by diphtheritic neuritis, tumors of the vagus, or accidental removal of the vagus.

*Sensory* phenomena in connection with parts supplied by the cardiac branches of the pneumogastric are unusual, but any uncomfortable sensations arising from palpitation or irregularity are conveyed by branches of the pneumogastric.

*Trophic* influence in the pneumogastric is inferred from the fact that the heart has been found in a state of fatty degeneration after injury to the nerve.

**LESIONS OF GASTRIC AND ESOPHAGEAL BRANCHES.**—Among phenomena ascribed to effect on these branches are spasm of the esophagus and difficulty in swallowing. The vagus is also the sensory nerve of the stomach, and pain in this organ is felt through this nerve. The severe gastric crises which occur in *tabes dorsalis* are due to central irritation of the vagus nuclei. The senses of hunger and thirst are also believed to be conveyed through it, and have been lost in disease involving the root, but appetite is not always lost after section of the nerve, while in some cases of disease of the nerve there has been excessive appetite. On the other hand, loss of appetite is

due to so many causes that it cannot be ascribed to pneumogastric lesion without careful investigation.

The pneumogastric is also the motor nerve of the stomach, though motion of the organ is not entirely arrested after its section. Vomiting is probably produced through its agency, and is excited by central and reflex irritation. Meningitis, which so frequently excites vomiting, does so through it; the pressure of a tumor on the nerve has had a similar effect, also direct pressure on an exposed nerve.

**LESIONS OF PULMONARY BRANCHES.**—While the vagus sends branches to the lungs, little is known of their office. They are supposed to go to the bronchial muscles, and it is held that asthma is a neurosis of these fibers. Irritation of the afferent pulmonary fibers certainly produces spasm. Stimulation of the respiratory center also causes energetic respiratory movements, while rapid congestion and even hemorrhage have been noticed after section, though these effects may possibly be of reflex origin excited through the sympathetic, since the vasomotor fibers in the vessels of the lungs are derived from the sympathetic. After section of the vagus animals die of broncho-pneumonia. This has not been considered the result of trophic influence, but because of the entrance of foreign particles into the bronchi in consequence of paralysis of the larynx and esophagus; this was shown by Traube as far back as 1871, and confirmed by Frey by numerous experiments in 1877. Such broncho-pneumonia has also been ascribed to paralysis of the bronchial musculature and of the vaso-constrictor fibers which causes neuroparalytic hyperemia of the pulmonary tissue. Spiller's case, recently reported,<sup>1</sup> has some bearing on the subject. This patient suffered an injury of the left glossopharyngeus and vagus by a fracture of the base of the skull. He died 46 days after the accident and at necropsy numerous areas of bronchopneumonia were found. It seemed improbable that the pulmonary condition was caused by the entrance of foreign bodies into the lungs in this case, because the patient was unable to swallow. Saliva, however, doubtless passed into the trachea and carried with it micro-organisms. The patient was tested with a glass of water and his choking was so alarming that the attempt was not repeated. He was nourished by rectal enemas and the stomach tube was passed only on the day before his death. The choking was probably the result of impaired function of the epiglottis. Spiller thinks it reasonable to attribute the pulmonary condition to the paralysis of the vagus nerve, although the pulmonary lesions were not recognized until the necropsy was made.

The phenomena of hiccough may be the result of disease of this nerve, as they are also the result of disease of the respiratory center.

**Prognosis in Pneumogastric Lesions.**—This varies greatly. In central and nuclear disease it is unfavorable; it is unfavorable also when it is the result of pressure from intrathoracic tumors, especially aneurysm. In hysterical and purely local affections the prognosis is more favorable.

**Treatment.**—This is, of course, that of the casual lesion, if it can be discovered. Syphilis is the more curable of the central causes. Other causes of central disease are not removable.

<sup>1</sup>Univ. of Penn. Med. Bull," March, 1903.

Of diseases of the trunk, neuritis of the vagus is as amenable to treatment as the polyneuritis of which it is a part. The laryngeal symptoms due to involvement of the recurrent laryngeal are as remediable as the causes which produce them. If they are caused by aneurysm of the aorta or cancer, treatment is useless; if caused by siphilitic and scrofulous growths, the prognosis is more hopeful.

In the paralyses of more purely local origin, especially the hysterical, phonic, and diphtheritic forms, electricity offers the most promising results. The method of its employment will be found detailed under diseases of the larynx. Either form of electricity may be used. Strychnin is a useful remedy, used locally as mentioned. The method preferred is by hypodermic injection, the nitrate being employed in doses of from 1/60 to 1/30 grain (0.0011 to 0.0022 gm.) daily.

In addition to strychnin, other tonics should be used to restore the general health of the patient. Laryngeal gymnastics have been recommended and used with some success. They consist in pressing firmly with the thumb and forefinger on each side of the upper and hinder part of the thyroid cartilage, the patient being requested to make a simple sound during the compression.

The treatment of laryngeal spasm demands also the removal of the cause if possible, in addition to which sedatives, local and general, especially the bromids and cocain, may be used. Chloral, chloroform, and nitrite of amyl by inhalation may be necessary to break up the spasm.

## LESIONS OF THE ELEVENTH PAIR OR SPINAL ACCESSORY NERVE.

**Anatomical.**—This nerve, purely motor in its function, has two portions—an internal, which passes to the pneumogastric and innervates the laryngeal muscles, and an external or spinal portion. The former has been considered. It should be regarded as probably a part of the vagus, and the eleventh nerve is called by some the vago-accessory nerve. The latter, *i. e.*, the spinal portion, is essentially a set of motor fibers from the cervical spinal cord, which ascends into the cranial cavity and passes out again with one of the cranial nerves to be distributed to the sternocleidomastoid and trapezius muscles, whose innervation they share with the spinal nerves. The purpose of the trapezius is chiefly to raise the shoulder; that of the sternocleidomastoid is to assist in turning the head to the opposite side, the chin being at the same time raised. This is accomplished by drawing the occiput toward the side of the muscle acting.

**Lesions.**—The nuclear origin of the nerve may be involved and contribute to the phenomena of bulbar palsy, or it may share in progressive central degeneration, causing wasting in the muscles supplied, which may be a part of a more general muscular atrophy. The trunks of the nerve or both nerves may be compressed in the foramen magnum by meningitis or tumor. Outside the skull there may be wounds, tumors, caries of the vertebræ, and resulting abscesses, and sometimes abscesses springing from

the cervical glands. Rarely the spinal accessory may be invaded by rheumatic neuritis.

The resulting conditions are *paralysis* and *spasm*. Those of the internal or accessory portion have been described under lesions of the pneumogastric. It remains to consider only those of the external branch.

**Symptoms of Paralysis of the External Branch of the Spinal Accessory Nerve.**—The seats of the paralysis are the sternomastoid and trapezius muscles. When one sternomastoid is involved, the head may still be moved to the opposite side, and there is no wry-neck, or torticollis, though in some cases the head is held obliquely. The trapezius is not so much involved because it is well supplied with cervical and thoracic nerves, but a portion which passes from the acromion to the occipital bone is motionless. The middle portion of the muscle is also weakened, the shoulder droops downward and forward, and the inferior angle of the scapula is rotated inward by the action of the rhomboids and the levator anguli scapulæ. Elevation of the arm is also partial, because the trapezius does not fix the scapula at a point whence the deltoid can work. The paralysis is well seen when the patient takes a deep breath or tries to shrug his shoulders. Wasting almost always accompanies the loss of power, and there is usually reaction of degeneration.

In bilateral paralysis the power of holding the head in the upright position is impaired. If both sternocleidomastoids are affected, the head tends to fall backward; if both trapezii, it falls forward so that the chin rests on the sternum. The latter is the characteristic position of the head in progressive spinal muscular atrophy, and in children who have chronic meningitis about the foramen magnum, pressing on both nerve trunks, and in cervical meningitis the result of caries. A peculiar drooping of the head is sometimes seen during the first year of life in children, which Gowers says may be due to injury to the spinal accessory nerves in difficult labor. In recent cases the nerves may give characteristic reaction of degeneration. In central disease the reaction varies, as it does in progressive spinal muscular atrophy.

**Treatment.**—This must have for its object, first, the removal of the cause, or the morbid process which produces it. After this the weak muscles are to be treated by massage and electricity. Faradization is, perhaps, most efficient for this purpose, and either form of current will answer.

**Symptoms of Accessory Spasm (Non-rheumatic Torticollis; Wry-neck).**—Though the muscles supplied by the spinal accessory are not the sole ones responsible for these conditions, they are the ones chiefly concerned. The terms are applied to unnatural positions of the head resulting from contraction of these muscles. There are two principal varieties:

1. Fixed wry-neck, or congenital torticollis.
2. Spasmodic wry-neck.

These two may be regarded as *true* torticollis, and are to be distinguished from two somewhat similar states which may be called *false* torticollis. The first of these is the ordinary rheumatic "stiff neck," which is really a rheumatic condition due to exposure to cold, and characterized by pain and tenderness, for the relief of which the position is assumed, and

should not be called wry-neck. The second is a twist-neck, not due to muscles, but to some other cause, most frequently disease of the cervical vertebrae. This deviation puts the sternocleidomastoid muscle on the stretch, and thus may give rise to the impression that it is responsible.

1. CONGENITAL TORTICOLLIS, OR FIXED WRY-NECK.—This depends on the shortening of some muscle, commonly the sternocleidomastoid, which is also often atrophied, hard, and firm. It is met most frequently in children, and is thought to be due, in some cases at least, to injury of the muscle produced by traction during birth. In others it is ascribed to developmental shortening of the muscle, due to the inclined position of the child's head in the pelvis. It is not always noticed immediately after birth because of the natural shortness of the child's neck. A similar condition may result from injury to the muscle during life, producing inflammation and cicatricial contraction. It affects the right side almost exclusively. It is more or less constantly associated with facial asymmetry, first noticed by George Wilks and further studied by Golding Bird, who suggested that the two conditions are parts of one affection which has a central origin. In fixed wry-neck the head is turned toward the side opposite to that of the contracted muscle, which stands out conspicuously, and cannot be turned toward the latter. While the sternocleidomastoid is the muscle almost invariably responsible in these cases, the trapezius is occasionally the seat of similar atrophy.

**Treatment.**—The treatment is by section of the contracted muscle. Some appliance may be necessary for a time to keep the head in proper position, especially when secondary changes in the articulations have taken place. In simple rheumatic wry-neck I have used an appliance consisting of webbing or "saddle girth" about three inches wide, stretched from side to side of the bed and raised a few inches above the mattress—the distance to be regulated by circumstances—on which the patient lay at night, instead of on a pillow on the side to which the head is drawn. This expedient may be used after operation. The facial asymmetry is likely to remain after the wry-neck is cured, and may even become more conspicuous.

2. SPASMODIC WRY-NECK.—This is a condition analogous to the facial spasm, occurring as a symptom of disease of the facial nerve. There are two forms, the tonic and the clonic, which may alternate in the same case or, as is most usual, occur separately and remain so.

**Etiology.**—It is for the most part an affection of adults, and, according to Gowers, is more common in females—that is, in 22 out of 32 cases. While this must be true of England, the opposite seems to be the case in this country, since of eight or ten cases observed by Osler in Philadelphia and Montreal, all were men. It is more common in middle life, two-thirds of all cases occurring between the ages of 30 and 50. In women under 30 it is likely to be of a hysterical origin; rarely it is ascribable to the same cause in boys. It is prone to occur in neurotic families. Very rarely it occurs in the first year of infantile life, ceasing after a few months. Cold has been assigned as a cause; also traumatism.

In the *tonic* form, when the sternocleidomastoid is responsible, the head

is continually turned to the opposite side, the chin is raised, and the occiput is drawn down toward the affected side—the *caput obstipum spasticum*. When the trapezius is involved, the head is still more depressed toward the same side. In combined and bilateral spasm of these muscles the head is drawn backward, producing the *retrocollic spasm*. In prolonged cases the muscles involved are prominent and rigid, and there may be spinal curvature with the convexity toward the sound side.

In the *clonic* form there are paroxysmal twitchings of the head, which may be very severe and correspondingly distressing. When there is predominating unilateral spasm of the sternocleidomastoid, the head is turned to the opposite side and the chin is raised with every contraction of the muscle. In unilateral spasm of the trapezius the head is drawn more backward with each contraction and toward the shoulder of the affected side. In bilateral and combined spasm there is clonic retrocollic spasm, with shaking and nodding movements—the so-called “salaam convulsions” sometimes seen in children. They may be produced also by contractions of the other muscles of the neck. Tonic and clonic spasm of the splenius may occur either alone or in combination with that of the trapezius and sternocleidomastoid. In splenius spasm the head is also drawn backward and toward the affected side, and there will be noticed muscular swelling to the outside of the cervical portion of the trapezius. The splenius is, according to Gowers, associated with the sternomastoid about half as often as the trapezius. The retrocollic spasm is commonly associated with a wrinkling of the forehead in both the tonic and clonic form.

In the clonic form the contractions may come on suddenly or be preceded by stiffness and irregular pain. The movements occur every few minutes, and the head cannot be kept still, although the movements cease during sleep. They are increased by emotion, excitement, or fatigue. Sometimes there is pain, but at other times there is merely a sense of fatigue. The muscles in time may become hypertrophied, but never waste.

**Pathology.**—This is very obscure. Reasoning, rather than demonstration, leads to the conclusion that the muscular contractions probably depend on the overaction of nerve-cells, and not on irritation of nerve-fibers; the movement usually involves the deep rotators on one side of the neck and the sternocleidomastoid muscle on the opposite side. It is therefore a movement of associated muscles, and this suggests a cortical origin, at least in many cases.

**Diagnosis.**—The distinction lies between true and false torticollis, in which there is deviation of the head from some other cause than muscular contraction, and it is only the form of true torticollis due to shortening of one sternocleidomastoid which is likely to be confounded with the false. In the spurious form the sternomastoid is tense on the side toward which the face is turned, and in the true form the tension is on the side opposite. In retrocollic spasm the invariable association of contraction of the frontalis muscles, producing the peculiar wrinkling of the forehead, distinguishes it from simple tremor. The hysterical form occurs in women under 30, and this fact is presumptive evidence of its presence, while hysterical spasm is also apt to spread from the neck to the trunk; in the true form of torticollis it is limited to the neck.

**Prognosis.**—The prognosis is always grave, and the more severe and extensive the spasm, the more unfavorable. Relief is more possible in the first half of life than in the second. Cases do, however, occasionally get well, and temporary relief is more frequent.

**Treatment.**—If the cause can be found which is responsible, it ought to be removed. If discovered in an acute stage, absolute rest in bed and fomentations or dry heat are indicated. Electricity has, perhaps, more reputation than any other remedy. The faradic brush may be applied over the skin of the affected muscles and to the swelling. Gradually increasing faradic currents may be used. If the galvanic current is used, a weak one is preferred, and the anode, or positive pole, is placed below the occiput or highest accessible part of the nerve, and the negative on each contracting muscle, for 10 minutes at a time.

Sedatives and narcotics have also some reputation. Among these the bromids and cannabis indica are included in large doses. Five-minim (0.3 c.c.) doses of the fluid extract of cannabis indica may be given, rapidly increased. The drug is proverbially unreliable. The hypodermic use of morphin is of undoubted value in relaxing the spasm, but the dangers of its protracted use almost preclude it. It would be unfair to the drug, however, to omit the statement of Gowers that, "continued for several months in doses increased gradually to  $1\frac{1}{2}$  or 1 gram a day, it has entirely removed the spasm." Naturally, such persons are weaned from the drug with difficulty. The hypodermic use of atropin in the affected muscles has also been recommended.

Mechanical supports for fixing the head are recommended, but are not well borne. Surgical measures have been employed—such as section, excision, stretching of the nerve, and section of the muscle—with, at best, but temporary results. Mention should be made, however, of the deep-seated operation of W. W. Keen and Noble Smith, which consists in dividing the spinal accessory nerve and the posterior branches of two or three cervical nerves which also supply the splenius and complexus. This reduces the spasms that reside in these muscles to a slight degree, while the otherwise paralyzing effect of the division of branches of the spinal nerves is comparatively unimportant.

## LESIONS OF THE TWELFTH PAIR OR HYPOGLOSSAL NERVE.

**Anatomical.**—This is the motor nerve of the tongue, and supplies also the depressors of the hyoid bone and the hyoglossus and geniohyoid of the elevators. It arises from the medulla oblongata beside the olivary body. Its cortical center is probably the lower part of the ascending frontal gyrus. It is subject to paralysis and spasm.

**Etiology.**—1. *Cortical disease* is frequently responsible for paralysis of the tongue on the opposite side, as is seen in the numerous cases of hemiplegia associated with this condition. The same accident occurs when the fibers between the cortex and the nucleus in the medulla oblongata are invaded, and probably this is the most frequent cause of paralysis of the

tongue. Apoplexies and other causes of compression, softening, thrombosis, and embolism, are agencies operating to this end.

2. *Nuclear disease* is another cause. It is usually degeneration, rarely sudden softening: the former as a part of bulbar palsy and tabes dorsalis, and the latter from vascular obstruction. The effect is almost always bilateral, the nuclei being so close together that it is scarcely possible to involve one only, although such isolated result has occurred in sudden cases and, rarely, in slow ones, as in tabes dorsalis and general paralysis.

3. *Infranuclear disease* may operate at various sites—

(a) Within the medulla oblongata the root fibers may be invaded by a tumor or by softening.

(b) Outside the medulla oblongata the fibers may be damaged by the products of meningitis, simple or syphilitic, and by new formations. The nerve may be compressed in its foramen by outgrowth of bone. Outside the skull the nerve is compressed by tumors, by inflammatory products, or injured by disease communicated from caries of the upper cervical vertebræ and by penetrating wounds. Hence the spinal accessory and vagus nerves are often implicated coincidently and there is paralysis of the palate, occasionally of the vocal cords, with or without wasting of the trapezius and sternomastoid. The hypoglossal may be the seat of neuritis.

**Symptoms.**—1. *Of Hypoglossal Paralysis.*—These are motor only. When there is supranuclear disease in addition to the palsy of the tongue, there is hemiplegia, but no wasting of the tongue, which is protruded toward the affected side, nor change in electrical reaction. In nuclear disease the lesion is apt to be bilateral palsy. The tongue lies motionless in the floor of the mouth, and speech and deglutition are seriously impaired. Mastication is interfered with mainly because the tongue cannot regulate the position of the food, the proper muscles of mastication being intact. There are atrophy and reaction of degeneration. The mucous membrane is thrown into folds. The condition is likely to be a part of a bulbar palsy. In infranuclear disease only one nerve is affected, there is wasting with reaction of degeneration and fibrillary twitching. Speech is not much impaired, nor is swallowing.

2. *Of Spasm.*—Spasm of the tongue as an isolated event is very rare. It may be unilateral or bilateral. It commonly occurs as a part of some other convulsive affection, as epilepsy or chorea, or spasm of the facial muscles. It may also occur in hysteria. In the biting of the tongue in epilepsy the organ is thrust between the teeth by spasmodic contraction of the genioglossus and caught by the jaws through a spasm of the masseters. Spasm of the tongue occurs in some forms of stuttering, the spasm often preceding the explosive utterance of words. In other cases there are various protrusions and deviations of the tongue, produced in some instances by irritation of the fifth nerve, variously induced, as by a carious tooth. The spasm may be clonic, the tongue being thrust in and out many times in a minute, at others more slowly. It may be associated with facial spasm. It may occur during sleep.

**Diagnosis.**—This is generally easy. If there are hemiplegia and palsy, but no wasting of the muscles of the tongue, no reaction of degeneration, the lesion is supranuclear. If there is paralysis of the tongue on the one

side and of the limbs on the opposite, there is probably a unilateral lesion in the medulla oblongata, involving the nucleus or the fibers arising from it. When the disease is on the surface of the medulla oblongata, the paralysis is commonly unilateral, and is associated with paralysis of the corresponding half of the palate and vocal cord, because of the involvement of the spinal accessory nerve. Spiller believes it is because of involvement of the vagus.

**Prognosis.**—The prognosis is usually unfavorable because the lesion is incurable.

**Treatment.**—The treatment embraces that of the disease producing it. The lingual paralysis may be treated with electricity—with an electrode in the shape of a tongue depressor.

The treatment of spasm has been by sedatives, including bromids, by iodid, and by electricity.

## DISEASES OF THE SPINAL NERVES AND BRANCHES.

### CERVICAL PLEXUS.

**AFFECTIONS OF THE PHRENIC NERVE.**—Paralysis of this nerve may be the result of a lesion in the anterior horn of the gray matter of the cord, at the level of the third and fourth cervical nerves; of a lesion to these nerve-roots in disease of the membranes of the cord or of the vertebræ; or by compression by aneurysms or other tumors. Exposure to cold, producing neuritis, may cause it, and it may be a part of a diphtheritic palsy.

**Symptoms.**—The result is *paralysis of the diaphragm*, which is complete if both nerves are involved, as in the case in disease of the cord or its membranes; partial when a tumor or other cause affects one nerve. Respiration is still carried on by the intercostals, and when the victim is quiet, there is little or no embarrassment, but examination shows the abdomen to be retracted in inspiration and protruded in expiration. In other cases, in consequence of increased movement of the thorax, the upper abdominal walls are drawn outward with inspiration—a movement not to be mistaken for movement of the diaphragm. On exertion, however, there is *dyspnea*, which is also observed if the paralysis is sudden. The effect of paralysis of a single phrenic, involving one-half of the diaphragm, is scarcely noticeable.

A further effect is to aggravate any lung affection, as bronchitis or pneumonia. There is difficulty in coughing effectually, and, therefore, of emptying the lungs of mucus, accumulation of which may result in impairment of resonance at the base of the lungs in bronchitis, and in the physical signs of edema.

**Diagnosis.**—Nervous breathing resembles the breathing of paralysis of the diaphragm in that this muscle is used very little, while the upper thorax is freely used. If, however, the attention of persons thus breathing is distracted, or they are watched when not conscious of observation, the diaphragmatic breathing will at once become apparent.

The diaphragm does not move when it is inflamed or in diaphragmatic

pleurisy, but it is because of the extreme pain which its motion causes under these circumstances.

The diaphragmatic palsy from diphtheritic neuritis is only a part of the symptoms due to such neuritis. In diaphragmatic paralysis due to spinal disease there is usually atrophy of other muscles, together with other symptoms of that disease.

**Prognosis.**—This depends upon that of the disease of which it is a part, except in diphtheritic neuritis, in which it is the direct result of the disease, and where the prognosis is unfavorable.

**Treatment.**—The treatment is that of the disease of which it is the result. If there is neuritis, effort should be made to galvanize the nerve by pressing one pole outside the clavicular portion of the sternomastoid, and the other pole over the epigastrium or the corresponding half of the diaphragm. Counterirritation may also be applied in the triangle of the neck outside the clavicular portion of the sternomastoid.

## BRACHIAL PLEXUS.

**OF THE COMBINED PLEXUS.**—This may be affected above the clavicle by causes producing pressure on the nerve-trunks—the five lower cervical and first thoracic—after they leave the spine and before they unite to form the plexus. Such causes are tumors and other morbid processes in the neck. More frequently, causes operate below the clavicle, of which the most frequent is prolonged luxation of the humerus, especially under the coracoid process. One or more branches may be thus involved, producing a corresponding degree of paralysis, to which is added wasting of muscles, with reaction of degeneration and trophic changes in the skin. Fracture of the humerus is another cause. Blows or falls on the shoulder and injuries in the neck may produce the same results, as may also compression during birth. The muscles involved may be the deltoid, supraspinatus, infraspinatus, biceps, and brachialis anticus.

Neuritis of the brachial plexus also occurs rarely as a primary inflammation. The result ultimately may be complete loss of power in the arm. A still rarer disease is neuroma of the plexus.

**LESIONS OF INDIVIDUAL NERVES.**—*Of the Long Thoracic or Posterior Thoracic (Serratus Palsy).* This nerve is particularly subject to pressure through its long course and position, especially in the posterior triangle of the neck. Such pressure may be direct, as by carrying heavy burdens on the shoulder, or as the result of severe muscular effort in carrying or wielding a hammer, or long exertion with the arm raised, as in whitewashing a ceiling. The result may be a neuritis. Neuritis may also be caused by cold. The same nerve may be involved in progressive spinal muscular atrophy or poliomyelitis anterior. From natural causes it is more common in men.

The result is a dislocation of the scapula of the corresponding side, which presents a winged appearance in consequence of projection of its angle and posterior border, rendered especially distinct when the arm is moved forward, since the scapula is no longer held to the thorax by the

serratus. In severe cases faradic irritability is lost, though voltaic excitability may remain. Severe neuralgic pain may precede the paralysis.

The course of serratus palsy is slow, and the paralysis is sometimes permanent.

**Treatment.**—The treatment consists in maintaining the nutrition of the muscles by electrical stimulation. Counterirritation may be applied over the scalenus muscle, because it is in it that the nerve is most frequently injured. Among the conditions to which the now popular vibratory stimulation has been applied with more or less success is brachial neuritis. The arm should be kept at rest, and to this end should be carried in a sling, embracing the elbow in such a way as to raise the shoulder.

**NERVES OF THE ARM.**—1. *Of the Circumflex Nerve.*—This rises from the posterior cord of the plexus and supplies the deltoid and teres minor, and the skin over the deltoid. It may be injured by dislocations, blows, bruises, pressure by a crutch, or position long maintained, as during illness. Neuritis may result from these causes and from cold, or by extension of inflammation from the joint.

There is loss of power in the deltoid and the arm cannot be raised, also a loss of sensation in the skin over the lower part of the muscle. The muscle wastes and the shoulder becomes flattened. The joint may relax and a space arise between the head of the humerus and the acromion. On the other hand, adhesions may form, partly trophic, since the articulation is supplied by the same nerve. Movement may be further impaired by thickening of the ligaments.

Paralysis of the deltoid is to be distinguished from ankylosis, in which the scapula moves with the arm, which it does not do in palsy.

2. *Suprascapular Nerve.*—This nerve rises from the trunk formed by the union of the sixth, fifth, and a branch of the fourth cervical, but its own fibers are derived from the fifth and partly from the fourth cervical. It is occasionally injured alone or with the circumflex in dislocation of the humerus, and by falls on the shoulder, or by carrying heavy weights. The result is palsy of the supraspinatus and infraspinatus muscles. The first is of little significance, but the latter causes a defect of rotation outward of the humerus, interfering with many movements, of which one is carrying the hand along in writing. The scapula is rotated so that the lower angle is rotated upward and inward.

3. *Musculospiral Paralysis.*—The musculospiral nerve arises from the posterior cord of the brachial plexus, and apparently derives its motor fibers from the nerve-roots forming the plexus except the first thoracic. With its branches the muscular, cutaneous, the radial and posterior interosseous, it supplies the triceps, all the muscles of the back of the forearm, the extensors of the wrist and fingers, both the supinators, as well as the skin on the radial side of the back of the hand, back of the thumb, index-finger, and half of the middle finger. As the musculospiral nerve is called the radial by the Germans, its paralysis is described in German literature as radial palsy.

It is more frequently paralyzed than any single nerve, because of its position—winding around the head of the humerus after it leaves the plexus.

It is often bruised by crutches, producing the so-called "crutch palsy," by blows and fractures, and especially by pressure when sleeping with the arm over the back of a chair or with the arm under the body. Even a sudden and violent contraction of the triceps, as in pulling on a tight boot, or forcible extension of the forearm as in throwing a ball, may bruise it. More rarely it is the subject of a neuritis from cold.

In a lesion of the nerve high up all the muscles previously named are involved; when near the middle of the humerus, the triceps generally escapes. The supinator longus and extensor carpi radialis longior usually are involved, but escape if the lesion is below the origin of the branches supplying them, and sometimes in partial injury of the nerve higher up. A characteristic symptom of extensor palsy is the "wrist-drop," while the inability to supinate is also striking. Sensation is rarely lost, though there may be tingling without loss of sensibility.

FIG. 134.—Wrist-drop in Musculospiral Paralysis—(Leube).

Paralysis of the musculospiral is to be distinguished from the wrist-drop of lead palsy, which is, however, bilateral, while the supinators are unaffected and the onset is gradual. However, in lead palsy the supinator longus may be affected, and in wrist-drop from pressure this muscle may escape. Bilateral wrist-drop is common in other forms of neuritis, especially the alcoholic, but the gradual mode of onset, the involvement of the legs, and the sensory symptoms are their characteristics.

The prognosis is usually favorable, the pressure palsy disappearing in a short time, while recovery is the rule even when delayed.

Erb's rules as to prognosis apply as follows: If both faradic and galvanic irritability are maintained, recovery may be expected in from 14 to 20 days; if these are lessened for the nerve and increased for the muscle, while  $An\ C > Ca\ C$ , with contraction sluggish, recovery may take place in from four to six weeks, sometimes in from eight to ten weeks. When there is evidence of degeneration of the nerve, the prognosis is more unfavorable, so that recovery may be delayed for from two to fifteen months.

4. *Ulnar Nerve*.—This comes through the inner cord of the plexus from the last cervical and first thoracic. It is the first of all the brachial nerves to be affected by disease ascending from the thoracic to the cervical part of the cord. It supplies the ulnar flexor of the wrist, the ulnar half of the deep flexor of the fingers, the muscles of the little finger, the interossei, two of the lumbricales, the adductor, and the inner head of the short flexor of the thumb. Its sensory portion supplies the ulnar side of the hand, back and front,—more of the back—the ulnar side of the little finger and the adjoining sides of the little and ring fingers. It communicates with the posterior branch of the internal cutaneous nerve and sends a communicating branch to that branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers. (Gray.)

The course of the nerve, superficial behind the elbow and at the wrist, makes it vulnerable. It may be injured in wounds of the forearm and about

FIG. 135.—Position of Wrist, Hand, and Fingers in Ulnar Paralysis—(Leube).

the elbow, in dislocations and fractures about the shoulder and elbow, and continued flexion of the elbow. Neuritis is a possible cause. The most common cause is probably a blow upon the arm.

The hand moves toward the radial side because of paralysis of the ulnar flexor, and adduction of the thumb is impossible, the first phalanges cannot be extended, and in long standing cases the "claw-hand" may be produced, consisting in overextension of the first phalanges and flexion of the others. There may be wasting of the muscles supplied by the nerve. There is loss of sensation in the sensory distribution.

A similar condition of the ulnar nerve may be produced by lesion of the lower cervical portion of the cord.

5. *Median Nerve*.—Its motor fibers arise from all the cervical roots that enter the brachial plexus. They supply the pronators, the radial flexor of the wrist, flexors of the fingers—except the ulnar half of the deep flexor—the muscles that abduct and flex the thumb, and two radial lumbricales. The sensory fibers supply the radial side of the palm and the front of the thumb, the first two fingers, half of the third finger, and the dorsal surface of the same fingers.

Isolated palsy of this nerve is not frequent, but it may be caused by

wounds or fractures of the forearm, rarely from injuries of the upper arm. There may be neuritis from compression.

The wrist can only be flexed toward the ulnar side, and the thumb is in a state of persistent extension and cannot be opposed to the tips of the fingers. Pronation is impossible beyond the midposition to which the supinator can bring the forearm; an attempt is made to supplement this by rotating the humerus inward and separating the elbow from the side. The second phalanges cannot be flexed on the first, nor the distal phalanges of the first and second fingers, while in the third and fourth fingers this action can be performed by the ulnar half of the deep flexor. There is conspicuous wasting of the thumb muscles, which gives a characteristic appearance.

There may be complete or partial loss of sensibility. If there is anesthesia, it is more marked on the palmar surface.

**Treatment of Lesions of Nerves of the Arm.**—The first principle of treatment is the removal of the cause, whatever it may be, as determined from the etiology. If neuritis is present, it must be treated. Rest by supports or splints may be necessary, on the one hand, and electrical stimulation and massage on the other.

## LUMBAR AND SACRAL PLEXUSES.

**THE LUMBAR PLEXUS.**—This is sometimes damaged by growths in the abdomen, especially of the lymph glands, by inflammatory process, by psoas abscess, and by diseases of the bones and vertebræ affecting the nerve-roots. The obturator nerve may be injured during parturition; the anterior crural nerve by the same cause, by wounds of the groin or thigh, by dislocation of the hip, and sometimes by growths about the spine.

**Symptoms.**—In paralysis of the *obturator*, adduction of the thigh and crossing of the legs are impossible, while outward rotation is also deranged.

In paralysis of the *anterior crural* extension of the knee is impossible; there is wasting of muscles, with anesthesia of the anterolateral part of the thigh and of the inner side of the leg and big toe. There may be pain in the area of distribution.

Paralysis of the *superior gluteal nerve*, which is rare in the isolated form, causes loss of the power of abduction and circumduction of the thigh from paralysis of the *gluteus medius* and *minimus*.

**THE SACRAL PLEXUS.**—This suffers from compression by growths in the pelvis, pelvic inflammations, and compression during labor. In addition to spontaneous neuritis, there may also be a neuritis ascending to it from the sciatic nerve. The sciatic may be affected by wounds, dislocation of the hip, disease of the bone, and morbid growths. It is also occasionally the seat of neuroma.

The result of lesions of the *sciatic* varies with its seat. If near the sciatic notch, there is paralysis of the flexors of the leg and all the muscles below the knee, while injury below the middle of the thigh involves only the latter muscles, the flexors of the legs escaping. There is anesthesia of the outer half of the leg, of the sole and greater portion of the dorsum

of the foot, but the leg may escape, perhaps through the intermediation of other nerves. Frequently there is wasting of the muscles, with other trophic symptoms. In lesion of one sciatic the leg is fixed in extension by the action of the quadriceps extensor, and the patient can walk, even when all the muscles below the knee are paralyzed, the foot being raised by over-flexion of the hip.

The *small sciatic* is implicated only when the pelvic plexus is impinged upon, and it rarely suffers alone. The effect is palsy of the gluteus maximus with difficulty in rising from the sitting posture, and a strip of anesthesia along the back of the middle third of the thigh and upper half of the calf.

Injury to the *external popliteal* or *peroneal* nerve results in paralysis of the tibialis anticus, long extensor of the toes, peronei, and extensor brevis digitorum. There results inability to flex the ankles or extend the first phalanx of the toes, or to raise the foot from the ground in walking—there is foot-drop. Talipes equinus ultimately results, and may be attended with persistent flexion of the first or proximate phalanges from contraction of the unopposed interossei. In walking the whole leg must be lifted, and there is the steppage-gait of neuritis. In old cases there may also be wasting of the anterior tibial and peroneal muscles. There is also anesthesia in the outer half of the front of the leg and on the dorsum of the foot.

Lesion of the *internal popliteal* produces paralysis of the popliteus, calf muscles, tibialis posticus, long flexors of the toes, and muscles of the sole. The symptoms are loss of plantar flexion, inability to extend the ankle-joint, and, if the disease is high enough to involve the branch to the popliteus, loss of power to rotate the flexed leg internally; the foot cannot be adducted, nor can the patient rise on tiptoe. Talipes calcaneus results, and the toes may assume a claw-like position from secondary contraction, due to over-extension of the proximal and flexion of the second and third phalanges. There is also loss of sensation on the outer lower part of the back of the leg and on the sole of the foot.

**Treatment.**—The treatment of lesions of the nerves of the legs is similar to that of lesions of nerves of the arms. Secondary contractures are to be guarded against, being favored by position. Fatigue and exposure to cold should be avoided, as they favor fresh attacks of neuritis.

## EFFECT OF SECTIONS OF SENSORY NERVES. SENSORY MECHANISM OF PERIPHERAL NERVES.<sup>1</sup>

The recent studies of Head and Sherren on the effect of nerve section go to show that the sensory mechanism of the peripheral nerves includes three systems: 1. protopathic sensibility; 2. epicrotic sensibility; 3. deep sensibility. When a nerve is cut only a small area supplied by it becomes totally analgesic, the remainder being variously modified as to sensibility through the distribution to it of adjacent nerves giving rise to the systems named.

By protopathic sensibility is meant altered sensation in which stimula-

<sup>1</sup>"The Afferent Nervous Systems from a New Aspect." Henry Head, "Brain," part xi., Nov., 1905. "The Consequences of Injury to the Peripheral Nerves in Man." *Ibid.* Abstracted in "Review of Neurology and Psychiatry," vol. iv., p. 47, 1906. This abstract is so admirably condensed that it has been necessary to follow it quite closely.

tion by the prick of a pin is felt more severely than over healthy skin, the pain is more widespread and the site of stimulation is not always accurately localized. The patient cannot tell the two points of a compass when separated by less than two centimeters. The power of recognizing differences of temperature is so modified that he cannot recognize cold above  $22^{\circ}$  C. or heat below  $40^{\circ}$  C. In considering the peculiarities of this area it is not the fibers of the cut nerve that show this modified sensibility, but the fibers of neighboring nerves that supply certain forms of sensation to this impaired area.

The epicrotic sensibility presents well-marked and definite qualities, such as greater sensitiveness to touch as shown by the recognition of gentle stimulation, as by cotton wool, more precise and definite sense of localization, the perception of the two points of the compass as distinct when separated by less than two centimeters, and the discrimination of fine grades of temperature. Epicrotic sensibility is not only an addition to the protopathic sensibility, but it has a remarkable inhibitory or modifying effect on the protopathic sensibility, inasmuch as the pain felt by a prick is less severe and radiation of pain and of cold is much less extensive than when protopathic sensibility is alone present.

The deep sensibility which responds to pressure and to movements of joints is capable of evoking pain when pressure is excessive or when a joint is injured. It is best demonstrated in an area where the skin is totally analgesic through division of a purely sensory nerve. Because it is thus present, where the skin is totally insensitive it is inferred that the sensory nerves supplying deeper structures, like muscles, tendon, bones, and joints, reach their destinations not by the purely sensory nerves, but by the nerves supplying the muscles. Support for this inference is found in the facts that Sherren has found afferent fibers in the nerves supplying the muscles and that section of motor nerves deprives the muscles and deep structures of all sensation. If an injury severs the ulnar nerve at the elbow before the muscular branches are given off, then deep sensibility of certain fingers is destroyed. But if the ulnar is cut at the wrist, then the deep sensibility of the fingers persists. If the injury severs the tendons as well as the ulnar nerve at the wrist then the deep sensibility of these fingers is lost. Hence, it is argued that the fibers supplying the deep sensibility of those fingers reach their destination by running along the tendons.

Much information is gained by studying the phenomena attending the gradual repair of the nerve. Some time elapses before sensation begins to be restored, and the restoration takes place in an orderly manner. The first sign is a diminution of the analgesic area due to the gradual spreading over it of protopathic sensibility, which proceeds until the whole analgesic area is covered. The time required for recovery is from two to three months, and more than six months may elapse before complete restoration of protopathic sensibility is restored. After this there is often an interval of two or three months before improvement takes place in epicrotic sensibility. When it begins it appears as a blurring of the margin separating the protopathic from the epicrotic sensibility. There is a simultaneous return of all the forms of sensation by which epicrotic sensibility is recognized—of light touch, better localization, appreciation of finer grades of temperature,

etc. Recovery is gradual, and usually more than a year is required to complete it.

If the nerve has been bruised or incompletely divided, it may fail to conduct impulses, and the resultant loss of sensation may at first resemble that which follows complete division. Recovery, however, in such cases pursues a different course from that following a complete division of the nerve. Thus, at the end of a period varying with the extent of the injury, an insensibility to prick and light touch return simultaneously, and as recovery progresses protopathic and epicrotic sensibility return together. By observing the form of recovery one can tell whether the nerve is completely severed or merely injured.

"A difference in the distribution of protopathic and epicrotic sensibility is also observed, depending partly on the distance of the section from the spinal cord. Thus section of a peripheral branch of a nerve near its final distribution presents a different result from section of a nerve near its exit from the spinal cord. If the forearm and hand be divided into a pre-axial (radial) and post-axial (ulnar) half, it is found that the nerves supplying one of these halves overlap only to a slight extent the areas supplied by the nerves of the other half, while the peripheral branches that supply one of these areas overlap among themselves to a very considerable extent. Thus section of the internal cutaneous high in the arm produced an area of total analgesia embracing the greater portion of the ulnar half of the forearm and hand, while at the same time the epicrotic sensation is lost over the remaining portion of the ulnar half of the forearm and hand. This shows that there is very little overlapping of the nerves supplying the radial half of the forearm with the field supplied by the internal cutaneous. Division of one of the two branches of the internal cutaneous presents a very different result—the overlap being so great that little or no analgesia results from section of one branch only.

"Injury to the cords of the brachial plexus produces not only very considerable changes in the sensibility of the parts supplied by the nerves constituting the cord, but they sometimes show a great difference in the relationship of the protopathic and epicrotic area. Here the areas of protopathic and epicrotic sensibility are nearly co-extensive.

"A further difference in the relationship of these two forms of sensibility is shown when the posterior nerve roots are cut. In two cases division of several posterior nerve roots resulted in the loss of protopathic sensibility over an area greater than that of epicrotic sensibility; that is to say, there was an abolition of the sensation to prick over an area larger and more sharply defined than that which became insensitive to light touch. Moreover, this insensibility to prick was accompanied by an inability to appreciate temperature below 15° C. and above 60° C., although 40° C. and 23° C. appeared definitely warm and cool."

The practical applications of the above in interpreting phenomena of deranged innervations is evident. Seats of lesions and progress in improvement may be inferred by the study the phenomena observed.

## DISEASES OF THE MEMBRANES OF THE BRAIN.

Although, anatomically considered, the brain is enveloped by three membranes—the tough dura mater, the delicate arachnoid, and the highly vascular pia mater—the diseases of the membranes are practically confined to the dura on the one hand, and the arachnoid and pia conjointly on the other, the last two being always affected together. The dura is, however, separable into two layers—a thin internal layer with its endothelial lining, and a looser external layer which serves as a periosteum to the bones; these two layers may be affected separately.

The term pachymeningitis is applied to inflammation of the dura mater, and leptomeningitis to that of the pia and arachnoid; the latter is commonly meant when the word meningitis is used alone.

## PACHYMEINGITIS.

SYNONYM.—*Inflammation of the Dura Mater.*

## EXTERNAL PACHYMEINGITIS.

**Etiology.**—External pachymeningitis is *always acute* and is commonly circumscribed. It usually results from injuries to the head, especially *fractures*; from *caries* of the petrous portion of the temporal bone, caused commonly by middle-ear disease; or from *syphilitic disease* of the bone with pus formation. Sometimes no cause is discoverable. Rarely pus infiltrates between the two layers of the dura mater. More frequently there is pus between the dura and the bone. This may occur in syphilis, which, too, may cause thickening of the bone.

**Symptoms.**—These are indefinite and are often obscured by those of its causal disease. They are pain, delirium; sometimes, but not always, fever; sometimes convulsions, and signs of pressure. Such pressure may or may not be sufficient to cause paralysis of the opposite side.

**Treatment.**—The treatment is that of the causing disease, with surgical interference to remove pressure and give vent to pus.

## INTERNAL PACHYMEINGITIS.

This is *usually chronic*. Three forms are commonly noticed—purulent, pseudomembranous, and hemorrhagic.

PURULENT and PSEUDOMEMBRANOUS INTERNAL PACHYMEINGITIS are not recognized before death. The former may follow an *injury primarily*, but commonly it is an *extension from* inflammation of the *pia*. Pus between the dura and arachnoid is rare. Pseudomembranous internal pachymeningitis may occur as a secondary process in *infectious diseases*.

INTERNAL HEMORRHAGIC PACHYMENINGITIS.—Hemorrhagic pachymeningitis, or *hematoma* of the dura mater, is a rare, but well-recognized condition; it is much more common in infirmaries and hospitals connected with almshouses and asylums. It occasionally occurs in children.

**Etiology.**—It is probably most frequently a result of chronic alcoholism, though it has been found in chronic insanity without association with alcoholism, especially in general paralysis of the insane; also in acute fevers, when it is associated with profound anemia. Syphilis is a possible cause; in like manner, tuberculosis. It occurs chiefly in males over 50, but also in those between 30 and 40. In mild degree it is sometimes found in chronic cardiac, renal, or pulmonary diseases, when it is commonly first recognized at necropsy.

**Pathology and Morbid Anatomy.**—The original dictum of Virchow continues for the most part to be held—viz., that it begins as a hyperemia in the area of the *middle meningeal artery*, extending thence forward, backward, and downward. The arteries become tortuous, dilated, and surrounded by thickened adventitia, while the capillaries, being over-filled, produce a rose-colored flush on the under surface of the membrane. To this succeeds a delicate web-like tissue containing wide, thin-walled capillaries three or four times the natural width, between which is a delicate reticulum of spindle cells extending over the greater part of one or both hemispheres. This becomes afterward paler and firmer. Upon this succeeds another delicate vascular layer, succeeded by another and even another. From three to seven layers are thus superposed until a product of from  $1/8$  to  $1/5$  inch (3 to 5 mm.) in thickness results. The delicately-walled capillaries, however, easily give way, causing hemorrhages which vary in extent from mere points to large collections of blood—the smaller being interstitial and the larger between the youngest vascular layer and the next older. The proportion of blood and organized membrane varies greatly, now one predominating and now another. At times there seems to be blood only. The hemorrhage is believed by some to be the initial event.

Both products are subject to degenerative changes, the effused blood being disintegrated and partially absorbed, while the blood-vessels become obliterated and substituted by lines of pigment deposit along their course. There may also be serous infiltration, cystic degeneration, and even diffuse supuration.

**Symptoms.**—The symptoms are indefinite. There may be *apoplectic form seizures* coincident with fresh hemorrhages, *drowsiness*, or *coma*. *Muscular weakness* was very marked in a case under my own observation. *Headache* in the region involved, *vomiting*, *nystagmus*, *convulsions*, generally unilateral, and even hemiplegia may be present, and, toward the close, *optic neuritis*; extensive disease may, on the other hand, exist without any symptoms whatever.

**Diagnosis.**—In the absence of distinctive symptoms the possibility of the presence of hematoma should be remembered when there are other signs of general paralysis or chronic alcoholism. If to such symptoms great muscular weakness is added, further suspicion is justified.

**Prognosis.**—This is absolutely unfavorable so far as recovery is concerned.

**Treatment.**—This consists only in the relief of symptoms as they

arise. Indications of hemorrhage should be treated by rest in bed, elevation of the head, and an ice-cap.

### LEPTOMENINGITIS.

SYNONYM.—*Inflammation of the Pia Mater.*

Of leptomeningitis there may be an acute and a chronic variety. In addition, other adjective terms are used to indicate its seat and the nature of its cause; such as basilar meningitis, meningitis of the convexity, tuberculous meningitis, etc. Epidemic meningitis has received separate consideration.

### ACUTE LEPTOMENINGITIS.

**Definition.**—An acute inflammation of the pia and arachnoid membranes, attended by exudation between two membranes.

**Etiology.**—All ages are subject to meningitis, that of the convexity being possibly more frequent in adults because they are more subject to traumatic agencies which cause it, while the basilar form is more common in children. It is rather more frequent in males, and there is a hereditary tendency to one form—tuberculous meningitis.

Of the direct causes—

1. An eruption of *miliary tubercles* is the most frequent. This cause may operate at all ages, but is most active in children. In adults it generally starts from a recognized tuberculosis elsewhere; in children the process is almost always part of a general tuberculosis. Tuberculous meningitis takes place generally at the base of the brain, constituting the chief form of *basilar meningitis*.

2. *Adjacent disease*, which may be outside of the dura mater, such as caries, especially in the petrous portion of the temporal bone. Even disease outside the skull, like erysipelas or suppurative disease of the scalp, may be a primary focus. In these cases it is usually unilateral, and may be accompanied by thrombosis of the sinuses and abscesses; or the disease may result in abscess within the brain.

3. The bacterium or toxin of the acute *infectious diseases*—pneumonia, ulcerative endocarditis, measles, scarlet fever, smallpox, typhoid fever, acute rheumatism, and septicemia. Care must, however, be taken not to confound the simple intense delirium in some of these affections with meningitis, remembering, too, that the latter complication is, under any circumstances, a rare one. The toxin of pneumonia is the most common cause, and perhaps after this that of smallpox. The inflammation thus caused is chiefly of the *convexity*, except in septicemia, when it is general.

4. Chronic Bright's disease and other cachectic conditions. In these the inflammation is commonly basilar.

5. Sunstroke.

6. Mental excitement and brain work—doubtful causes.

7. Rarely in acute inflammation, syphilis, whose product is also basal.

8. Finally, unknown causes may produce meningitis of the convexity or of the base. Possibly, as Gowers suggests, organisms otherwise power-

less may become sufficient causes during ill health. Thus may be caused some undoubted though rare cases of non-tuberculous basilar meningitis of children—*leptomeningitis infantum*.

In tuberculous meningitis, which is chiefly basilar, the eruption of tubercles precedes the inflammation. There may even be tuberculosis of the pia without inflammation. In tuberculous meningitis the inflammation is never actually purulent, though the lymph has often the appearance of pus. The tubercles are most abundant about the optic chiasm, over the pons, and in the fissure of Sylvius, but the cortex is often affected. According to Spiller's experience the brain cortex has contained more tubercles than were found at the base.

**Morbid Anatomy.**—The early results of leptomeningitis are the same in all varieties. They consist, first, in a hyperemia of the capillaries producing a diffuse pinkish tinge. The next visible changes are a turbidity and an opacity of the arachnoid which extend to the pia, where opacity is especially distinct along the blood-vessels, consisting, in fact, in an infiltration of the lymph spaces and lymphatic sheaths with leukocytes. As the cellular accumulation increases the exudate beneath the arachnoid assumes a yellowish-white, creamy appearance. The sub-arachnoid fluid increases, constituting *hydrocephalus externus*. In suppurative cases it becomes pus, which forms a greenish-yellow layer at the convexity or base, or both.

Ventricular effusion is present in the majority of instances—about four out of five—constituting *hydrocephalus internus*, generally associated with closure of the openings of the fourth ventricle. The effusion is usually limited to a few ounces, but it may be large in quantity, distending the ventricles and compressing the cortex. The walls of the ventricles and the choroid plexuses may be inflamed, and the ventricular effusion may be the result of such inflammation.

In all varieties of meningitis, and especially in the tuberculous, the superficial layer of the cortex is also involved, being at least hyperemic, and sometimes softened; it may also be the seat of punctiform hemorrhages, constituting *red softening*. This is especially prone to occur in tuberculous meningitis, because of the extension of the tuberculosis along the blood-vessels which dip into the cortex. In pulling off the pia these blood-vessels are dragged with it, leaving a ragged appearance of the cortex.

*Leptomeningitis infantum* presents an appearance similar to that of tuberculous meningitis. It involves chiefly the posterior part of the meninges and cerebellum, closing sometimes the foramen of Magendie, whence the term *occlusive meningitis*. It may also cause an acute, sometimes purulent, hydrocephalus.

**Symptoms.**—These are varied and not always distinctive of the different forms. First, it is important to remember that all except those which are peculiar to inflammation of the base may be present in any of the serious infectious fevers without meningitis, especially pneumonia, typhoid fever, and smallpox; but in some cases of typhoid fever the typhoid bacillus has been found in the cerebral membranes. When secondary to these affections, they are accompanied by the symptoms of the disease to which they succeed.

Meningitis is usually ushered in by *premonitory symptoms*, which, again, are not distinctive, being those usual to acute disease. Perhaps *irritability* is more constant than in other acute diseases. In case of children, *vomiting* with a slight cause, or without discoverable cause, is a symptom of more suspicious nature. It is especially frequent in basilar meningitis, of which it is more or less characteristic. It has this peculiarity, that it is not usually accompanied by nausea and retching. Generally there are *high fever*, *coated tongue*, and *constipation*, although fever is not invariable. The usual temperature is from  $103^{\circ}$  to  $104^{\circ}$  F. ( $39.5^{\circ}$  to  $40^{\circ}$  C.), but it may reach from  $105^{\circ}$  to  $106^{\circ}$  F. ( $40.5^{\circ}$  to  $41.1^{\circ}$  C.), and toward the close of fatal cases,  $108^{\circ}$  F. ( $42.2^{\circ}$  C.). It is especially likely to be mild or absent in the meningitis of Bright's disease or of debilitated children. The *pulse* is increased in frequency at first, but later may be slow and irregular.

Of the symptoms the direct result of the disease, *pain in the head* is the most constant. Commonly frontal, it may be general. Its constancy and severity are characteristic. Yet it is subject to such exacerbations as may cause the patient to cry out, constituting the *hydrocephalic* cry of children. The headache is invariable, followed sooner or later by *unconsciousness*. Delirium is an early symptom and soon follows the headache; at first wandering, it soon becomes active, and may alternate with drowsiness or stupor.

General *convulsions* are also another symptom, occurring in all forms and at all ages, but more frequently in the tuberculous meningitis of children. When the inflammation is at the base, *rigidity of the neck* with retraction of the head is very marked, especially when the inflammation extends down the membranes of the spinal cord. *Optic neuritis* is another symptom, usually late in occurrence—at the end of the first week—and possibly due to involvement of the sheath of the optic nerve within the skull. *Strabismus* is also common. There may be weakness of the eye muscles and slight *ptosis*. The *pupils* are usually *contracted* in the early stage from intolerance of light; later, they are *dilated*. *Inequality* of the pupil is even a more characteristic symptom, though transient and variable. It occurs in connection with inflammation of the convexity as well as of the base.

The *facial nerve* may be involved in basilar cases, producing slight paralysis, as may also be the *fifth nerve*, producing anesthesia and trophic changes in the cornea. On the other hand, *hyperæsthesic* skin is often present; also *hyperæsthesia* of the *special senses*, especially hearing and sight.

Symptoms in the limbs may present themselves, such as *muscular rigidity*, *unilateral convulsions*, and even *hemiplegia*, but the last is rare. When they occur, they are late symptoms.

**Diagnosis.**—The diagnosis is not always easy, because so many symptoms may be simulated by simple congestion due to the poison of the *infectious diseases*. The *basilar symptoms* are the most distinctive, and it is a real help to know that a possible cause is present, either predisposing or exciting; such, for example, as the tuberculous taint, or tuberculous disease, or middle-ear disease. Retraction of the head, so characteristic of this form, may result from *rheumatism* of the muscles of the back of

the neck. Sir William Jenner pointed out a difference between the relation of headache and delirium in general disease and meningitis: In general disease the headache ceases when the delirium begins; in meningitis the headache continues and coexists with the disease. Convulsions, too, when present, occur at the beginning of a general disease, particularly in scarlet fever, while they occur late in meningitis. Optic neuritis and other eye symptoms are common in meningitis.

A rapidly growing *intracranial tumor* often gives rise to difficulty in the diagnosis between it and meningitis. In tumors which may be tuberculous or gliomatous, symptoms in the extremities, such as weakness, hemiplegia, and convulsions, are manifested only after the tumor once begins to interfere with function, which it may not do at first; the loss of power, moreover, comes on gradually, while in meningitis all these symptoms are rapidly developed. Higher degrees of optic neuritis, as observed by the ophthalmoscope, are found in connection with tumor rather than with meningitis. The duration of the disease will settle the question ultimately, as meningitis is of short duration—from two or three days to as many weeks—while tumors last for months.

Meningitis, especially tuberculous, is sometimes mistaken for *hysteria*, but the almost invariable presence of fever in meningitis and its total absence in most cases of hysteria should prevent error. In children the symptoms even of tuberculous meningitis are sometimes closely simulated in bad *cachectic states*, in which there is no meningitis whatever. What is regarded as meningitis after *sunstroke* is a prolonged state of mental hebetude with symptoms usually aggravated on slight exposure to the sun.

**Prognosis.**—The prognosis in leptomeningitis is unfavorable, although not necessarily hopeless. In meningitis of the convexity recovery is possible; in undoubted tuberculous meningitis it is very rare, and yet it may occur. But I have so often known an erroneous diagnosis of tuberculous meningitis with corresponding prognosis followed by complete recovery in children, that I have grown very cautious in making a prognosis. Especially in general tuberculosis should we avoid too unfavorable a prognosis, because mistakes here are quite frequent. In meningitis from adjacent bone disease much depends on the accessibility of the bone lesion, but as this is generally difficult of access, the prognosis is correspondingly serious. This is especially the case in ear disease. In syphilitic meningitis if the diagnosis is made early, chances of recovery or improvement are better.

**Treatment.**—The *treatment of adjacent disease* which may cause the meningitis is of the first importance. Surgical interference should be promptly resorted to in middle-ear disease. In the absence of such disease the treatment is mainly symptomatic. The utmost *quiet* and the avoidance of all causes of excitement are paramount. It is the one disease, outside of ophthalmia, in which the darkening of the room may be justified. The *head* should be *raised*. *Leeching* is a most valuable measure toward cure, when possible, and temporary relief when cure is impossible. Leeches should be applied to the back of the ear and to the temple. *Ice* should be kept applied to the head. *Counterirritation* by blisters to the back of the neck is also very useful, and not so painful or annoying as

its appearance suggests. It has even been applied to the whole scalp after shaving the head, but I have never felt justified in doing this, especially when the diagnosis of tuberculous disease is quite clear. The *bowels* should be kept free.

The *diet* should be liquid—milk and animal broths of a light kind are the best food. Such drugs as meet the symptoms should be given. *Phenacetin* to relieve pain in the head if the ice and abstraction of blood do not do it. The temperature is kept down by *sponging* and even by cool *bathing*. *Mercury* is still an acknowledged drug in meningitis not tuberculous; and as chances of error of diagnosis always exist, it may be employed in any case. It should be administered to the production of slight salivation, preferably by inunction because the effect is more rapidly produced. The mercurial ointment should be used.

#### CHRONIC LEPTOMENINGITIS.

**Etiology and Morbid Anatomy.**—This comparatively rare disease affects chiefly the convexity of the brain, and is the result of alcoholism, syphilis, or tuberculosis.

In milder degrees, seen in alcoholics, the pia arachnoid is opaque, as seen over the sulci, the opacity and thickening being more marked along the borders of the blood-vessels. In syphilis there are often foci or thickened patches, thickest in the center and receding toward the edges. These may reach dimensions to justify the term gummy outgrowth or tumor. The blood-vessels are the seat of endarteritis. In the tuberculous forms in children the base of the brain is affected, as in acute tuberculous meningitis. Internal hydrocephalus may be a consequence when there is obstruction of the orifice of the fourth ventricle.

**Symptoms.**—These are those of the acute form in a milder and more prolonged manner—headache, vomiting, mental symptoms, sometimes convulsions, rigidity, retraction of the head, optic neuritis, more rarely strabismus, and nystagmus. They may last from a month to a year or more. Fever is more frequently absent in chronic meningitis, but careful observation will generally find some elevation of temperature.

**Diagnosis.**—It is, in fact, the chronic variety of leptomeningitis which is separated from *tumor* with the greatest difficulty. Loss of motor power is more characteristic of tumor. Optic neuritis is also a more decided symptom in tumor, and goes on increasing, while it seldom reaches an advanced stage in chronic meningitis. Other eye symptoms—strabismus, irregularity of pupil—are more distinctive of meningitis. Strabismus occurs in *hysteria*, but it is always convergent and there is total absence of fever, as shown by the absence of elevation of temperature.

**Prognosis.**—This is not so unfavorable as in the acute variety. The syphilitic form is quite amenable to treatment, the alcoholic less so; the tuberculous is almost always sooner or later fatal. Caution in prognosis is demanded by occasional error in diagnosis.

**Treatment.**—The cause must be carefully sought. If syphilitic, iodids and mercurials must be used, as for this disease. In alcoholism and tuberculosis the symptoms must be treated by measures already indicated.

## AFFECTIONS OF THE BLOOD-VESSELS OF THE BRAIN.

## HYPEREMIA.

SYNONYMS.—*Cerebral Hyperemia; Congestion of the Brain.*

**Definition.**—A condition of the brain in which the blood-vessels are surcharged with blood. The congestion is *active* as the result of increased flow of blood to the brain, as in alcoholic hyperemia; *passive* when there is obstruction to its outward movement, as in constriction of the vessels in the neck.

**Etiology.**—The causes of *active* hyperemia are prolonged mental activity, excitement, and overwork, pre-eminently alcohol and the causes of the acute fevers; the hypertrophy and overaction of the heart which attend aortic regurgitation may be causes. The causes of *passive* congestion are mainly mechanical, including mitral valvular heart disease, emphysema, straining, or other cause obstructing the return of blood from the brain—such as tumors pressing on the vessels of the neck, or tight clothing.

**Morbid Anatomy.**—While, from the standpoint of morbid anatomy, our ideas may be very definite as to what should constitute active and passive hyperemia, it cannot be said that a definite set of symptoms is associated with either in the case of the brain. In the first place, the amount of blood in the brain varies greatly within the limits of health, and while it might be said that physiological hyperemia ends where abnormal mental phenomena present themselves, it is undoubtedly true also that an overfullness of the vessels of the brain may exist for some time without the symptomatic expression which finally appears. With the appearance of such symptoms we commonly date the clinical beginning of the pathological state known as chronic hyperemia.

The difficulties are increased by the fact that in acute active and passive hyperemia, at least, no postmortem evidences of it remain, the congestion having disappeared with death, although an unusual distinctness of the puncta vasculosa has long been regarded as postmortem evidence. The difficulty of recognizing such condition makes this sign an unreliable one. In chronic hyperemia there result, sometimes at least, a turbidity and even an opacity of the pia mater, with slight thickening, together with elongation and tortuosity of the vessels, which are regarded as characteristic.

**Symptoms.**—These are not very distinctive. The symptoms of active hyperemia, so far as recognizable, are a sense of fullness or pressure, headache, mental excitement, irritability, confusion of ideas, insomnia, vertigo, ringing in the ears, and, in extreme cases, hallucinations, delirium, and mania. These symptoms are increased when the head is held downward or there is straining. The phenomena of so-called "rush of blood to the head" are probably the result of active hyperemia. They include a suffusion of the skin of the face and head and a feeling of warmth in these situations, strong beating of the carotids, headache, tinnitus aurium, spots before the eyes, vertigo, and sometimes actual falling.

It is not easy to separate the phenomena of passive hyperemia from those of active congestion. They are, however, less pronounced and slower in their development.

**Treatment.**—The indications for treatment are, nevertheless, plain. The *head* is to be kept *raised*. *Purgation* is the first measure to be thought of. The saline and hydragogue cathartics are especially indicated, because of their depleting effect. The *ice-cap* should be used. In extreme cases even *blood-letting* may be necessary, the efficiency of which is sometimes seen in the relief afforded by bleeding of the nose. Leeches applied behind the ears often afford magical relief to the symptoms commonly ascribed to congestion of the brain. Wet cups may be placed upon the back of the neck for the same purpose. The diet should be spare and easily assimilable, in acute cases liquid only.

Of medicines, the *bromid of potassium* theoretically fulfills the indications, and in full doses of from 15 to 30 grains (1 to 2 gm.) every three hours to adults is often useful, though it should not be allowed to substitute the other measures mentioned. *Phenacetin* is an admirable remedy for the headache, a single dose of 10 grains (0.66 gm.) being often sufficient. It may be repeated if necessary, or smaller doses may be given more frequently.

### ANEMIA OF THE BRAIN.

**Definition.**—The more usual application of the term anemia of the brain is to conditions in which the quantity of blood in the organ is diminished, although depraved states of the vital fluid without loss of bulk may also produce the same symptoms.

**Etiology.**—The causes leading to this condition are for the most part those which withdraw blood from the brain, but they include also such as prevent its access. Among the former are hemorrhages, profuse and rapid; bowel fluxes, such as those of cholera in adults and cholera infantum in children; and the opening of vascular areas by the removal of pressure caused by large tumors or ascitic fluid. Thus is explained the fainting which sometimes succeeds the removal of a large abdominal dropsy. In the second set of causes are feeble action of the heart, ligation of the carotid artery, or other obstruction in vessels carrying blood to the brain. Such obstructions are thrombi and emboli. The brain substance adjacent to the dilated ventricles in hydrocephalus internus is anemic from compression. The fainting due to sudden emotion, such as fright, is ascribed to a withdrawal of blood from the brain.

**Morbid Anatomy.**—This is more distinctive than in hyperemia. The membranes are pale, the blood in their vessels, except the larger ones, is scanty, and over the convolutions the vessels are quite empty. The gray and the white matter are both pale on section, and the *puncta vasculosa* are less distinct and less numerous. The cerebrospinal fluid is increased.

**Symptoms.**—Some of these are definite and the direct result of loss of blood to the brain. Such are the dizziness, confusion of ideas, flashings of light, roaring in the ears, nausea, and ultimate loss of consciousness

and even death which succeed hemorrhages or emotion. In other cases the skin is cold and clammy, and a cold perspiration starts to the surface. Other symptoms are less distinctive. They are ascribed to chronic anemia, but may result also from other causes. Such are mental apathy, disinclination to work, a sleepy feeling during the day, and insomnia at night. Nausea, headache, tinnitus, vertigo, hallucinations, and delirium are

FIG. 136.—Circle of Willis and Arteries of Brain—(Deaver).

also consequences more particularly of lowered composition of the blood, of anemia, in fact, the result of prolonged illness, like pulmonary consumption and Bright's disease. The convulsions characteristic of the latter disease have been ascribed to anemia and also to edema of the brain.

The hydrocephaloid symptoms, described by Marchall Hall as the direct result of prolonged diarrhea and of cholera infantum in children, are regarded as results of anemia. They include semistupor with eyes unclosed, later, dilated pupils, strabismus, convulsions, rigidity, and death.

**Treatment.**—The immediate consequences of the acute form of anemia are diminished or averted by placing the patient on the flat of the back with the head low; by diffusible stimulants, of which alcohol and ammonia are the types; also cardiac stimulants, and nourishing and easily assimilable foods. The chronic forms of brain anemia are treated by nutritious, easily assimilable foods, and tonics, especially iron and arsenic. In the hydrocephaloid condition in infants alcohol is the pre-eminent remedy, associated with warm baths and general restorative measures.

### EDEMA OF THE BRAIN.

**Definition.**—The term includes two conditions, the most definite and easily recognizable of which is an abnormal accumulation of cerebrospinal fluid within the pia arachnoid. In the second condition there is added to the first an abnormal moistness of the substance of the brain.

**Etiology.**—The most common cause is mitral stenosis, although any cause obstructing the return of blood from the brain as well as recurring irritative hyperemias, such as are produced by alcoholism and the psychoses, are also causes. Bright's disease is a cause of edema of the brain, local or general.

Local edemas of the brain are also caused by obstruction of single sinuses of the dura mater, or compression by tuberculous or other tumors of the veins of the velum interpositum, known as the *venæ Galeni*.

**Morbid Anatomy.**—The membranes are turbid, their vessels are distended and serpentine in their course, and the subarachnoid space is filled with clear fluid. The substance of the brain is anemic, moist, and glistening. In extreme cases there is compression of the cortex, with resulting flattening of the convolutions and widening of the sulci. The fluid in the lateral ventricles may also be increased.

**Symptoms.**—These are ill defined. There may be *hallucinations* and even *mania*, very similar, in fact, to those of anemia. Traube and Rosenstein ascribed the *convulsions of Bright's disease* to edema of the brain, while certain *unilateral* convulsions and *paralysis* in connection with this disease have been assigned to the same cause. Even death has been ascribed to sudden serous effusions of this kind, constituting acute edema of the pia mater, or *apoplexia serosa*. In recent years much has been written on cerebral edema under the name of meningitis serosa.

**Treatment.**—The treatment is that of the conditions to which the symptoms are secondary. The effects of cardiac stenosis must be overcome by cardiac stimulants; Bright's disease must receive appropriate treatment. Thrombosis of the sinuses admits of no treatment, though its effects may diminish by gradual contraction and possible liquefaction and removal of the thrombus. The psychoses should receive treatment appropriate to them.

### APOPLEXY.

**Definition.**—The term apoplexy is applied to a sudden loss of motor power with or without loss of consciousness due to cerebral hemorrhage, or the sudden plugging of a blood-vessel. Laceration of the brain with-

out hemorrhage produces a like effect. In point of fact, when the term apoplexy is used, cerebral hemorrhage is commonly intended.

Unconsciousness may also be produced by simple congestion, and it was formerly thought that a simple serous transudate could produce similar symptoms in a milder form and of shorter duration; whence the term "serous apoplexy." Concussion of the brain, also, causes similar symptoms.

## I. CEREBRAL HEMORRHAGE.

**Arterial Distribution.**—In the first place hemorrhage is *meningeal* or *central*. Meningeal hemorrhage may be outside of the dura between it and the bone, or between the dura and the arachnoid, or within the pia arachnoid. The extradural and subdural meningeal hemorrhages are both traumatic, one variety of which is produced during birth, but those in the pia arachnoid are due to the causes to be considered below. Central hemorrhages may also burst into the membranes as well as into the ventricles of the brain and in some instances the hemorrhage is almost entirely intraventricular. Meningeal hemorrhage may occur in the infectious fevers, in leukemia, and in anemia.

It is a rare event to find a rupture in any of the large arteries of the circle of Willis, although white patches of atheroma are often seen upon them at autopsy. But the free anastomosis of this circle scarcely allows of increase of intravascular pressure sufficient to cause rupture. Further, it is the "central" rather than the "cortical" branches of this circle which rupture, and especially the central branches of the *middle cerebral*, which, entering the brain at the anterior perforated space, pass to the corpus striatum and internal capsule. One of these is the so-called artery of "cerebral hemorrhage," thus named by Charcot because of the frequency of its involvement. It passes to the internal capsule and lenticular nucleus, where the majority of the massive hemorrhages of the brain occur.

**Etiology.**—Disease of the artery involved is responsible for the vast majority of cerebral hemorrhages. Indeed, except in the case of traumatic hemorrhages either with or without fracture of the skull, it is very doubtful whether hemorrhage ever occurs without such disease. The simplest form is the fatty degeneration and "erosion" of the intima, characteristic of advanced age. *Endarteritis*, however produced, is perhaps the most frequent cause. Its ultimate result, as shown by Charcot and Bouchard as far back as 1868, is the *miliary aneurysm* which very frequently precedes the rupture. It is a spindle-shaped, rarely lateral, dilatation, from  $\frac{1}{25}$  to  $\frac{1}{5}$  inch (1 to 5 mm.) in diameter. The inflammatory process preceding it consists in a proliferation and degeneration of the intima cells, followed by atrophy, which extends also to the muscular layer and the scanty adventitia. These, yielding to the intravascular pressure at the weak points, dilate to form the little aneurysm, which is later ruptured by some further increment of pressure. Embolism is also a cause of endarteritis which may result in aneurysm.

The "fatty erosion" of the intima which is the next most frequent cause of vulnerability is favored by age, by chronic interstitial nephritis,

and the overstrain of the vessels due to hypertrophy of the left ventricle, so often associated with that disease as well as with valvular heart disease.

While by far the larger majority of hemorrhages are preceded by miliary aneurysm or fatty erosion—fully nine out of ten—there still remain a number of instances in which careful search fails to find anything but *diffuse degeneration*; whence the miliary aneurysm and fatty erosion cannot be regarded as indispensable conditions. The *infectious fevers, leukemia, and anemia* are also causes of hemorrhage which is independent of miliary aneurysm.

*Age* is also a predisposing factor, most ruptures occurring after 50, although apoplexy has occurred under ten; while the occupations and dissipations of men furnish additional predisposing elements which accounts for its greater frequency in the male sex. Other predisposing causes are those usually responsible for endarteritis—viz., gout, alcohol, syphilis, Bright's disease, the apoplectic habit, as seen in the stout, short-necked, full-blooded individual; and, finally, heredity, which is, strictly speaking, a hereditary tendency to the favoring diseases.

The exciting causes are such as temporarily increase intravascular pressure, as violent exertion, straining, debauch in eating and drinking, and mental emotion.

**Morbid Anatomy.**—The *large central ganglia in the neighborhood of the lateral ventricles*—i. e., the optic thalami, the caudate and lenticular nuclei, and the adjacent white matter of the internal capsule and centrum ovale—are the favorite seats of miliary aneurysm and consequent hemorrhage. These aneurysms are found also, but much more rarely, in the smaller branches of the *cortical vessels*, in the *pons, cerebellum, crura cerebri, or medulla oblongata*. On section of the large ganglia these may be seen as small dark points, as large as a pin's head, and are often very distinct in arteries drawn out of the substance of the brain, especially the anterior perforated space. Coarser aneurysms are also found on the branches of the circle of Willis.

Given a massive hemorrhage, what is its effect on the brain substance, and what are the changes in the extravasated blood? The former varies somewhat with its situation. If extradural, the dura mater is torn away from the bone to a varying extent. If subdural or beneath the pia arachnoid, it separates these membranes from the brain substance, but in either event the convolutions are more or less flattened and the sulci more or less obliterated.

As already stated, central hemorrhage most frequently occurs in the neighborhood of the corpus striatum, through which, if large, the blood finds its way toward the outer section of the lenticular nucleus, pushing inward the optic thalamus and bursting into the lateral ventricle or into the white matter of the centrum ovale. The pressure exerted is often such as to flatten the convolutions, empty the parietal veins, and press the falx aside, sometimes even to produce a sense of fluctuation over the membranes. Hemorrhages may occur in the crura or pons or fourth ventricle, and also in the cerebellum, not infrequently from the superior cerebellar artery. Osler mentions two cases of death in women of twenty-five from cerebellar hemorrhage. Very rarely hemorrhages into the

ventricle may start in the choroid plexus or the ventricular walls. Blood in large quantities may be poured out at the base of the brain, and it may flow down into the cord from a rupture of any of the arteries going to or from the circle of Willis.

If the patient survives, changes take place in the extravasated blood, which promptly coagulates into a dark-red mass. This almost immediately begins to contract, permitting often the return of a certain degree of function by removing pressure. As time elapses the dark-red mass passes into a chocolate-brown pulp, composed of liquefying blood-clot and disintegrated nervous matter. The microscope, at this stage, recognizes numerous hematoidin crystals and granular fat-cells which are probably fatty by imbibition of fat-granules. The adjacent nervous tissue is stained yellow by the imbibed hematoidin. The clot itself becomes encapsulated by fibrin and gradually absorbed, being often substituted by a semitransparent or completely transparent fluid, forming the apoplectic cyst. If smaller, the walls approach and unite, leaving only a linear pigmented scar. Especially is this the case with small clots on the surface of the convolutions, which may leave only a staining of the membranes. In other cases of abundant cortical effusion, especially in infants, there may be circumscribed wasting of the convolutions and a cyst of the meninges or brain. The position and extent of the permanent lesion determine the presence of secondary descending degeneration. If the motor cortex or motor tract is involved, there may be found, in persons dying some years after a stroke of apoplexy with hemiplegia, degeneration in the pyramidal fibers of the pons and medulla oblongata, in the direct pyramidal fibers of the cord of the same side, and in the crossed pyramidal fibers of the opposite side, and to some extent in the crossed pyramidal fibers of the same side.

**Symptoms.**—*Premonitory* signs are occasionally present. There may be a feeling of fullness in the head, headache, tinnitus, vertigo, or numbness, tingling, pains in the limbs on one side, loss of memory of words or choreiform movements—prehemiplegic chorea,—possibly due to miliary aneurysm or otherwise diseased vessels.

With the bursting of a vessel of sufficient size there occurs the *apoplectic "stroke,"* or apoplectic shock. Its most striking feature is *sudden loss of consciousness*. If complete, the patient falls heavily to the ground, and there may be slight convulsive movement, but it soon ceases. More rarely a true convulsion ushers in the attack. The patient cannot be aroused, the face is suffused, cyanotic—sometimes, however, pale; the *breathing* is slow, noisy, stertorous often attended with a puffing sound during expiration. Corresponding with a blowing out of the relaxed cheek on the paralyzed side; it may also be the Cheyne-Stokes type. In contrast with the foregoing, the development of unconsciousness is sometimes much more gradual, requiring several hours or a day, corresponding to which it is presumed that the hemorrhage is slow, constituting the "ingravescent form."

The second major symptom of apoplexy is *motor paralysis*, of which hemiplegia is the most conspicuous form. In most cases the motor pyramidal tract, as it descends in the internal capsule, is either directly de-

stroyed or indirectly affected. Hence most patients who survive the primary shock present a hemiplegia—paralysis of half the body opposite that of the hemorrhage, and most frequent on the right side. It is most noticeable in the arms and legs. These are thoroughly relaxed, falling limp when allowed to drop, as the limb of one thoroughly etherized. More rarely there is early *rigidity*, especially on the paralyzed side. This symptom is possibly more frequently associated with hemorrhage into a lateral ventricle. *Reflex action* is early either totally suspended or only brought out in response to a deep pin thrust or severe pinching.

The signs of hemiplegia are not always easily elicited at first, because a certain degree of consciousness is necessary to stimulate attempt at motion, but it may be that the angle of the mouth hangs down lower on one side—the paralyzed side—while the puffing of the cheek alluded to may be present on the same side, or the limbs of one side may be appreciably more flaccid than those of the other, or a small amount of reflex response may be elicited on the sound side. The *pulse* is usually slow, full, strong, and tense. The *temperature* may be subnormal at first, rising to normal and even above, and in basal hemorrhage may be higher. In a rapidly fatal case it remains subnormal to the end. The *pupils* are *irregular*—*i. e.*, sometimes contracted, at others dilated, unequal. They respond to light either slowly or not at all. If the hemorrhage is where it can irritate the nucleus of the third nerve, the pupils are contracted. This may occur with hemorrhage into the pons or ventricles.

In *cortical lesions* quite often one of the early symptoms in hemiplegia is *conjugate deviation* from the paralyzed side and toward the side of lesion, from which we have the expression that “the patient looks at the lesion;” that is, in right hemiplegia the head and eyes look toward the left side. This symptom usually passes away, but sometimes continues for weeks, and, as Gowers suggests, is perhaps occasionally represented by nystagmus or movement in the direction concerned. Should, however, convulsion, or spasm, or early rigidity develop, the head and eyes are rotated toward the paralyzed side—*i. e.*, away from the side of lesion. This is true only of cortical lesions.

In lesions of the *pons*, on the other hand, where the conjugate deviation may also occur, the phenomena are reversed—the patient looks away from the lesion, in the absence of spasm—but if the convulsion or spasm or rigidity occur, the eyes and head look toward the lesion. These facts are a little confusing at first and may be expressed in the following.

In lesion of the cortex—

Without spasm, conjugate deviation is *toward* the side of lesion.

With spasm or convulsion or early rigidity, *from* the side of lesion.

In lesion of the pons—

Without spasm, *from* lesion.

With spasm, etc., *toward* lesion.

This may be due to the fact that these movements in health are innervated from both sides, and when a lesion occurs on one side of the cerebrum, the innervation is given over to the other side until the injured one resumes its function, or until irritation in it causes it to assert or exceed its function. In pontile lesions the destruction occurs possibly

below the decussation of the fibers innervating the parts affected in the conjugate deviation and the symptoms are reversed. Conjugate deviation in lesions of the pons is, however, a rare phenomenon.

Where unconsciousness exists the *feces* and *urine* are passed involuntarily, and the latter is sometimes slightly albuminous.

As to further progress in a few cases there is no reaction from the previously described condition. The symptoms all deepen, the breathing becomes rapid and rattling, the skin cool, the pulse weak and rapid, and the patient dies. In most cases, however, there is a certain abatement of the symptoms, even if the patient does not recover more fully. Consciousness returns partially or completely, the patient can be aroused by a loud voice, and one can recognize which side is paralyzed. There may, at this time, be a febrile movement, due to cerebral inflammation or disruption of heat-regulating centers, during which the patient may die; or there may be another hemorrhage which carries him off.

On the other hand, improvement may continue to a further degree. The consciousness and intelligence may return completely, and the signs of paralysis may gradually grow less, *more rapidly in the legs than in the arms*. They, however, almost never disappear completely, the patient continuing lame and requiring the use of a cane for the rest of his life. In severe cases a remnant of paralysis of the face can almost always be recognized, while articulate speech may also continue defective.

Such marked improvement is, for the most part, reserved for the milder attacks, in which there is great variety as to degree. In such the loss of consciousness is of short duration, or it may not occur at all. Such attacks are not infrequently ushered in by nausea, vomiting, vertigo, or sudden headache. The paralytic symptoms may still be marked, and permit a study rather more satisfactory than the fulminating cases. In such study it will be found that all muscles are by no means equally paralyzed. Thus it will be seen that the lower division of the facial nerve, which supplies the muscles of the cheek, nose, and mouth, is plainly paralyzed; while the upper division, distributed to the muscles of the eyes and forehead, is almost, if not entirely, intact. The forehead may be wrinkled with equal ease on the two sides, but an attempt to draw up the nose or purse the mouth fails, while one labionasal fold may be obliterated and one angle of the mouth lower than the other. The natural wrinkles of the forehead are commonly less distinct on the paralyzed side than on the other. This event—the comparative freedom from paralysis in the upper part of the face—may be explained by the fact that while both sides of the face receive fibers from each cerebral hemisphere, this is especially true of the muscles of the upper part of the face, which are always exercised bilaterally.

The *tongue* may not be paralyzed, but when it is, if protruded, it goes toward the paralyzed side, being pushed out by the geniohyoglossal muscle of the other side, the innervation being by the hypoglossal nerve. Occasionally paralysis of the tongue contributes to difficulty in articulation. The motor branch of the fifth nerve is sometimes involved on the hemiplegic side, and there is paralysis of the pterygoid, temporal, and masseter muscles.

Of the *trunk muscles*, the trapezius is almost solely involved, and that but slightly, permitting the shoulder to drop a little, and the paralyzed side of the chest may expand more than the normal side in ordinary breathing, while in voluntary deep breathing this is not the case. The reason of this possibly may be found in the exaggeration of the reflexes on the paralyzed side; ordinary breathing being a reflex action.

*Sensation* is but slightly impaired in most cases of hemiplegia due to cerebral hemorrhage, and such impairment usually grows rapidly less as time elapses, unless the optic thalamus is seriously damaged. It is hemianesthesia when anesthesia exists, and it is on the side opposite that of the lesion. There may also be trifling paresthesia at first. Any marked disturbance of sensation means that the posterior extremity of the internal capsule is involved, or, according to some authors, it indicates that the optic thalamus is invaded. Distinct impairment of the deep sensibility—the so-called muscular sense or sense of position—may indicate a lesion of the parietal lobe. There is sometimes temporary and even permanent *hemianopsia*, which implies some lesion of the fibers of the optic radiation posterior to the internal capsule or in the posterior portion of the optic thalamus—the pulvinar.

Astereognosis or the inability to recognize objects by touch is sometimes a symptom.

The *tendon reflexes* are increased in nearly all cases on the paralyzed side, though at the very beginning of a severe shock they may be abolished, and if this abolition of the reflexes persists, it is regarded as a serious sign. In cases of any duration even the periosteal reflexes are increased, and to a less degree the reflexes of the sound side are increased, because each side of the body is innervated from both sides of the brain, although the number of fibers passing to the same side of the body is considerably less than those passing to the opposite side. There is even, at times, ankle clonus, and, more rarely, wrist clonus. These events are explained by supposing a suspension of the inhibitory reflex cortical centers, due to the cerebral lesion. The *skin reflexes*, on the other hand, are diminished on the paralyzed side, remaining normal on the sound side.

The *rapid improvement* mentioned as occurring in some cases is usually confined to a few weeks or days, after which improvement goes on more slowly, the lower extremities recovering more completely than the upper. The *gait* resulting from partial recovery is peculiar. Short steps are taken by the affected leg, and the toe is dragged more or less, while locomotion is sometimes accomplished by sweeping the leg around in a semicircle by the iliacus and psoas and the vastus externus, while it is held stiff, as in a splint, by the quadriceps extensor muscle. In the upper limb the hand muscles are the last to recover.

Later in the history of the case *contractures* may come on in the paralyzed muscles, shown especially in flexures of the fingers, contracture of the forearm in a position of pronation, and partial flexion, with the upper arm adducted. The lower extremity is usually in the position of extension. This contracture is explained by some, and notably by Strümpell, as a "passive contracture," the position assumed being the natural one in a state of rest. On the other hand, Charcot and his pupils

hold that the contractures are due to secondary degeneration of the pyramidal tract. It is very doubtful whether secondary degeneration produces symptoms.

There are also sometimes *associated movements* of the paralyzed muscles, to which Hitzig has called attention. In these, movements of the sound side excite associated movements in the corresponding muscles of the other side, and attempts to move the affected side result in motion of corresponding muscles of the sound side. Sometimes, also, involuntary movements of the lower extremity occur when the patient attempts to move the corresponding arm. A *posthemiplegic chorea*, first described by Weir Mitchell, should also be mentioned. It is seen not so much in the hemiplegia resulting from cerebral hemorrhage as from focal disease of the posterior end of the internal capsule and optic thalamus. A form of *hypertonia* has recently been described in which the muscles are in a state of exaggerated tonicity without much paralysis. In this condition the position of the spastic limbs varies from time to time. It is seen in some cases in which a cerebral lesion has occurred early in life.

*Trophic symptoms* may appear late in the disease, seen at first in elevation of temperature, increase of color on the paralyzed side of the face, swelling of the eyelids, and contraction of the pupil; also swelling of the hands. It is to be remembered, however, that slight swelling may result from sluggish circulation of blood and lymph, contributed to by diminished muscular contraction and absence of use. In a more advanced stage the extremities become cooler and are often constantly moist. Among these vasomotor events Charcot has placed what he calls *acute malignant decubitus*—a disposition to rapid gangrene of the tissues over the sacrum. It may appear in a few days after the shock, beginning with a circumscribed redness and formation of vesicles, succeeded by deep-reaching necrosis. While this is probably, as Charcot regards it, a vasomotor phenomenon, it is also invited by the usual causes of gangrene in dorsal decubitus, such as irritation by urine, feces, and even inequalities in the bed-clothing. Charcot also considers an occasional arthritis, acute or chronic, a neuropathic event.

*General nutrition* is well maintained, the patient even gaining in flesh at times. More rarely there is rapid wasting.

The *mental condition* of patients who recover partially from the effects of hemorrhage is, for the most part, good, but it not infrequently happens that after a time mental weakness manifests itself in loss of memory and defective intellection, while imbecility sometimes ultimately supervenes.

**Diagnosis.**—The greatest difficulty lies in the differential diagnosis between cerebral hemorrhage, *embolism*, and *thrombosis*. I will, however, defer its consideration until cerebral embolism and thrombosis are treated.

In *fulminating cases* the coma is sometimes so profound that it is difficult or impossible to ascertain the presence of hemiplegia. The symptoms which aid in determining this have been mentioned on page 1157. To these may be added the increase of reflexes on the affected side, present in an early stage of the paralysis, conjugate deviation of the head and eyes, and rigidity of limbs on one side. It is these cases that are sometimes confounded with *epilepsy*, *opium poisoning*, *acute alcoholism*, or *uremia*. In *epilepsy* there is the history of previous convulsions, and

it is only when this has been overlooked that mistakes occur. In *opium poisoning* the coma is slow in its onset, the pupils are uniformly contracted, and the odor of laudanum is often on the breath. But here, too, the victim is often only discovered after coma has thoroughly developed. In *alcoholism* there is the odor of whisky, but many an innocent person has been treated as a drunkard on whose brain lay a clot pressing him to death. The young ambulance or police surgeon is wise who defers his opinion. Sometimes alcoholism and apoplexy are combined, in which event a conservative course will be no less astute. The coma of *uremia* in Bright's disease very strongly simulates that of apoplexy, especially in the rare cases of the latter in which there are convulsions. The presence of dropsy, or, in its absence, of the peculiar anemia of Bright's disease, and the finding of albuminuria and casts should suggest this disease, but albumin may be found in hemiplegia not of renal origin. It is to be remembered, too, that uremic convulsion may terminate in hemorrhage, while Bright's disease is also associated with a state of the arteries which disposes them to rupture. Coma in a puerperal woman, associated with dropsy and albuminuria, means uremia.

**Prognosis.**—To have had a stroke of paralysis is justly regarded as having received a blow which marks the beginning of inevitable decline in health and usefulness, though cases are constantly occurring in which a "slight stroke" is followed by complete recovery. Some of these are probably errors of diagnosis, yet all are not. The cortical hemorrhages are those most frequently followed by recovery. After these come a large number of cases of first attack, from which the patient recovers quite a considerable degree of health. Second attacks are prone to occur, which are more severe, and few survive a third attack.

The unfavorable cases are those in which the coma is profound and lasting. Such are hemorrhages into the ventricles and corona radiata, which are rapidly fatal. Meningeal hemorrhages are serious, but less so when traumatic than when due to diseases of the vessel. Cases attended by early and persistent fever and delirium are unfavorable, as are also cases complicating renal disease and alcoholism. Hemorrhages into the corpus striatum and internal capsule produce persistent hemiplegia, followed by contracture. When cases survive the primary stroke and improvement sets in, this is much more rapid in the first few weeks than later. In explanation of this it has been held that the symptoms thus rapidly removed are indirect focal symptoms, due to pressure of the clot on adjacent nervous tissue, while those more slow to yield are the result of destructive lesion.

**Treatment.**—The patient should be promptly placed in a horizontal position *with the head raised*. This is of the greatest importance, as it constantly happens that a patient in whom consciousness is returning immediately becomes comatose when the head is lowered. *He should then be bled* unless the pulse be small and feeble. The bleeding should be accompanied by a *laxative*, which should be given alone if there be any reason why phlebotomy should not be practiced. In view of the unconscious state of the patient the best laxatives are croton oil and elaterium. Two drops of the former should be mixed in a little glycerin or oil and

carried to the back part of the throat, or  $1/4$  grain (0.0165 gm.) of elaterium, dissolved in a small quantity of water, may be given in the same way. The rectum should be at once cleaned out by an enema of warm water. An ice-bag should be placed on the top of the head, hot water and mustard to the feet, while counterirritation may also be applied to the back of the neck, but it is doubtful whether any of these measures will accomplish much.

*Compression of the carotid artery*, formerly recommended and practiced on empirical grounds, has recently received the indorsement of Horsley and Spencer, these experimenters having found that bleeding from the lenticulostriate artery ceases when the carotid is compressed. It is especially in the ingravescens form that it has been recommended. F. X. Dercum and W. W. Keen<sup>1</sup> report two cases of ingravescens hemorrhage treated by ligation of the common carotid, of which one recovered.

If, after bleeding and purgation, the pulse continues bounding, the *tincture of aconite* or *veratrum viride* may be given in doses of a minim every half-hour until the pulse is influenced. *Iodid of potassium* can hardly be expected to promote absorption of the clot, but may be given if syphilis is suspected. It may, however, facilitate circulation by dilating the blood-vessels.

The foregoing treatment is for the period immediately succeeding hemorrhage. The remainder of treatment consists in measures to protect the patient against the effect of decubitus if this is prolonged, and in maintaining the nutrition of muscles and protecting against contractions. The former is accomplished by attending to the secretions, preventing the irritation of the body by putrid urine and feces or foreign substances like bread-crumbs, by bathing and drying the body thoroughly, by frequent changes of posture. The latter will also guard against pneumonia, which is rather prone to occur on the paralyzed side. This last disease may also be caused by the inspiration of particles of food, liable to happen if there is paralysis of the muscles of deglutition. The second indication is met by massage, faradization, and gymnastics, but they should be deferred for two or three weeks. *Warm salt baths* three or four times a week are useful to the same end. Tonics in the form of iron in small doses, quinin, and strychnin may be given, but alcohol in more than very moderate amounts is contraindicated.

Operative treatment has been suggested to relieve the pressure of a clot in cerebral hemorrhage, and when it is certain that the clot is meningeal, especially after fracture, satisfactory results show that it is justified. Careful attention should be paid to the facts mentioned under topical diagnosis with a view to determining the seat of hemorrhage and the place to trephine. Deep hemorrhage is, however, beyond reach.

## II. EMBOLISM AND THROMBOSIS OF THE CEREBRAL VESSELS.

### A. Of Cerebral Arteries.

SYNONYMS.—*Cerebral Softening; Acute Softening.*

**Definition.**—By *embolism* is meant the plugging of an artery by a foreign body carried by the blood-current from some point in the vascular

<sup>1</sup> "Jour. of Nervous and Mental Disease," September, 1894.

system to a situation beyond which it cannot pass. By *thrombosis* is meant plugging of an artery or vein by a clot formed *in situ*.

**Etiology.**—*Nature and Source of Embolism.*—The embolus is most frequently a vegetation from a diseased valve in the left ventricle. Less commonly it is a fragment of a clot in the same ventricle or in the auricular appendage or in an aneurysm, or it may be a calcareous particle from an atheromatous vessel or a piece of thrombus from the same. Even the territory of the pulmonary veins may contribute an embolus. Embolism is very much more frequent in chronic valvular disease than in primary acute endocarditis. It is prone to occur in recurring valvulitis, and especially in malignant mycotic endocarditis. Pregnancy with or without heart disease, the infectious fevers, and blood dyscrasiæ may be predisposing causes.

The embolus commonly enters the brain by the carotid, especially the left—which furnishes the most direct course—thence through the internal carotid to the *left middle cerebral* in the fissure of Sylvius; more rarely by the *vertebral* and its *posterior cerebral* branch.

*Thrombosis.*—In thrombosis there is also plugging of a living vessel, but by a clot formed *in situ*, which is either primary at the point plugged or secondary about a previous embolus. Some favoring cause commonly exists. This is most frequently roughening due to endarteritis, with or without atheroma. Weak heart and blood dyscrasiæ are also predisposing causes. Ligation of the carotid artery is sometimes followed by thrombosis of cerebral vessels.

The vessels most frequently affected in thrombosis are the *middle cerebral* and the *basilar* in its course or at its bifurcation; but the *vertebral*, the *posterior cerebral*, and the branches of the circle of Willis may be plugged.

*Relative Frequency of Thrombosis and Embolism.*—Embolism has been thought to be more frequent in women, but of 79 cases collected by Newton Pitt at Guy's Hospital, 44 were in men and 35 in women. Thrombosis is considered more common in men. Embolism is rare in children, being more frequent at from 20 to 50; thrombosis in older persons at from 50 to 70.

**Morbid Changes Due to Thrombosis and Embolism.**—*Degeneration and softening of the brain* are the direct result of obstruction of its arteries, and occur sooner or later when the shutting off of the blood-supply is sufficiently complete. The process generally begins within 24 hours and the minimum time required to complete it is from one to two days. The local anatomical product of embolism is much less distinctive in the brain than in the lungs or spleen. Thus, there is almost never a distinct hemorrhagic infarct, though there is often a condition resembling it, the area cut off being infiltrated with blood. At other times the region is paler than in health and slightly softer. In either event the area becomes gradually infiltrated with serum and a more or less complete liquefaction results, presenting a reddish, yellow, or white color, whence, the terms *red softening*, *yellow softening*, or *white softening*. These variations are not the result of any essential difference in the nature of the process, as was formerly thought, but are rather accidental. In

red softening the softened focus happens to contain an unusual amount of extravasated blood, due to punctiform hemorrhage or capillary apoplexy. This blood melts away and stains the softened mass. In yellow softening the proportion of fatty degenerated cells is larger, and it is found, therefore, chiefly in the cortex, where cells prevail. In white softening there are few or no cellular elements, hence the white softening is found in the white nervous matter. It is most characteristically seen about tumors and abscesses. As the gray matter of the cortex is also the most vascular part of the brain, it is here also that we find red softening. Certain superficial yellow spots known as *plaques jaunes* are found at times on the surface of the cortex in old persons. They are sharply circumscribed, measure from two to four centimeters (.8 to 1.6 inches), are made up of a yellow, turbid material sometimes crossed by trabeculae, and are the result of fatty degeneration of peripheral cortical arteries.

*Minutely examined*, the softened areas consist of fatty granules and oil drops, myelin drops, fragments of swollen nerve-fibers, fatty granular cells representing fatty neuroglia and nerve-cells, or leukocytes and neuroglia cells, and perhaps endothelial cells which have *imbibed* the oil drops, arising probably from disintegrated nervous matter. In the yellow softening these constitute the sum of altered materials. In red softening there are added in the early stages blood-disks, later pigment granules or hematoidin crystals, or there is general staining by dissolved hemoglobin. In the white softening the fragments of nerve-fibers together with myelin drops make up the chief bulk, as already stated. If collateral compensatory circulation is set up within two days, the destruction may not go so far, and the nervous elements may resume their function; or if this does not occur and the patient lives, the dead and disintegrated tissue may be gradually absorbed and eventually be replaced by a cyst, while a minute focus of softening may be replaced by indurated cicatricial tissue. If the embolus is derived from an infective focus, as ulcerative endocarditis, an abscess may result.

**Symptoms.**—Neither thrombosis nor embolism of the cerebral arteries is always followed by recognizable symptoms. All the large arteries of the base and the smaller arteries of the surface anastomose so freely that the effects of obstruction are promptly equalized. Nay, more; it is not unusual to find at the necropsies of elderly persons yellow spots of fatty degeneration; the *plaques jaunes* referred to, scattered over the convolutions where nothing was suspected before death. Moreover, softening may take place in the "silent regions" without exciting suspicion.

Very different is it with obstruction of the middle cerebral artery—the artery of the fissure of Sylvius. The clinical aspect differs, however, according as this vessel is plugged at its origin or a little further on in its course. Allusion has already been made (p. 1157) to the two separate systems with which the brain is supplied—the "cortical arteries" (Duret), passing to the cortex, and the "central" arteries, passing to the central ganglia. The central arteries are the first given off by the cerebral branches of the circle of Willis, and are terminal arteries, unprovided with anastomoses. The cortical arteries spring from a network of branches of the cerebral arteries in the pia mater, in which toler-

ably free communication exists between the tertiary branches of the same trunk, and even between the branches of different trunks. These two systems of cortex and center are, however, altogether independent of each other, and no anastomosis takes place between them, the zone at which they meet within the cerebral convolutions. In the case of the middle cerebral artery, when it is obliterated beyond the point at which its "central" branches come off, the superficial parts of the brain are alone affected, and since its branches in the pia mater anastomose with those of the anterior and posterior cerebrals, there may be no softening at all, and but a temporary loss of function. At other times softening does occur, the exact situation and extent of which vary with the arteries plugged. The blood-supply of the two central, the three frontal, and the three parietal convolutions being more or less cut off, there is motor paralysis of the opposite side of the body, and as the lesion is most frequent on the left side, there are right-sided hemiplegia and aphasia; the same phenomena, in fact, as follow hemorrhage, and which may be permanent or transient; or the lesion may be still more limited. The embolus may lodge in the artery passing to the third frontal convolution, or in that of the ascending frontal or ascending parietal. It may lodge in the branch passing to the supramarginal or angular gyrus, or to the lowest branch, which is distributed to the upper convolution of the temporosphenoidal lobe. If, on the other hand, the seat of the lesion is at the point where the Sylvian artery arises from the internal carotid, the central ganglia are involved, and there is almost certain to be softening of the corpus striatum and optic thalamus, because the arteries have no anastomoses, while the cortex escapes entirely because its vessels are distinct.

*Summary of the Effects of Plugging of the Cerebral Vessels:*

*Internal Carotid.*—There may be no symptoms or there may be transient hemiplegia, or permanent hemiplegia and coma ending in death in a week or 10 days. In the first alternative the circulation is maintained by the communicating vessels of the circle of Willis, which ordinarily dilate rapidly. If these vessels are small or absent, permanent hemiplegia and death must result, as a small part of the hemisphere only receives blood by the posterior cerebral. Thrombosis is very likely to extend from an initial focus in the internal carotid to its branches, and may extend to the ophthalmic artery.

*Anterior Cerebral.*—Because of the right-angled direction at which this vessel is given off from the internal carotid, it is rarely obstructed by embolus unless the parent trunk is plugged before this branch is given off, and then the mischief is trifling or *nil*. The symptoms are not so intense probably because the frontal lobe's functions are not so positive.

*Middle Cerebral.*—This is the most frequently plugged of all cerebral vessels. The result is hemiplegia, permanent if the embolus lodges before the central arteries are given off, since softening of the internal capsule ensues. If on the left side, there is aphasia, and there may also be impairment of sensibility for a time. The symptoms vary somewhat, according as one or more of the cortical branches are obstructed by a plug at the point of division of the vessel in the island of Reil. Occlusion of the first branch may produce softening of the third frontal convolution and aphasia if on the left side; occlusion of the second and third branches, softening of the ascending frontal or ascending parietal convolution and hemiplegia, partial when the softening is incomplete; of the fourth branch, softening about the posterior limb of the fissure of Sylvius, and if on the left side, sensory aphasia—defective perception of words—with corresponding impairment of speech.

*Posterior Cerebral.*—Plugging of this branch distributed to the occipital and temporosphenoidal lobes is a rare cause of softening. So far as ascertainable the phenomena are mostly sensory, including hemianesthesia from softening of the teg-

mentum of the crus, or of the internal capsule, or hemianopsia from softening of the cuneus, though the same symptoms may result from interruption of the optic tract when the cortex is intact. Complete but temporary loss of sight has resulted from plugging of one posterior cerebral artery.

*Basilar Artery.*—Total occlusion of this vessel may produce bilateral paralysis from involvement of both motor paths in the pons, with other symptoms of apoplexy of this center—viz., bulbar palsies, irregularity of heart and breathing, spasm, and rarely convulsions; the temperature may rise rapidly to 109° F. (42.6° C.) or thereabouts after an initial fall.

*Vertebral Artery.*—The left is more frequently plugged, rarely alone, along with the basilar. The nuclei of the medulla oblongata are affected, and we have symptoms of acute bulbar palsy.

*Cerebellar Arteries.*—Obstruction of the isolated cerebellar arteries is rare as compared with plugging of the parent trunk in the basilar. Even then the area of cerebral softening is limited, by reason of collateral anastomoses, and the symptoms may be obscured by those due to damage to the pons and medulla oblongata.

Inco-ordination of movement has been reported in one or two cases in which the region supplied by the posterior cerebellar was cut off. Occlusion of the posterior inferior cerebellar artery gives a distinct symptom-complex.

**Diagnosis.**—It has already been said that the chief difficulty lies in the differential diagnosis between cerebral hemorrhage, on the one hand, and embolism and thrombosis on the other. Sometimes, indeed, at first it is impossible. As to *embolism*, both it and hemorrhage are sudden. In embolism the patient is commonly younger, but not always so, and we look for valvular heart disease. According to Charles L. Dana, even in patients say between the ages of 30 and 50, when there is no heart disease, the chances are six to one in favor of hemorrhage. *An apoplectic seizure after parturition is likely to be embolic.* In embolism, too, there is less disturbance of temperature, the paralysis is more likely to precede the coma and convulsions if the latter are present; the turgid face, hard pulse, loud breathing, and greater general disturbance of a serious stroke of apoplexy from hemorrhage are wanting.

In *thrombosis* the difficulty in diagnosis may be even greater. The symptoms of thrombosis are slower in their development, but in the "in-gravescent" form of apoplexy, in which the hemorrhage is gradual, requiring sometimes a day or two, the development of symptoms is correspondingly slow. In thrombosis there are more frequently prodromata in the shape of slight seizures, quickly recovered from. Such events occurring in the aged, when there is evident atheroma of the blood-vessels and weak heart, point to thrombosis, in which, too, there is absence of stertorous breathing, of variations in temperature, and of pupillary disturbance. *Lesions in the pons and cerebellum* are more likely to be hemorrhages.

It is also important to be able to decide whether the obstruction is embolic or thrombotic. In the former the onset is sudden, without premonitory symptoms; in the latter it is gradual, and there are often premonitory symptoms. In embolism there may be convulsive twitchings, but hemiplegia quickly follows, with or without temporary loss of consciousness. In thrombosis the patient has previously complained of headache, vertigo, or tingling in the fingers; then paralysis may begin in one hand or foot and extend slowly, the hemiplegia often remaining partial. Speech may have been embarrassed for some days previous, and the memory defective. In thrombosis due to syphilis, especially, the hemiplegia may come on gradually without loss of consciousness. The same is true of the so-called senile softening, which is generally due to

thrombosis after atheroma of the cerebral arteries. In a few cases the onset is more sudden, and may happen during sleep. The temperature usually has a slight initial fall, followed by rise, as in hemorrhage. In embolism aphasia is quite a characteristic symptom, as it seems to occur more frequently on the left side than on the right.

In both embolism and thrombosis the hemiplegia tends to improve rapidly unless the vessel obstructed be a large one or there be rupture of a collateral branch. It is true that acute softening may terminate fatally within 24 hours, but usually the patient survives the onset, and at the worst dies after several weeks, the phenomena of the chronic stage being almost identical with those of that stage after hemorrhage. Spastic symptoms may also occur, and there is a tendency to the characteristic mobile spasm.

**Prognosis.**—A patient rarely dies of a first attack of cerebral embolism, unless a very large vessel is obstructed, such as the internal carotid or basilar, whose occlusion is fatal; next in seriousness after these is plugging of the middle cerebral and vertebral, while obstruction of the two vertebrals is always fatal. Every succeeding attack increases the danger. Embolism is less serious than thrombosis; and thrombosis due to syphilitic disease is more hopeful than senile softening. Sudden severity in thrombosis is serious, and deranged breathing is an unfavorable symptom. Convulsions may be a result of syphilitic thrombosis. When the embolism is due to valvular heart disease, the condition is likely to recur; when due to other causes, not. Thrombosis is prone to recur, especially when due to atheroma.

**Treatment.**—Neither thrombosis nor embolism demands blood-letting, as does hemorrhage. Indeed, it is strongly contraindicated. *Rest in bed*, with head raised, is important. If syphilis is the cause of thrombosis, it should receive the usual treatment—the iodid of potassium in ascending doses until doses of a dram or more are reached. There is no treatment for atheroma. Attention should be paid to the heart, kidneys, and bowels. The heart is commonly feeble, and digitalis and strophanthus are needed to keep its action uniform and strong, by which one condition of thrombosis is removed. The urine is scanty and highly colored, but the treatment for the heart is also the treatment for the scanty secretion, which calls also for diluents. The bowels should be kept freely open to aid in promoting the circulation. The latter is aided by nitroglycerin, which may be given in doses of 1/100 grain (0.0066 gm.) every two hours. The iodid of potassium is useful also for this purpose. Its effects are more permanent than those of nitroglycerin. From 5 to 15 grains of the iodid (0.33 to 0.99 gm.) should be given three times a day.

Moderate stimulation is beneficial. The aromatic spirit of ammonia and alcohol are the most useful for this purpose. Mental excitement is to be especially avoided after a return to consciousness, and physical rest should be continued. Stimulants are then best discontinued, or continued in great moderation. Care should be taken to protect against the effects of decubitus.

Unfortunately there is no treatment which will restore softened brain matter, although a certain amount of function may be vicariously

assumed. The same measures calculated to maintain nutrition and muscular integrity as are recommended in the treatment of hemorrhage should be taken.

### *B. Of the Cerebral Sinuses and Veins.*

**Description.**—Thrombosis occurs in the sinuses rather than veins and is *primary* or *secondary*. Primary thrombosis is the result of a state of the blood and circulation; secondary, a consequence of disease adjacent to the sinuses. The former is much the rarer, occurring half as often.

*Primary thrombosis* is met in the longitudinal sinus, more rarely in the lateral, sometimes in the cavernous. It is found associated with general malnutrition and prostration, more frequently in children during the first six months of life as the result of exhausting maladies, especially diarrhea. It is met also in older children. Brayton Ball and others have shown its association in young girls with chlorosis and anemia. It occurs in the aged also as the result of exhausting disease, like pulmonary tuberculosis and cancer.

Coagulation is favored by the trabeculae which cross the cavity of the sinus, and by irregularities in the shape and lining of the latter. It may or may not be associated with phlebitis.

Very little is known of primary thrombosis of the cerebral veins, except that it may occur in veins of the convexity as the result of meningitis, and from other causes that produce thrombosis of sinuses.

*Secondary thrombosis* occurs at any age, and is the result of disease adjacent to a sinus, commonly caries of bone, and is especially frequent as the result of disease of the internal ear. It spreads more frequently from the posterior wall of the middle ear, but also from the mastoid sinuses. Fracture, suppurative disease outside of the skull, especially erysipelas, and tumor compressing the sinus may produce it.

**Symptoms.**—There may be no symptoms in primary thrombosis, or there may be *nausea* and *vomiting*, *headache*, and *hebetude* increasing to *coma*. Dilatation of the pupils, choked disks, and paresis have been reported.

Secondary thrombosis is a septic process. It is commonly announced by a *chill*, followed by *fever* and *occipital pain*, succeeding on earache with suppurative otitis. The sinuses occluded are those near the ear, but the blood escapes by other channels, and the brain substance is not seriously invaded. The *symptoms of meningitis* are soon added. They are headache, somnolence, and stupor, or there may be active delirium and convulsions, rigidity, or optic neuritis, all the results of meningitis. Death is most frequently due to *suppurative pulmonary pyemia*, as was the case in 70 per cent. of Newton Pitt's cases, and the appearance of the latter disease under the circumstances is almost conclusive evidence of previous sinus thrombosis.

**Prognosis.**—This is always grave. The average duration of the secondary disease is about three weeks, and its termination is almost always fatal. Pitt reports a case of recovery in a boy of ten who had otorrhea for years, after removal by operation of a foul clot from the lateral sinus.

**Treatment.**—For primary thrombosis there is no treatment except that for its cause. For secondary, operative treatment is indicated by trephining or other measures to give exit to pus. Quinin and restorative measures are indicated. Gowers lays particular stress on the use of the tincture of the chlorid of iron.

### INTRACRANIAL ANEURYSM.

**Definition.**—Intracranial aneurysms are of two kinds, miliary and those of larger size. The former have been considered when treating of hemorrhage. The latter vary in size from that of a pea to a walnut.

**Distribution.**—Larger aneurysms affect the larger arteries at the base of the brain in the following order:

1. Middle cerebral.
2. Basilar.
3. Internal carotid.
4. Anterior cerebral.

The anterior or posterior communicating and vertebral arteries are also occasional seats; the posterior cerebral and inferior cerebellar rarely. William Osler found 12 of these aneurysms in 800 autopsies, and Newton Pitt 19 in 1900.

**Etiology.**—Intracranial aneurysms are found rather more frequently in the male sex, and most frequently between the ages of from 10 to 60. Osler and Pitt each found one at the age of six. Heredity exercises some influence. Endarteritis and embolism, both of which weaken the vessels are the chief causes. The former may be syphilitic or simple. The presence of endocarditis should especially invite examination for them at autopsies.

**Symptoms.**—*Death from apoplexy*, owing to rupture of the aneurysm, may be the first intimation. Not only are there often no symptoms, but when present they are vague. They may be those of tumor at the base of the brain, including optic neuritis and paralysis of the third and other cranial nerves. There are rarely *convulsions*. There may be *head-ache*, *vertigo*, *nausea*, *hebetude*, and even *coma*, *hemiplegia*, and *hemianopsia*. A *murmur* may be heard on auscultating the skull, while occasionally the patient himself is conscious of a murmur or recognizes the pulsations in his head.

**Diagnosis.**—This is usually impossible, but the foregoing symptoms, associated with endarteritis, may excite suspicion. *Syphilitic disease* being as likely to produce tumor, the history of its presence gives no assistance in diagnosis.

**Treatment.**—None exists which can be specifically directed to the disease.

### THE CEREBRAL PALSIES OF CHILDREN.

**Definition.**—Referring to the division already made of the motor path into an upper cortico-spinal segment, extending from the cells of the cortex to the gray matter of the cord, and a lower spino-muscular,

extending from the ganglia of the anterior horns to the motorial end-plates, the diseases now to be considered have their anatomical seat in the former, and are characterized by paralysis, with spasm or disordered movements, exaggerated reflexes, normal electrical reactions, without rapid or extreme wasting. They result from a destructive lesion of the motor centers, or of the pyramidal tract in the hemisphere, internal capsule, crus, or pons. They are hemiplegic, diplegic, or paraplegic.

#### SPASTIC INFANTILE HEMIPLEGIA.

SYNONYMS.—*Hemiplegia spastica cerebialis* (Heine); *Hemiplegia spastica infantilis* (Bernhardt); *Acute Encephalitis der Kinder* (Strümpell); *Die atrophische Cerebrallähmung* (Henoch); *Agénèse cérébrale* (Cazauvielh); *Sclérose cérébrale atrophie partielle* (other French writers).

Hemiplegia in infants and children with spastic symptoms.

**Historical.**—In 1884 Strümpell, in a paper, "Ueber die acute Encephalitis der Kinder," called attention to the possibility of encephalitis in children. Numerous papers on infantile hemiplegia have appeared in Germany, France, and America, among which may be especially mentioned those of Gaudard, Wallenberg, Jules Simon, Morse, Ross, Gowers, Sarah J. McNutt, Weir Mitchell, B. Sachs, Wharton Sinkler, H. C. Wood, J. Lewis Smith, and William Osler.

**Distribution.**—The disease is somewhat more common in girls than in boys, 63 out of 120 cases studied by Osler at the Nervous Infirmary in Philadelphia being of this sex. Of these cases 15 were congenital, 45 arose in the first year, 22 in the second, 14 in the third, one in the fourth, three in the fifth, sixth, and seventh, one in the eighth, ninth, tenth, and older. In ten the age of onset was not given. The hemiplegia was right-sided in 68 and left-sided in 52 cases.

**Etiology.**—Among the causes may be mentioned abnormal conditions of the mother during pregnancy, including accidents, possibly disease, especially syphilis, in a few cases fright or distress, the effect of the last two being doubtful. Especially frequent causes are difficult or abnormal labor, injury with forceps producing depressions and fractures of the cranial bones during delivery. After birth are penetrating wounds of the head, ligation of the common carotid, and infectious diseases, including whooping-cough, diphtheria, scarlet-fever, measles, meningitis, typhoid fever, vaccinia, and mumps. Previous convulsions may cause the lesion on which the paralysis depends, and in a few cases embolism may be responsible.

**Morbid Anatomy.**—The morbid states of the brain found at autopsy are mainly *sclerosis* and *porencephalia*, the latter a defect consisting in arrest of development of the brain resulting in the absence of convolutions or even lobes, causing irregular subpial cavities. *Embolism* and *thrombosis* of vessels, especially of the Sylvian artery, and *hemorrhage* into the ventricle and substance of the brain, have been found in a few cases. The sclerosis involves either groups of convolutions, an entire lobe, or even an entire hemisphere. The *skull* may be flattened on the affected side, broad and prominent above the mastoid processes, sometimes thickened. The *dura* may be thickened and adherent and in one case contained extensive osseous plates; the *arachnoid* turbid and thickened and the amount

of cerebrospinal fluid increased. The *pia mater* may be thickened and adherent, and drag portions of the cortex away on being removed, leaving a roughened surface, while there may be nodular projections of sclerosed tissue. The *reduction of weight* of the sclerosed hemisphere may be very considerable; in one case, referred to by Osler in his monograph, the atrophied hemisphere weighed 5 1/2 ounces (169 gm.), the normal being 20 ounces (653 gm.). The lateral *ventricle* may be greatly *dilated*, and the brain tissue over it very thin, while *cysts* have been found in the sclerosed areas—the remnants of old hemorrhages. The Rolandic area is that most frequently involved.

In 90 cases studied by Osler the lesions in 50 were atrophy and sclerosis, in 24 porencephalia, and in 16 embolism, thrombosis, or hemorrhage.

**Symptoms.**—The symptoms are complex and varied, but may be divided into three classes: those of the *onset*, those pertaining to the *paralysis*, and the *residual* symptoms.

The most important symptoms of the onset are *convulsions* and *coma*, although the hemiplegia may come on suddenly, without spasm or loss of consciousness, in children apparently healthy. In the majority of cases, however, the disease begins with convulsions, partial or general. Loss of consciousness almost always accompanies the convulsions, and may last from a few hours to many days. Rarely coma occurs without convulsions. Among other symptoms may be mentioned *fever*, transient or persistent; according to Strümpell and Guadard, it is an invariable accompaniment of the convulsions. *Delirium* is a common symptom, as is also *soreness* of the general surface. *Vomiting* and *screaming spells* are also noticed.

The *hemiplegia*, which is noticed as soon as the child recovers consciousness, is usually complete. Less commonly there is first, *paresis*, which gradually extends to complete loss of power; and in some instances a total *paralysis* is established after repeated convulsions. The *face* is not always involved, and, as a rule, in facial paralysis of cerebral origin the superior muscles are intact, and the child can close the eyes and elevate the brows. The facial palsy usually disappears rapidly and completely.

As to residual symptoms, the *residual paralysis is most marked in the arm*, which is subject to slow wasting, and is commonly useless for the ordinary purposes of life. The *atrophy is moderate*, but there may be arrested development, leaving a wasted and withered member. In extreme cases the arm is held close to the side, the forearm strongly flexed at right angles and in a semiprone position, the hand flexed and the fingers contracted, the palm usually embracing the thumb. Motion may be almost lost in the arm and completely in the fingers, though in most cases there is considerable power of movement, the patient being able to lift the arm above the head, while flexion and extension can be made at the elbow and wrist. The finger and more delicate movements of the hand are rarely recovered. The *leg*, as a rule, *recovers more rapidly* and completely than the arm, and the palsy may disappear entirely in it, while it rarely does in the upper extremity. In the leg the wasting is also less pronounced, while arrested development is also less frequent. A persistent halt is apt to remain—indeed, almost always does—as evidence of impaired power; this may consist in simply favoring the affected side, noticeable only on rapid walking. A

decided dragging of the limb is, however, more usual, and there may be tremor of the leg while moving.

The frequency with which *rigidity* is present has given rise to one of the names of the disease, *spastic infantile hemiplegia*. It is not, however, an invariable symptom, and the paralyzed limbs may be relaxed a long time after paralysis sets in. When rigidity is present, it is lessened during sleep, and is increased by emotion and forcible attempts to overcome the spasm. Contracture may ultimately result, after which relaxation is no longer possible. A form of rigidity without much paralysis is known as *postapoplectic hemi-hypertonia*, and has been previously referred to.

The *reflexes* are almost always *increased* in the affected limbs, ankle clonus being often obtainable in addition to exaggerated knee-jerk. The reflexes may even be increased on the sound side. Rectus clonus and clonus of the flexors of the fingers are rarely present, while in a very few cases the reflexes are absent.

*Sensation* is rarely affected, but vasomotor derangements are sometimes present. *Electrical reactions* are *normal*, as a rule.

Posthemiplegic *chorea*—*hemiataxia*—is not infrequent. More uncommon are *mobile spasm* and *athetosis* and posthemiplegic *tremor*. These interesting symptoms were first described by S. Weir Mitchell and Hammond in a study of cases of cerebral palsy.

*Aphasia* is present in a majority of cases almost invariably transitory, associated most commonly with right hemiplegia, very rarely with left.

*Defects of intelligence* are very common, the degree of feeble-mindedness ranging from low-grade imbecility to total idiocy. Psychoses may occur late in life, even when there have been no defects in childhood.

*Epilepsy* is very frequent, and is sometimes confined to the paralyzed side, but also tends to become general. The attacks usually begin within two or three years, sometimes within a few weeks, after the onset of the hemiplegia, but may be delayed from eight to ten years, or even longer. The seizures may present *three well-defined degrees*—the first, in which the child is simply dazed for a moment or two, or longer, without any motor involvement; second, Jacksonian epilepsy, without loss of consciousness, in which the spasms are confined to the affected side,<sup>1</sup> and third, general convulsions, beginning in the paralyzed limbs, and usually accompanied by loss of consciousness. The Jacksonian epilepsy is most common, but all forms may occur in any one case.

**Diagnosis.**—Infantile *spinal* paralysis (anterior poliomyelitis), most frequently must be excluded, usually without difficulty. The history of the case, including the presence of some of the causes named, the frequent onset with convulsions, the hemiplegia, the absence of rapid wasting of the affected muscles, the retained electrical reactions, are characteristic of infantile cerebral hemiplegia in its early stages; while rigidity of muscles, increased reflexes, the peculiar gait, and residual palsy, with mental imbecility and epileptic seizures, distinguish the later stage.

*Tumor of the brain* sometimes produces similar symptoms. Tubercu-

<sup>1</sup> Jacksonian epilepsy is usually without loss of consciousness, unless the convulsions are very severe or involve a large portion of the body.

losis and glioma are the forms most common in children. *Pressure paralysis* by obstetrical forceps affects the face and upper extremities, but other symptoms are wanting, and it is scarcely likely to be confounded with infantile hemiplegia.

**Prognosis and Treatment.**—The prognosis is favorable so far as life and the recovery of considerable locomotive power are concerned; unfavorable as to recovery from mental defect and epilepsy. An institution for feeble-minded children, in which the subjects have the benefit of training and watching, is the safest permanent home for them.

#### BILATERAL INFANTILE SPASTIC HEMIPLEGIA.

**SYNONYMS.**—*Spastic Rigidity of the New-born* (Little); *Tonic Contraction of extremities*; *Essential Contractions*; *Permanentes Kinder-Tetanus* (Stromeyer); *Spastic Diplegia*; *Spastic Paralysis of Children* (Adams); *Spastic Diplegia* (Gee); *Spasme Musculaire Idiopathique* (Delpech); *Birth Palsies* (Gowers); *Little's Disease*.

**Definition.**—Double hemiplegia in infants and children with spastic symptoms.

**Historical.**—Delpech was probably the first to describe the disease fairly correctly. To the German orthopedic surgeon, Heine, belongs the credit of first appreciating these conditions and their cerebral origin and separating them from common infantile paralysis. His paper was written in 1860. Little's paper, published two years later in England, so attracted attention that his name became applied to the disorder. Stromeyer, Adams, and Rupprecht have furnished careful accounts.

**Etiology.**—Most cases of bilateral hemiplegia in children date from birth, and are the result of *injury during birth*. The infectious fevers are responsible for a certain number, and a few are direct results of convulsions. In a word, the causes are those of infantile hemiplegia. J. H. W. Rhein<sup>1</sup> reports a case of spastic diplegia following pertussis.

**Morbid Anatomy.**—As may be inferred from the name, the lesions are bilateral and involve motor areas of the cortex almost solely. They consist in *sclerosis* or *porencephalous* defect, of which the most frequent primary cause is compression by a blood-clot due to meningeal hemorrhage from the veins or longitudinal sinus. A meningo-encephalitis may, however, be responsible for the sclerosis.

Descending degeneration of the pyramidal tracts or imperfect development of these tracts has been found in a few cases.

**Symptoms.**—These are to be distinguished from those of the next form, cerebral spastic paraplegia, which the disease closely resembles when the arms are so slightly affected that the palsy is scarcely appreciable. The cerebral spastic paraplegia of childhood is due to lesions similar to those of the bilateral spastic hemiplegia. In the diplegic state *all the extremities* must be more or less *spastic*, although the legs almost always are more so than the arms. These cases are further characterized, as are those of spastic paraplegia, by their occurrence *at or very soon after birth*.

<sup>1</sup> Rhein, J. H. W. "Spastic Diplegia Following Pertussis," "Journal of Amer. Med. Assoc.," March 4, 1905.

There may be *convulsions* or a prolonged succession of convulsions immediately after birth. After this or without it there may be noticed a *limpness* or flaccidity of *muscles*, an expression of *paresis*, often overlooked, because present at a time when the muscular development of the child is so slight that little is expected of it. Soon, however, the *inability to hold up its head* may be observed, and when the time comes for it to walk, it is noticed that the limbs are clumsily used, and when examined, they are found to be *stiff*. As the child grows older it slowly acquires some power so as to be able to sit, but the *legs* are *crossed* and the head is not well supported by the neck muscles. If it is held up, the legs are extended and strongly adducted, and crossed with the feet in the pes equinus or equinovarus position. Occasionally the legs are partially *flexed*, while stiffness varies greatly, involving, in extreme cases, the whole body, sometimes one side more than the other. It is sometimes constant, at other times not. It may be greater on one side than another. The *arms* are usually *stiff* in flexion.

To the spastic symptoms described are added, in certain cases, *spasm* and certain movements known as *athetoid*. In the former, in an attempt at voluntary movement, as taking hold of an object, the fingers are thrown out in a stiff, spasmodic, or irregular manner, or there may be constant irregular movements of arms and shoulders, movements which are usually characterized as choreic. In fact, such cases have been named *chorea spastica*, being differentiated from the congenital choreas by the spastic feature. Spasm rarely affects the muscles of the face, though it does occasionally, causing a continual *grimacing*, which does not always disappear during sleep.<sup>1</sup>

The *athetosis* is double or bilateral, resulting in the most grotesque and distorted movements. They consist in a constant flexion and extension of muscles, more particularly of those of the fingers of one hand and forearm. Flexion of the fingers of one hand may take place, while those of the other may be extending, and the same may be true of different fingers of the same hand. The shoulder and trunk muscles may be also affected, producing a rhythmical and orderly twisting and bending of the body; or those of the neck, producing a turning of the head from side to side. These movements are all increased under excitement or with the effort to do anything.

*Mental defect*, consisting in imbecility and various grades of idiocy, is more or less characteristic of these cases, but is commonly less than in infantile hemiplegia.

The form resulting from premature birth should be distinguished from that caused by injuries at birth, or by lesions acquired later, as in the former convulsions and athetoid movements do not usually occur, mentality may not be affected, and improvement may be slowly progressive even after many years.

<sup>1</sup> Athetosis was first thoroughly studied by W. A. Hammond in 1871, also by Charcot, who considered it identical with posthemiplegic chorea or a modified form of it. This is probably correct in cases when there has been hemiplegia, and athetosis occurs in the muscles of the side which was hemiplegic. It occurs in connection with hemiplegic weakness and contraction due to tumor of the brain. Frequently it is seen as a sequel of infantile palsy. Epileptics, idiots, and alcoholics also, exhibit it in the bilateral form. Rarely it is an independent affection, said to be the result of cold or psychical derangement, and is even held to be congenital.

## INFANTILE SPASTIC PARAPLEGIA.

SYNONYMS.—*Paraplegia cerebralis spastica* (Heine); *Tetanoid Pseudoparaplegia* (Seguin); *Spastic Spinal Paralysis* (Erb); *Tabes dorsalis spasmodique* (Charcot).

**Definition.**—Spastic paralysis of the legs in infants and children.

**Historical.**—A common affection of children, though only recently understood, it was fully described and correctly named by Heine in 1849. Delpech and Stromeyer in Germany and Adams and Little in England also described it. Erb and Seeligmüller in Germany and Gee in England brought the subject to the notice of physicians, and Erb contrasted it with the spastic paraplegia of adults. Ross, Hadden, Gowers, d'Heilly, Gilbert, and Osler have treated the subject as one of the cerebral palsies of children. It must be distinguished from the spastic paralysis occurring in adults and found in a very few cases to be due to primary degeneration of the pyramidal tracts.

**Etiology.**—The causes are those of spastic diplegia and infantile hemiplegia, and also premature birth, the child being born at a period when the central motor tracts are very imperfectly developed; premature birth causes an arrest in the development of these tracts.

**Morbid Anatomy.**—This is less known than the morbid anatomy of the other forms of cerebral palsy. It may be due to cerebral lesion involving especially the centers for the lower limbs, to imperfect development of the motor tracts, or to other causes. A few cases with necropsy are recorded.

**Symptoms.**—These are almost *identical* with those already described as belonging to the *spastic paraplegia of adults*, with which the earlier writer classed it. Spastic paralysis of the lower extremities, dating from birth or appearing within the first few years of life, with talipes equinus or equinovarus, adductor spasm, rigid stiff gait, the patient walking on his toes or by crossed-legged progression—*all without wasting*—these are, in a word, the symptoms. The order of sequence of events is very similar to that described under spastic diplegia. In attempting to walk the heels are everted and knees approximated, because of spasm of the adductors, which may be so strong as to make it impossible to separate the thighs. The spastically extended legs may, however, be gradually forced into flexion after the manner of the “lead-pipe” contraction. If, however, the attempt be made to extend the leg, the spasm returns. If the extension be gradually insisted upon, it often happens that when the extension is nearly complete, the spasm suddenly completes it, as the spring acts on the blade of a pocket-knife, whence the name “clasp-knife” rigidity.

*Mental imbecility* is not so serious as in spastic diplegia or even as in infantile hemiplegia, and may be entirely absent, especially in those cases resulting from premature birth.

**Diagnosis.**—The distinction between *spastic diplegia* and *paraplegia* is not a very important one. The two conditions are probably the results of different degrees of similar lesions having different locations. There is an affection of children known as *pseudoparalytic rigidity*, idiopathic contraction with rigidity, or tonic contraction of the extremities, with which it is sometimes confounded, but the following table of differences from Osler's monograph will aid in separating the two conditions.

## PSEUDOPARALYTIC RIGIDITY.

Follows a prolonged illness. Is often associated with rickets, laryngismus stridulus, and the so-called hydrocephaloid state.

Begins in hands and feet as carpopedal spasm; often confined to hands and arms.

Spasms painful and attempts at extension cause pain.

Intermittent and of transient duration.

## SPASTIC PARALYSIS; DIPLEGIA AND PARAPLEGIA.

Usually exists from birth. History of difficult labor [or of premature labor], of asphyxia neonatorum, or of convulsions.

Arms rarely involved without legs and not in so marked a degree.

Usually painless.

Variable in intensity, but continuous.

The spasm in the pseudo cases is altogether more severe and difficult to overcome. The disease is associated with rickets and other constitutional diseases.

*Tetany* is characterized by a different history and causation. Bilateral rigidity may also be produced by *tumors* of the pons and cerebellum.

**Treatment.**—The treatment varies with the stage existing at the time the physician is called. If in the stage of initial convulsion, there is no remedy like chloral, which should be given in doses sufficient to control the fits. In the mild degrees, or with a view to keeping up an effect first obtained by chloral, the bromids may be used. If chloral fails, chloroform may be inhaled.

In established paralysis medicines do not avail much and recoveries are rare. Hygiene and good food, gymnastics, manipulation, massage, passive motion, and surgical appliances may be used. Baths and electricity should not be forgotten.

The epileptic convulsions should be treated as when occurring under other conditions, though the cortical lesions occasioning the disease preclude any expectation of permanent relief. Operative procedure has been suggested in certain selected cases and carried out, but with results which have been disappointing.

The mental deficiencies are best treated in an institution for feeble minded children, where all such cases should be taken, whatever the circumstances of the parents.

## HERPES ZOSTER.

**SYNONYMS.**—*Acute hemorrhagic inflammation of the dorsal root ganglia; zona; cingulum; ignis saccr; zoster; shingles.*

**Definition.**—Herpes zoster, as shown by the studies of Head and Campbell, is an acute inflammation of the posterior ganglia of the spinal nerve-roots associated with extravasations of blood and destruction of the ganglion cells and their axis cylinder processes.

**Etiology.**—There is usually a specific cause. In some cases there is a prodromal period of illness and neuralgic pain, on the third or fourth day of which the eruption makes its appearance. Atmospheric influences, such as severe cold and dampness, may act as causes. So may checking of profuse perspiration and mechanical violence producing injury to nerves, all favored by lowered resisting power due to mental and physical fatigue. Arsenic

has been regarded as a cause and this belief has the support of such an authority as Jonathan Hutchinson.

**Symptoms.**—The chief symptom is a painful vesicular eruption, along the course of the afferent spinal nerves, covering their respective skin fields and is therefore correspondingly irregular. It is, as a rule, confined to one side of the body, though in rare instances, especially about the head, it invades both sides. According to the locality, it is called *zoster capitis*, *z. faciei*, *z. orbicularis*, *z. nuchæ*, *z. brachialis*, *z. pectoralis*, *z. abdominalis*, and *z. femoralis*, and in these different varieties corresponding ganglia are involved; the Gasserian ganglion in *zoster* of the face, the otic ganglion in *z. orbicularis* which may be complicated with transient paralysis and sometimes severe auditory and visual symptoms. On the head it may invade the scalp as well as the forehead, appearing in the course of the supraorbital nerve and upward over the scalp. The circular involvement of the chest, *zoster pectoralis*, whence the name *herpes zoster*, is rarely complete, indeed seldom embraces half the circumference.

Everywhere there is the same severe burning pain in the seat of the eruption which is seated on an angry red surface. While rupture of the vesicles is infrequent, their contents may sometimes become purulent and result in chronic ulceration. There may be an extension of the process from the posterior ganglia to the adjacent meninges, causing pains down the spine, girdle pains, and exaggerated knee-jerks with leukocytosis.

It is met in both sexes, in children as well as adults. In the case of persons past middle life, the disease is often very exhausting, being sometimes the beginning of a decline in health which is permanent. Among the sequelæ is a most inveterate form of neuralgia.

**Prognosis.**—The prognosis is most favorable in children, and in ordinary circumstances ten days to three weeks suffice to cover its duration, although it may be prolonged much beyond this period. Subjects rarely have more than one attack, although Dühring refers to a case of Kaposi which had nine relapses all on the right side of the body but not in exactly the same region. The disease commonly runs an acute course, terminating spontaneously in recovery except in those rare cases followed by neuralgia.

**Treatment**—This appears to be without effect in cutting short the disease and is commonly limited to soothing local applications. The pain is often so severe as to require the hypodermic injection of morphine. Morphine may be employed locally in the shape of a dusting powder. Solutions of carbolic acid ten to 15 grains to an ounce of water (0.3–0.5 gm. to 30 c.c.), may be used locally, and it is generally comforting to have the parts protected from the atmosphere by a light covering. Dusting with stearate of zinc is a soothing treatment.

## GENERAL OR LOCALIZED HYPOTONIA OF THE MUSCLES IN CHILDHOOD.

SYNONYMS.—*Myatonia Congenita*; *Congenital Myohypotonia*.

**Definition.**—A congenital affection consisting in atrophy with corresponding weakness of muscles (hypotonia and atonia), especially of the extremities and more of the lower; associated with loss more or less complete of the tendon reflexes. In advanced cases the weakness resembles paralysis, but closer observation discovers feeble contractions in the muscles but not sufficient to move the limbs. The muscles of the trunk and the neck are most rarely affected, while those of the eye, tongue and throat escape, as does the diaphragm, while the intercostal muscles may be invaded. The electrical reaction is affected proportionately to the myatonia. Intelligence and sensation are undisturbed. Neither hereditation nor family tendency seem to play any part. Although always congenital the symptoms are not always noticed immediately after birth. Oppenheim who was the first to investigate it believes the morbid change is in the muscles which are arrested in their development, and thinks it has no relation to *muscular dystrophy*. He admits the possibility of disease in the cells of the anterior horns of the cord whence it is, however, distinct, the latter developing acutely in a previously normal child.

Congenital myatonia differs from *progressive muscular dystrophy* especially in the absence of family tendency, in being congenital, and in the absence of progressive increase in the symptoms; from *amaurotic family idiocy* in that in the latter the symptoms increase and the ophthalmological changes are pathognomonic. It occurs in more than one member of a family.

No case came to necropsy until one described by Spiller<sup>1</sup> in 1905 in which, however, no changes in the nervous system were found, but the muscles were wasted, in places almost absent, while a large amount of fatty connective tissue was present with increase of its nuclei. The muscles presented also in places a hyaloid appearance. Postmortem rigidity was delayed. The microscopic examination showed arrest of development of the muscular fibers, but no change in the central nervous system or peripheral nerves. A still later necropsy seemed to show in that case some alteration of the nerve cells of the spinal cord.

Improvement has been observed in some instances.

## MULTIPLE SCLEROSIS OF THE BRAIN AND SPINAL CORD.

SYNONYMS.—*Insular Sclerosis*; *Disseminated Nodular Sclerosis*; *Sclérose en plaques*.

**Definition.**—A chronic affection of the brain and spinal cord, consisting in the presence of numerous sclerotic patches scattered through the nerve centers, characterized especially by intention tremor, scanning speech, and nystagmus.

<sup>1</sup> Contributions from the Laboratory of Neuropathology, University of Pennsylvania, for the year 1905

**Etiology.**—Its precise cause is unknown. The infectious diseases, especially scarlet fever, are alleged causes; so are cold, exposure, mental emotion, and syphilis, but without definite foundation. Hereditary predisposition has been noticed. The disease is more common between the ages of 18 and 35, though Strümpell met a case which came to autopsy at 60. Both sexes are equally subject. Prichard states that more than 50 cases have been reported in children, but it is doubtful whether the diagnosis was invariably correct. It has been thought that the disease depends on anomalies of the vessels, but this view is not held by all.

**Morbid Anatomy.**—The sclerosed patches are widely scattered through the brain and cord, rarely in the cord alone. They may generally be recognized by their gray color and unnatural firmness. On section, they appear as grayish-red areas. Histologically they consist of thickened neuroglia traversed by a few healthy nerve-fibers. In the vessels there is an increase of the nuclei and, later, a thickening of the walls. Fatty granular cells are present in fresh cases. Many of the axis-cylinders are preserved in the sclerotic patches for quite a long time after destruction of the medullary sheaths. The favorite seats of the plaques in the brain are the centrum ovale, the walls of the lateral ventricles, the corpus callosum, and the cerebellum; while they are quite numerous in the pons, less so in the medulla oblongata, but numerous in the cord, especially the white substance. The brain cortex is not often invaded.

**Symptoms.**—By no means every case of multiple sclerosis can be recognized, so often are the symptoms united with those of other lesions whose effects predominate, while the slowness of the onset necessitates delay in the recognition of even typical cases. Typical cases do, however, occur, and they present a set of symptoms whence their recognition is more or less easy.

One of the most important of these symptoms is *tremor*, known as "*intention tremor*," because associated with any voluntary effort to perform an act, as picking up an object, raising a glass of water to the lips, or apposing the ends of the fingers of the two hands. This does not prevent the ultimate attainment of purpose. When the patient is quiet, the tremor ceases, and in this respect it can be differentiated from the trembling of paralysis agitans. It is not confined to the arms, but occurs also in the head and trunk, so that the head trembles when it is raised from the pillow. It is increased by excitement.

Another characteristic symptom is what is known as *scanning speech*, a slow, measured, yet indistinct and obscure utterance, depending upon disturbances in the innervation of the tongue and larynx, probably due to the presence of sclerotic patches in the pons and medulla oblongata. There may be tremor in the tongue and lips when speaking. The third symptom is *nystagmus*—oscillatory or lateral movements of the eyeball when the eyes are directed to an object. In addition there may be *spastic symptoms* manifested chiefly in the presence of *increased reflexes*—including periosteal as well as tendon reflexes—in both upper and lower extremities, but the skin reflexes remain normal. There is ankle clonus, and the gait is often spastic. *Parosis*, at first absent, ultimately appears, amounting at times to complete *paralysis*. Indeed, spastic rigidity and paresis may be among the earliest signs of the disease. The sphincters remain intact, at least until toward the

close. There are *no disturbances of sensibility* in the majority of cases. *Optic atrophy* is present in 40 per cent. of cases and in 15 per cent. in *tabes dorsalis*, and associated with such *derangements of vision* as amblyopia, achromatopsia, and even blindness. *Optic neuritis* may occur with subsequent atrophy, especially in the temporal halves of the optic nerve. There may be also derangements of innervation with diplopia.

*Mental weakness* and *imbecility* are sometimes present, more rarely *melancholia* or *exaltation*. *Apoplectiform* attacks also occur, following prodromal symptoms, such as *vertigo* and *headache*, and succeeded by hemiplegia, which, however, subsequently disappears.

**Diagnosis.**—This is not difficult in typical cases. The intention tremor, the scanning speech, and nystagmus are characteristic, and when associated with spastic weakness, the diagnosis of multiple sclerosis is probably correct. The apoplectiform seizures and mental weakness are also valuable signs. When the symptoms are mixed with those of other nervous lesions, diagnosis is not so easy. In *paralysis agitans* tremor occurs during rest as well as motion; in multiple sclerosis only when motion is attempted. Strümpell says: "The circumstance, indeed, that the anomalous cases will not properly fit the molds of any other form of disease should make us think of the possibility of multiple sclerosis."

The disease known as *pseudo sclérose en plaques*, described by Westphal, seems to have most of the symptoms of multiple sclerosis except nystagmus. The tremor movements are said to be more violent. Strümpell has found slight degeneration of the pyramidal tracts in a few cases of this kind. It is probably a diffuse sclerosis which is not always easy to detect with the microscope, but may be sufficient to cause a peculiar hardness of the brain and cord before they have been put in any hardening fluid.

**Prognosis.**—This is unfavorable after a long and tedious course, terminating in the bedridden state.

**Treatment.**—This is unavailing. The end possibly may be delayed by galvanism and tepid bathing.

## PARETIC DEMENTIA.

**SYNONYMS.**—*Chronic Diffuse Meningo-encephalitis; Dementia Paralytica; General Paresis; Progressive General Paralysis of the Insane.*

**Definition.**—A chronic progressive meningo-encephalitis, or meningo-rachitis, with resulting mental and motor derangements, terminating in dementia and paralysis.

**Historical.**—Boyle in 1822 and Calmeil in 1826, by their descriptions, first separated paralytic dementia from other diseases which run a like course. The minute anatomical changes causing the symptoms are a matter of comparatively modern study.

**Etiology.**—At least 75 per cent. of all cases are caused by syphilitic infection, and observations reported by Krafft-Ebing seem to indicate that the proportion is much greater. Starting out with this assumption, we have at once an explanation of its greater frequency in the male sex, though

many women have it; while it is rather a sad commentary on the fidelity of man that it is much more frequent among married men. It is possible, however, that syphilis was contracted before marriage, as the development of parietic dementia may be delayed for a number of years after a syphilitic infection. The fact that it occurs most frequently between the thirtieth and fiftieth years, that it is a disease of the better classes—especially army officers and artists—and that it is pre-eminently a disease of the cities, should be added. Although other factors apparently enter into the causation of general paresis, those who have most closely studied the subject are disposed to assign to them a predisposing rôle. Such influences are heredity and exhausting mental work, such as comes of public political life and ambitious financial ventures. Intemperance, chronic lead-poisoning, and traumatism are included among causes.

**Morbid Anatomy.**—An *atrophy* of the brain, and especially of the frontal lobes, may be set down as the most important morbid change. The convolutions are wasted and pale in color, the fissures are wider, and the weight of this portion is reduced to one-fourth or one-third the normal, while the consistence is firmer and more resisting to section. Other macroscopic changes are a *thickening of the dura mater*, *pachymeningitis interna*, *edema* of the pia with thickening, opacity, and adhesion to the cortex. Minute examination of the cortex recognizes *thickening of the vessel-walls* and cellular infiltration of the adventitia of the arterioles and lymphatic sheaths—in other words, the effects of mild inflammation. To these are added demonstrable *destruction of nerve elements*, especially of the fine medullary nerve fibrils known as “tangential fibers” in the frontal convolutions, island of Reil, and elsewhere; also *atrophy of the ganglion cells*. Associated with this are neuroglia proliferation and numerous Deiters’ spider cells. Here enters a contested question as to whether the nerve changes are primary, or secondary to an interstitial encephalitis. Tuczek, Wernicke, and Strümpell hold to the former view; while Rindfleisch and Mendel adopt the latter, making the destruction of nervous tissue secondary to the overgrowth of neuroglia.

The white matter is also involved, the central ganglia as well. Coincident *changes in the spinal cord*—first described by Westphal—consisting in fascicular systemic degeneration of the *lateral columns* and *posterior columns*, either alone or jointly, are quite constantly present. To these is ascribed a large part of the ataxic and spasto-paralytic symptoms. From this brief statement of the character and situation of the morbid changes it will be seen that they are widespread, while they are also degenerative.

**Symptoms.**—So widely scattered a distribution of morbid changes naturally brings about corresponding differences in the variety and severity of the symptoms. As further characteristic, no absolute constancy is observed in the order of their development. As a rule, however, the *first stage* is characterized by abnormal mental processes, and these are at first what may be comprehended under the single expression *peculiarity* or “*queerness*” of conduct. The patient will perform acts wholly unnatural to him, and will surprise his friends and family by breaches of decorum and morality. An *apathy* and *loss of memory*, causing the omission of obligations, are also constant. At first these may pass unnoticed as temporary, but their per-

manence is gradually established. In lieu of this may be present an *irritability* and intense *restlessness*, so that the patient cannot remain in one spot, but walks constantly to and fro. Not often in this stage is there much volubility, but rather a *morose silence* is observed. In this stage, too, the patient may make rash and ruinous financial ventures, and lose his own money and that of his friends, or he may become very generous, giving away freely all he possesses, and more, too. The power of arithmetical calculation is defective or gone. He may be self-satisfied and intensely egotistical. On the other hand, he may be conscious of these ills and be anxious about them, as well as experience a discomfort or malaise, for which he may consult the physician.

Nor are *motor disturbances* wholly wanting in the first stage. They are chiefly *derangements of speech and handwriting*, and are of no small diagnostic value. The speech is slow and hesitating, yet the patient stumbles over syllables, especially when the word is complex or rather difficult to enunciate. As to the handwriting, it is tremulous, characterized by the omission of letters and substitution of wrong ones, as well as erroneous spelling—all motor defects.

*Other symptoms* of the first stage are *inequality of the pupils, ocular paralysis*, in tabetic cases often reflex immobility of the pupils. There may be absence of the patellar reflexes, and in spastic cases increase of reflexes. There may be *neuralgic pain* and attacks of *migraine*.

The *second stage* is characterized by more *exalted mental symptoms* and excitement, with a *higher degree of motor disturbance*. The former consist in exaggeration of all previously maintained mental symptoms, amounting to noisy, boisterous, and maniacal excitement, and even uncontrollable violence. In this stage belong, too, those extraordinary delusions of grandeur—expansive delirium—in which the patient imagines himself or herself to be a person of great consequence and unlimited wealth. This is not, however, invariable, and there may be an exaggerated degree of the opposite condition of melancholy sometimes present in the first stage, or the two conditions of delirium and depression may alternate or may be absent. *Sleeplessness* may be added to restlessness and mental excitement, causing rapid decline of strength.

*Motor disturbances* are greatly increased in this stage, but a uniform order of invasion is by no means always observed, while remissions and temporary improvement are often noticed. *Speech* becomes almost impossible and incomprehensible. There is *paraphasia*—persistent repetition of words—and reading and writing are impossible. The voice can no longer be modulated, and is weak and rough from imperfect innervation of the vocal cords.

The *gait* becomes defective, and the patient often trips in walking. There may be *ataxia* and other tabetic symptoms; apoplectic seizures with *paralysis*; or *epilepsy* with grand or petit mal and aura, sometimes one-sided and followed by monoplegia or hemiplegia. There may be loss of *sensibility*, with *bladder and rectum paralysis*. The *tendon reflexes* may be lost and the pupil be immobile, or the opposite condition of spasm with increased tendon reflexes prevails. The paralytic attacks may occur in the earlier stages, though in mild degree, manifested by vertigo or obscuratio and loss of

consciousness, lasting for a short time and then passing away. There may be local twitching in the face and extremities and even typical Jacksonian epilepsy. Finally, *bulbar* symptoms may appear with invasion of the medulla oblongata. Ultimately, the patient becomes helpless, bedridden, and completely demented, dying from exhaustion or intercurrent disease. In a few cases none of the mental symptoms described are present, but a gradual decline of mental power takes place until complete dementia supervenes.

An *acute variety* is also sometimes met, properly termed "galloping," in which the disease runs its whole course in a few months, and is especially characterized by emaciation and rapid loss of strength due to restlessness, sleeplessness, and insufficient food. The *pulse* and *temperature* are essentially normal, or at least there are not characteristic variations.

**Diagnosis.**—To recognize paretic dementia *ab initio* is perhaps impossible, but to watchful observation the disease commonly reveals itself after the symptoms have existed for a short time. The early symptoms resemble those of *neurasthenia*, but differ from those of the latter disease in their steady progression. Other affections possibly mistaken for it are *cerebral syphilis*, *tumors of the brain*, and *multiple sclerosis*. In *cerebral syphilis* the onset is usually more sudden, and paralytic symptoms appear earlier. Headache is more frequent and severe, and there may be convulsive seizures; affections of the tongue and speech are wanting, while the train of mental symptoms is less complete and characteristic, and expansive delirium, as a rule, does not occur. The epilepsy is more commonly Jacksonian. It is to be remembered that the syphilitic virus produces both, and it is not unnatural that the two should sometimes merge. *Tumors of the brain* frequently, but not always, produce symptoms more localized, and often also optic symptoms, including choked disk. The symptoms of *insular sclerosis*, which include dementia, are often identical with those of paralytic dementia, and the two diseases cannot then be differentiated. Intention tremor is more characteristic of sclerosis. The cerebral symptoms of some forms of *plumbism*, it is said, also sometimes closely resemble those of paralytic dementia.

**Prognosis.**—The prognosis is almost always unfavorable, although the course of the disease varies somewhat. The most rapid cases of the galloping form may terminate in a few months, but two or three years is the more usual duration; sometimes much longer, it may be 10 years or more. Death ensues from exhaustion, hastened by the complications and secondary conditions which naturally supervene on an illness so prolonged and in which nutrition is so interfered with; or it may be due to intercurrent disease.

**Treatment.**—In view of the general acknowledgment of the syphilitic origin of chronic diffuse meningo-encephalitis and the acknowledged efficiency of antisiphilitic treatment over tertiary manifestations of the disease, it is rather surprising that attempts at curative treatment are so futile. The treatment is confined mainly to iodids and mercurials. Mercurials are best used by inunction, and the iodids in ascending doses. These, however, do not arrest the disease.

As to the rest, treatment must be symptomatic. The bromids and

chloral, with quiet, hygienic surroundings, and sometimes enforced retirement, are measures demanded for the relief of the nervous excitement.

For the opposite condition of depression and melancholia change of scene by travel and residence in different localities should be enjoined. Further than this the use of a proper hygiene, with bathing, frictions, whole some outdoor life, and an abundance of nourishing and easily assimilable food constitute about the sum of the means we can bring to bear against the disease.

### PARALYSIS AGITANS.

**SYNONYMS.**—*Chorea sclotyrbe sive festinans* (Sauvages); *Chorea procursiva* (Bernt); *Shaking Palsy*; *Parkinson's Disease*.

**Definition.**—A chronic nervous disease characterized by muscular weakness, tremor, or shaking in the extremities, muscular rigidity, and forward-bent gait.

**Historical.**—The disease was first fully described by Parkinson, of London, in 1817, so accurately that little of importance has since been added to his description.

**Etiology.**—Shaking palsy is commonly a disease of the second half of life, but occasionally occurs between 30 and 40, and has been observed as early as the twentieth year. It is a little less frequent among women than men—11 to 14. Among the causes held responsible for it are exposure to cold and wet, fright, mental excitement, business worry, injury, —whether to nerves or other parts of the body—alcoholism, sexual excesses, and the infectious diseases, including malaria, while heredity is said to have a slight influence. The etiology of the disease is largely a matter of conjecture and inference.

**Morbid Anatomy.**—This is unknown so far as essential lesions are concerned. Various lesions have been described, while the brain, spinal cord, and peripheral nerves of the most typical cases have been examined with results not entirely satisfactory.

As the phenomena are similar in kind, if not in degree, to those of senility, it is held by Dubief, Borgherini, Koller, Sass, Jacobson, Ketscher, and Sanders that they have for their anatomical basis the lesions of senility somewhat intensified, and that the disease differs from true senility only in its earlier onset. Other investigators conclude that this is not the case, and that paralysis agitans is a disease *sui generis*, although there are many changes in the spinal cord and brain, which are common to the two affections, consisting essentially in increase in interstitial tissue and proliferation of neuroglia cells in the spinal cord, medulla oblongata, pons, and the motor cortex in a less degree. Charles L. Dana<sup>1</sup> says: "The most logical conclusion one can reach is that in paralysis agitans there is early a functional disturbance and later a destruction and degeneration of the dendrites of the anterior horn cells which interfere with the even flow of motor impulses, and finally lead to motor weakness and rigidity, owing to the cell being

<sup>1</sup> "Paralysis Agitans and Sarcoma," "Am. Jour. of the Med. Sci.," November, 1899.

practically cut off from the brain." Dana continues: "The difference between this condition and that found in spastic paraplegia due to a sclerosis of the voluntary motor tracts is manifest, for there the dendrites of the anterior horns which subserve reflex purposes are normal, while in paralysis agitans all are somewhat affected. The rigidity of this disease is much like that found late after total transverse cord lesions."

H. C. Gordinier,<sup>1</sup> on the other hand, says the primary seat of the pathological changes is in the blood-vessels, starting with an endarteritis and peri-arteritis and consequent proliferation of the neuroglia in the immediate neighborhood, with the production of patches of perivascular sclerosis, which are characteristic of the disease. Also that "the alterations which have been observed in the nerve-cells of the anterior cornua and cranial nerve nuclei, together with the slight changes in the cells of the motor cortex, are secondary, due, in all probability, to a gradual diminution of nutrition dependent on the vascular changes." The truth is, the pathology of this disease is unknown, and is at present a subject for speculation.

**Symptoms.**—The disease is not a very rare one in this country, and the county almshouses almost always contain one or more cases—easily recognized by the characteristic shaking or tremulousness of the hand. Though commonly gradual in onset, the symptoms may come on quite suddenly, and at first only after exertion. Indeed, there may even be a *prodrome* in the shape of neuralgic pains, paresthesia, dizziness, and the like. The more sudden cases follow fright or trauma. The *tremor* is most marked in the fingers and hands, where it commonly begins, and whence it extends to the arms and lower extremities. The upper arm muscles are rarely involved. It most frequently passes from the right arm to the right leg, thence into the left arm, and thence into the left leg; or the course may be crossed—that is, from the right arm to the left leg. It may remain in one limb to the exclusion of the others. In the fingers the movements between the thumb and index-finger is frequently that of rolling pills, but the movement may not always be characteristic. At the wrist it is one of pronation and supination. In the feet it is most marked at the ankle-joint. It affects the writing, making it trembling, as in the aged, and ultimately it becomes impossible to write. The muscles of the head and face are last involved, sometimes not at all, and when present, the motion is vertical and quite rhythmical, usually about five times in a second. At first the tremor ceases during sleep, but continues during the waking state even when the muscles are at rest, but ultimately it continues even during sleep—in fact, sleep is sometimes prevented thereby. It frequently is partially arrested by voluntary motion and is increased by emotion. Should rigidity become excessive, the motion may cease.

The rate of tremor varies greatly, being at first slower, and increases in rapidity as the disease advances. Roughly, it may be put down at from three to five times a second. There may be intermissions of the tremor of days and even weeks.

*Muscular weakness* is a less striking symptom, but may be estimated by the dynamometer, and increases with the duration of the disease and the intensity of the tremor. It is most striking at least in the extensor muscles,

<sup>1</sup> "The Pathology of Paralysis Agitans," December, 1899.

the *flexors* being disposed to *rigidity* and *spasm*, which early produce a slowness and stiffness of motion which is characteristic. It is this flexor spasm which brings the thumb and forefinger into the writing or pill-rolling position. At other times, hyperaction of the interossei muscles over that of the common extensors of the fingers results in the position so characteristic of arthritis deformans—that is, with the first phalanx bent, the second extended, and the terminal phalanx also bent. Ultimately extension is impossible. Occasionally the opposite state of fixed extension exists.

The *attitude* and *gait* ultimately assumed by the subject of shaking palsy are also the result of rigidity, which sooner or later affects most of the muscles. The head is bent forward, the back is bowed, the arms are held away from the body and flexed at the elbows, and the knees are approximated so that they are often rubbed in walking; while the general appearance is that of a man in danger of falling forward. The position of the body due to flexion also gives rise to a “propulsive” gait, caused by carrying forward the center of gravity, so that, when started, the patient is apt to “get a-going” and cannot stop until he comes up against some object. On the other hand, a push backward, bringing the centers of gravity behind the point of support, is apt to make the patient fall, because he cannot move back fast enough to save himself by “retropulsion.” Charcot regards both these phenomena as “forced movements,” but Strümpell prefers to explain them by simple physical laws, as previously described. Sometimes the characteristic position of the patient exists without the shaking, and for this the name “*paralysis agitans sine agitatione*” has been employed.

The similarity in the rigid bent condition of the vertebral column and the deformities of the hands in this disease and rheumatoid arthritis, together with other points of resemblance has suggested to W. G. Spiller a similar origin of the two diseases.

The *facial expression* is also very strikingly altered. The face is indeed without expression, stiff and mask-like, giving rise to the name “Parkinson’s mask.” There is often a dribbling of saliva from the partially closed mouth. On the other hand, sometimes the mouth is kept closed, and is found full of saliva—a condition ascribed to delayed deglutition rather than to increased secretion. The speech is slow, hesitating, and monotonous, and the voice may be piping and shrill. On the other hand, if the lips and tongue share in the tremor, the speech is stuttering, as though the patient were in a hurry to speak—quite different from the scanning speech of insular sclerosis.

The remaining nervous and organic functions are essentially normal. Sensation is usually unaltered, and the bowels and bladder are usually unaffected, as is also the temperature, although it is said that the surface temperature is sometimes elevated. Charcot has noticed an alteration of the temperature sense. There is sometimes a tendency to unnatural perspiration.

**Diagnosis.**—This is usually very easy, and can generally be made at a glance. *Multiple sclerosis* resembles it in some respects. Both have tremor, but in multiple sclerosis this is shown more particularly when the patient attempts to do something, as to bring a glass of water to his lips or approximate his fingers. The speech is rhythmical, “scanning,” instead of

stuttering, as in shaking palsy; there is nystagmus, and the disease begins almost invariably in the lower extremities, while the attitude is not that of paralysis agitans. *Chorea* is characterized by movements, but these are irregular and more intermittent.

**Prognosis.**—A well-established case of paralysis agitans is not curable by medicines. On the other hand, the disease lasts indefinitely, the patient getting slowly worse, with perhaps the intermissions alluded to, until he dies of some intercurrent disease or from the effects of some accident growing out of his condition.

**Treatment.**—Under the circumstances this must, for the most part, be by tonics and general hygienic measures. As the disease advances the patient should be guarded against accident; and especially when in bed his position should be changed for him if he cannot change it himself, as is often the case.

Cases have improved under the use of the iodid of potassium and arsenic, and hyoscin has been especially recommended by Erb—hypodermically, in doses of from 1/150 to 1/100 of a grain (0.00044 to 0.00066 gm.) of the hydrobromate. Good results have also been reported from the use of atropin, of which from 1/100 to 1/60 grain (0.00066 to 0.0011 gm.) may be used subcutaneously or by the mouth.

Measures calculated to improve the general health are indicated, such as sea-bathing, massage, electricity, fresh air, and outdoor life.

#### OTHER FORMS OF TREMOR.

##### SYNONYM.—*Ballismus*.

In addition to the tremor in paralysis agitans, a similar tremor occurs under other circumstances, sometimes without assignable cause, when it is known as *simple* tremor, or it may be induced by fright or overexertion. A *hereditary* tremor has been described by C. L. Dana. *Senile* tremor is the well-known form of tremor which comes on with advancing years, at times earlier than others, but usually not until after 70 years. The existence of a tremor due to senility was denied by Charcot, but is accepted by most neurologists.

*Toxic* tremor is due to a number of toxic agents, among which tobacco and alcohol are the most frequent. Lead is another of these causes. Finally, *hysterical* tremor occurs as a part of hysterical phenomena in women. *Asthenic* tremor is due to simple weakness, and is especially seen in exertion during convalescence from acute disease.

#### TUMORS OF THE BRAIN.

##### SYNONYMS.—*Neoplasmata cerebri; Intracranial Tumors*.

**Definition.**—Cerebral tumors, clinically considered, include not only tumors of the meninges and substance of the brain, but also all intracranial and even such extracranial tumors as ultimately invade the brain. Among the latter are tumors of the orbit or nasal cavity, of the antrum, and of the sphenopalatine fossa.

**Varieties.**—The principal varieties of cerebral tumor, approximately in the order of frequency, are:

1. Tyroma, or tuberculous tumor. 2. Glioma. 3. Sarcoma. 4. Carcinoma. 5. Cystic, including parasitic cysts and cysts arising in sarcomata and gliomata. 6. Gumma. 7. Histioid tumors. Among these occur in irregular order, cholesteatoma, lipoma, myxoma, angioma, fibroma, psammoma. Even dermoid cysts, as well as parasitic cysts—including the echinococcus or hydatid cyst and the cysticercus cellulose, are met. Of these tumors, psammoma and glioma are peculiar to the brain. According to M. Allen Starr's tables, gliomata and gliosarcomata practically equal in number the sarcomata, but the term gliosarcoma is regarded by many unfavorably.

**Etiology.**—Except sarcoma, tumors are found in males more frequently than in females. Tubercle is more common in childhood; parasites, glioma, sarcoma, and gumma in early and middle life, and cancer in middle and late life, but is rare even then. Brain tumors of any kind are rare after 60. Heredity appears to have slight, if any, influence. A few brain tumors are metastatic, especially carcinoma, and to a less degree sarcoma. Eichhorst relates several remarkable cases in which trauma seemed to be the exciting cause.

**Distribution.**—Certain tumors seek by preference special localities. Thus, *tuberculous* tumors are most numerous in the cerebellum and about the base of the brain. *Glioma* starts from the neuroglia in any part of the brain, but more frequently the cerebrum or pons, and may also attain a large size—larger than any other brain tumor; it is further characterized at times by its great vascularity, leading sometimes to rupture and apoplectic symptoms. Glioma may also occur in the eye. *Sarcoma* develops most frequently in the membranes of the brain and sheaths of the vessels; it may be primary or secondary; it is often encapsulated. *Myxoma* and *fibroma* occur in the same localities. *Carcinoma* is usually secondary, but may be primary; it arises more frequently in the membranes or pituitary body, but may be found in the substance of the hemispheres; it is especially secondary to primary cancer of the breast, lungs, or pleura. *Syphiloma* elects the hemispheres or the pons and vicinity; it is generally superficial, grows from the meninges, or is attached to arteries, attaining sometimes a large size. It may be multiple. *Parasitic tumors* are found in the membranes, the substance of the brain, and the ventricles. The hydatid cysts developed by the echinococcus are usually on the surface of the brain; the cysticercus, usually multiple, on the surface or in the ventricles. *Psammoma*, or sand tumor, is found commonly in the neighborhood of the pineal gland.

**Symptoms.**—The symptoms of cerebral tumor are in no way specialized by the kind of tumor present, and depend entirely upon the effect exerted on the surrounding brain substance, chiefly by pressure. They do, however, vary somewhat with the part of the brain involved. It occasionally happens that a brain tumor may produce no symptoms whatever, being thoroughly latent, and disclosed only by the autopsy. On the other hand, apparently insignificant tumors cause very decided symptoms. Such differences may depend in part on the location of the tumor, and in part on the rapidity of its development.

As in all local diseases of the brain, two sets of symptoms usually present themselves: (1) Diffuse and (2) Focal symptoms.

1. *Diffuse or General Symptoms.*—These are symptoms which may be associated with various forms of nervous disease. The most constant of these is perhaps *headache*, which varies in intensity and constancy. Probably the severest headaches it is given human beings to suffer are caused by brain tumors, exhibiting every variety of pain—sharp, cutting, shooting, boring, or dull and pressing. At times it is moderate, producing a sense of discomfort only. It may be intermittent or constant. It may be over the entire head, or half of it, or be still more localized in the forehead or back of the head, extending also from the former over the face and the latter down the neck. It may be increased by mental excitement of any kind, by noise, or by alcoholic drink or strong light. There may be tenderness on pressure, or pain in percussing the head. The seat of pain is, however, for the most part, no indication of the seat of the tumor, though the presence of pain limited to the occiput and back of the neck suggests a tumor in the posterior fossa of the skull, the occiput, or the cerebellum. Localized pain on tapping the skull is a more reliable index.

Astereognosis is an occasional symptom.

*Vomiting* is another characteristic symptom of brain tumor. It may occur independent of headache, but is often associated with it. It is further characterized by being independent of food ingestion, may be without nausea, and is apt to be worse in tumors of the cerebellum and pons.

*Dizziness* is also a very frequent symptom, and often an early one. It is at times intermittent, at others constant, and it may be so severe as to make it impossible for the patient to walk. It is most serious in tumors of the posterior fossa and of the cerebellum. Along with vertigo may be *slowing of the pulse*.

*Mental symptoms* may be present. They may be intermittent, and variously manifested in peculiarities of temper, such as sullenness, indifference, absent-mindedness, and loss of memory; or the opposite condition of maniacal excitement or delirium; or there may be drowsiness and even coma. Such mental states may, indeed, be the only manifestations of tumor.

*Speech.*—The patient may *talk slowly*, and the facial expression is sometimes altered.

*Apoplectic seizures* and *epileptiform attacks*, especially of the Jacksonian variety, are distinctive symptoms. The former may be due to hemorrhages in the tumor or around it, and may be followed by transitory paralysis and paresis. Epileptic convulsions, especially if unilateral, point, though not unmistakably, to tumors in the hemispheres impinging on the cortex. *Choreiform movements* are sometimes present.

*Choked disk*, *papilloedema* or *papillitis* and *optic neuritis* are the most constant and most valuable diagnostic symptoms of brain tumor. Choked disk consists, in brief, in a swelling of the optic nerve, with overdistention and congestion of the retinal veins, and narrowing of the retinal arteries. It is usually bilateral, rarely unilateral. There is still much difference of opinion as to the mechanism of choked disk, but it is thought by many to be the result of intracranial pressure forcing the cerebrospinal fluid from the

subarachnoid space into the lymph sheath of the optic nerve, causing compression of the nerve and the vessels within it. The vision is not necessarily deranged in choked disk, and its defects are not uniform, varying from slight amblyopia to total blindness. The swelling may diminish and improvement in vision ensue, but retinitis or neuro-retinitis may set in with consequent nerve atrophy, producing permanent impairment of vision. The choked disk is sometimes the only symptom of brain tumor, and its subject first consults the oculist for relief. On the other hand, it is not caused by brain tumor alone, but it may result from meningitis or abscess, in fact anything which produces intracranial pressure. Papilloedema occurs in from 80 to 90 per cent. of all cases of intracranial tumor. It may be absent, even though a brain tumor of considerable size exists. By optic neuritis a milder degree of papillœdema is generally understood.

The *senses of smell and hearing* may be impaired by tumors impinging on the olfactory or auditory nerves, and there may be *pruritus* and other modifications of cutaneous sensibility; also *neuralgic pains*. If the tumor is on the floor of the fourth ventricle, there may be *polyuria* and *glycosuria*. Finally, sooner or later the *appetite* may fail and the *nutrition* suffer, although the opposite condition of large appetite and good nutrition may obtain. In the terminal stage there may be *irregularity of breathing* (Cheyne-Stokes) and slowing of the pulse, while the final issue is often preceded by a *febrile movement*. The local temperature in brain tumor is usually raised from 92° to 95° F. (33° to 34.9° C.), and even 98° F. (36.7° C.).

2. *Focal Symptoms*.—These are symptoms peculiar to the seat of irritation or destruction, and become, therefore, of value in diagnosis. They are the results either of irritation or destruction of nervous tissue, irritation causing contraction and spasm, while destruction causes paresis and paralysis. For convenience in localization the brain may be divided, as in Fig. 137, after C. L. Dana, into:

1. The prefrontal area, including all anterior to a line starting from the upper end of the ascending branch of the fissure of Sylvius at right angles to another drawn between the frontal and occipital ends of the brain.

2. The central region, bounded in front by the line just named and behind by a line limiting the posterior central convolution prolonged downward to the Sylvian fissure.

3. The parietal lobe.

4. The occipital lobe.

5. The temporal or temporosphenoidal area.

6. The pons and medulla oblongata.

7. The cerebellum.

The boundaries of these territories are shown, as far as possible, in the accompanying illustration.

In addition there are: (8) The corpus callosum; (9) the great basal ganglia and capsules; (10) the corpora quadrigemina, and pineal gland; (11) the crura cerebri; (12) the base of the brain.

1. *Tumors of the prefrontal area*, especially on the right side, often give no localizing symptoms whatever, motor or sensory, while general symptoms may also be absent and the tumor truly latent. Then, again, general symptoms may be well marked, including mental torpor and imbecility, childish-

ness, irritability, and emotional phenomena. These symptoms occur whichever side of the brain is affected, but possibly are more pronounced in tumors of the left frontal lobe. If the tumor extends downward into the inferior frontal convolution, it may cause aphasia; or if backward, it may occasion irritative spasm or destructive paralysis. Involvement of the optic tract may cause hemianopsia and optic neuritis; of the olfactory system, anosmia; if the tumor invades the orbit, oculomotor paralysis and protrusion of the eye. Percussion tenderness may aid in localizing the tumor.

2. *Tumors in the central or motor region* (possibly true only of tumors in the precentral convolution) may cause irritative lesions, resulting in spasm. If the tumor is in the upper third of this area, the spasm may begin in the toes, in the ankles, or in muscles of the leg; if in the middle

FIG. 137.—Showing Focal Symptoms of Brain Tumor—(after Dana).

third, spasm beginning in the fingers, in the thumb, in the muscles of the wrist or shoulder; if in the lower third, in the muscles of the face, the angle of the mouth, or tongue. In a word, the phenomena of Jacksonian epilepsy are present. All of these may be preceded or associated with sensory disturbance, such as numbness and tingling, and may be limited to one muscle group before extending to another, constituting the "signal symptom" of Seguin. There may be an aura, and the muscular sense is also sometimes affected.

Destructive lesions cause paralysis, and this may have the same distribution as the convulsions which sometimes precede. If on the left side in right-handed persons, aphasia and agraphia may result.

3. *Tumors of the parietal area* may produce no symptoms of sensory or motor phenomena, but there may be impairment of stereognostic percep-

tion, and often of ordinary sensation and of the sense of position with ataxia. With the involvement of the angular gyrus and lower parietal lobule may come word-blindness and mind-blindness. If the tumor is upon or near the central area, spasms and paralysis of the various muscular groups described under 2 may develop. Paralysis of the third nerve has occurred in connection with tumors in the neighborhood of the angular gyrus; no satisfactory explanation for this has been offered—possibly it is due to pressure at a distance.

4. *Tumors of the occipital lobe*, if in the cuneus or neighboring parts, may produce homonymous lateral hemianopsia; and if double, total blindness; if elsewhere on the left side, there may be mind-blindness; and if the tumor extends also into the angular gyrus, word-blindness, along with hemianopsia; if obtruding further forward into the parietal lobe, hemianesthesia, hemiataxia, and perhaps some hemiplegia from involvement of the internal capsule may occur.

5. *Tumors of the temporosphenoidal area on the right side* rarely produce symptoms; on the left side, in the posterior part of the first and upper posterior part of the second gyrus, they cause word-deafness. Disturbances of the senses of smell and taste may result from involvement of the hippocampal convolution.

6. *Tumors of the pons and medulla oblongata* produce two sets of phenomena by:

- (a) Irritation or destruction of fibers in the pons and medulla oblongata.
- (b) Pressure on the nerves emerging in this region.

Either may occur alone or both jointly. Lesions here are especially likely to produce alternate paralysis: that is, involvement of certain of the cranial nerves on one side and the limbs on the opposite side.

If the tumor is in the cerebral peduncle, there may be a palsy of the third nerve on the same side and a hemiplegia on the opposite side; if lower down and in the pons, a palsy of the fifth on the same side and hemiplegia on the other; if still lower down, it may involve the sixth nerve, producing internal strabismus, the seventh producing facial paralysis, and the eighth causing deafness. If the tumor is very large, it may produce a hemianesthesia as well, and there may be forced movements of the body, either toward or from the side of lesion. Conjugate deviation of the eyes away from the side affected may also occur. This is in direct contrast to the conjugate deviation sometimes noticed in cerebral lesions, in which the head and eyes are turned toward the side of lesion.

Tumors of the medulla oblongata may produce hemiplegia and hemianesthesia, and, if the tumor is large, symptoms of bulbar paralysis. From irritation of nerves on the same side, the ninth, tenth, eleventh, and twelfth, difficulty in swallowing, irregular action of the heart, irregular breathing, and vomiting may arise. Sometimes also there is retraction of the head, or sensory symptoms including numbness and tingling and finally convulsion. If the cerebellum is impinged upon, there may be unsteadiness of gait, but this is frequently caused by implication of the cerebellar peduncles without involvement of the cerebellum.

7. *Tumors of the cerebellum* produce very characteristic symptoms, though here, too, there may be latency if the growth is limited to the hemi-

spheres. If the middle lobe is invaded, vertigo, vomiting, headache, papilloedema, with blindness and cerebellar ataxia, are present. *Papilloedema is more common in cerebellar than in cerebral tumors* and is usually an early sign. The pressure causing papilloedema is not directly on the occipital lobe or optic tract, but is generally on the cranial contents, and possibly interference with the circulation of fluid in the ventricles causes pressure on the optic chiasm by an excess of fluid in the third ventricle. More rarely nystagmus and neuralgic pains in the neck and occiput occur. The irregular and staggering gait of cerebellar ataxia is very striking, the patient reeling like a drunken man, or he may be thrown sideways or forward, rarely backward, by forced motion.

If the medulla oblongata is compressed by the tumor, vomiting from this cause may ensue, also bulbar symptoms and glycosuria.

8. *Tumors of the corpus callosum* are rare. The symptoms are similar to those of tumors in the third and lateral ventricles of the brain, extending peripherally. They cause general symptoms of brain tumor, with gradually developing hemiplegia, and later paraplegia. With this there are mental dullness and drowsiness and indisposition to speak. The cranial nerves are not involved.

9. *Tumors of the basal ganglia and the internal capsule* produce symptoms similar to those that occur in the corpus callosum. They are partly pressure symptoms. There is progressive hemiplegia, with which there is likely to be hemianesthesia. Sometimes there are choreic and athetoid movements if the tumor involves the optic thalamus and adjacent parts of the internal capsule. Tumors of the caudate nucleus alone, or of the lenticular nucleus alone, are generally latent; so are those of the anterior three-fourths of the optic thalamus, except that choreic and athetoid movements referred to may be noticed, due to irritation of fibers of the internal capsule, or, as supposed by some, to irritation of the anterior cerebellar peduncle. Tumors of the basal ganglia are often infiltrative (glioma) and therefore cause few symptoms at first. Tumors in these areas are very likely to give pressure symptoms. A large tumor of the thalamus may involve the fibers of the optic radiation and cause hemianopsia or sometimes hemianesthesia. This may be differentiated from hemianopsia due to lesions of the occipital lobe by the presence of the hemianopic pupillary reaction, in accordance with which a ray of light thrown on the insensitive part of the retina will not produce a reflex contraction of the pupil. Papilloedema is likely to be an early symptom of tumors in this vicinity.

10. *Tumors of the corpora quadrigemina* usually involve the crura as well. They are characterized by inco-ordination, forced movements, and oculomotor palsies, to which may be added hemianopsia, or blindness due to destruction of the primary optic centers; the pupillary reflex is lost and there is nystagmus.

11. *Tumors of the crus* from involvement of the third nerve are especially characterized by oculomotor paralysis on one (the same) side and hemiplegia on the other. Tumors of the crus are, however, rare.

12. *Tumors of the base*, if of the anterior fossa, produce symptoms much like those of tumors of the prefrontal area, adding, however, anosmia from destruction of the olfactory lobe; while there may be also involvement of the

optic and oculomotor nerves and of the orbital contents. Tumors of the middle fossa and of the interpeduncular space produce pressure on the optic chiasm with consequent neuritis and bitemporal hemianopsia, by which lesions of this area are distinguished from those in the anterior fossa.

**Diagnosis.**—This consists first in the recognition of the presence of tumor from the general symptoms, and then the determination of its location in either hemisphere from the focal symptoms. The same symptoms may be produced by any agency causing pressure on these structures. *Papilloedema*, which is so constant a symptom of tumor, may be caused by *Bright's disease*, *cerebral syphilis*, *lead encephalopathy*, and *anemia*. The albuminuria, hypertrophy of the right ventricle, polyuria, and tube-casts usually help to recognize the first. Other symptoms of lead-poisoning indicate that disease, and the usual symptoms of anemia point to it. *Meningeal thickening*, *hemorrhage*, *aneurysm*, and *abscess* may also produce pressure symptoms.

The nature of the tumor may be determined in part by what has been said of the preference for certain localities and the age of the patient, and in part by the history, say of tuberculosis or syphilis or primary growths elsewhere. The surface temperature is of uncertain value in diagnosis. Death may be sudden, especially from growths near the medulla oblongata. It is usually the result of increasing pressure. The X-ray has recently been applied to the diagnosis of brain tumor with uncertain results; a change in the percussion note over a tumor is also of doubtful value.

**Prognosis.**—This is generally unfavorable. It is true that in some rare instances the brain tumors cease to grow after a time. Various observers find the ratio of removable tumors from five to ten per cent. Of 1121 cases collected from different authors by M. Allen Starr in his article on "Tumor of the Brain" in Dercum's "Nervous Diseases," 80, or 4.25 per cent., were regarded as operable, but four-fifths of all persons operated on perish. When due to syphilis, they may in some cases be melted away by mercurials and iodids. Calcification is a rare, but happy, termination of tuberculous growths. The duration of tumor averages two or three years; the extremes average from a month to many years.

**Treatment.**—This is *medicinal*, *hygienic*, and *operative*. The first is limited in its purpose to the cure of syphilitic tumors and, perhaps, in a slight degree, to tuberculous. The astonishing effect of the mercurial and iodine treatment upon syphilitic new formations is nowhere so well shown as upon cerebral gumma. Unless syphilis can be excluded with absolute certainty, the *iodid of potassium* should be given in any case in ascending doses, limited only by their effects. In the absence of syphilis the larger doses are not well borne. In addition, *mercury* should be used, at first preferably by inunction until the specific effect is produced, after which it may be discontinued, to be renewed as indicated. Instead of inunction, the *bichlorid* may be given internally in doses of 1/12 grain (0.005 gm.) three times daily, or until the physiological effects are produced. When the tumor is once under control, it is still necessary to keep up the treatment in such doses as experience may determine to be necessary. Usually the iodid of potassium is sufficient for this purpose. When, however, the symptoms of tumor disappear and remain absent many years under iodids, the diagnosis of tumor

may be doubtful. This would seem to be verified by the following case: I had under observation for 30 years a patient in whom the disease has been kept in check by a dose of 60 grains (4 gm.) a day, which had occasionally to be doubled for a time. The evidence of a syphilitic lesion in this case seemed conclusive, since following acknowledged infection there occurred secondary symptoms of syphilis, the full train of classic symptoms of brain tumor, including ophthalmic symptoms studied by an experienced ophthalmologist. The case, however, came to necropsy and only meningitis was found. If mercury is necessary in this stage, the *binioid* may also be used in doses of from 1/24 to 1/12 grain (0.0025 to 0.005 gm.), as required, though I have not the confidence in it that I have in the separate use of the iodid of potassium and the bichlorid of mercury.

In tyroma the usual constitutional treatment of tuberculosis by cod-liver oil, iron, and other tonics, with nourishing food and healthful indoor and outdoor life, is to be carried out.

The usual remedies indicated to relieve pain are to be used, bromids, if necessary, in large doses, phenacetin, antifebrin, and antipyrin, and, if necessary, morphin. The ice-cap may be used, and, above all, leeching tried. The most magical effect is sometimes produced by free leeching, though it is unfortunately temporary. Other symptoms should be treated by appropriate remedies.

The hygienic treatment is of the greatest importance. Excesses of every kind should be avoided, alcohol should be rigidly excluded, as well as all sexual excitement and mental excitement of any kind, for the slightest increment of blood in the brain may bring on a convulsion and cause death.

Exploratory operation being much less dangerous than formerly, with the aseptic precautions of the present day, should be made whenever the tumor can be localized with any approach to accuracy. Although cerebral localization has been developed to a very high degree, it must still happen that we frequently fail to locate a tumor accurately. Cerebral decompression is important for relief of symptoms, especially when the location of the tumor cannot be determined, and if performed early may save the eyesight as well as remove some other symptoms.

### SUPPURATIVE ENCEPHALITIS.

SYNONYMS.—*Suppurative Inflammation of the Brain; Cerebritis; Abscess of the Brain.*

**Definition.**—By encephalitis is meant inflammation of the substance of the brain as contrasted with inflammation of its membranes. What is spoke of as inflammation of the brain in popular parlance is really inflammation of the membranes of the brain, or meningitis. A literal application of the term encephalitis is here intended.

**Etiology.**—The causes of cerebritis are: (1) Traumatic; (2) an adjacent focus of inflammation extending to the brain substance; (3) pyemia.

Under traumatic causes are included blows upon the head and falls, more commonly those attended by fracture or punctured wound; although it is not necessary that there should be even a scratch upon the skin.

Under adjacent disease, whence extension of inflammation is especially frequent, is to be included caries of the petrous portion of the temporal bone due to disease of the middle ear or labyrinth, the most common of all causes of abscess of the brain. Disease of the orbit or of the nasal passages is another focus of the same kind. The route of such a communication may be through either the sinuses of the brain or the lymph paths.

Pyemic abscess of the brain is rare. Causal foci are malignant endocarditis, gangrene of the lung, chronic bronchitis with bronchiectasis, bone disease, suppuration of the liver, and the specific fevers, among which may be included *la grippe*.

Encephalitis occurs most frequently between the ages of 10 and 40, and about three times as often in the male sex as in the female.

**Morbid Anatomy.**—Abscesses of the brain are usually solitary, though there may be two or three, or even more. The abscesses may be from one-half to three inches (one to eight cm.) in diameter, rarely more, though an entire lobe has been involved. The abscess itself is a very interesting product. Unless very recent, it is surrounded by a distinct wall which is composed of *three layers*. The inner is smooth, made up for the most part of granular fatty cells. Outside of this is a layer of germinal tissue containing spindle cells and more perfect fibrillated tissue. Externally again is another layer of fatty cells. The pus within the abscess is usually greenish-yellow in color and acid in reaction, while its corpuscles are distinctly nucleated. The *zone outside of the abscess is edematous*, the cells are swollen, sometimes disintegrated, with blood points scattered throughout, becoming sparser as the periphery is extended.

The locality of the abscess may be preceded by the condition known as *red softening*, which is often spoken of as the first stage of the inflammation, but it is most important to remember that red softening is not peculiar to abscess. It consists simply of brain substance broken down into a reddish, blood-stained pulp. In this substance are found fragments of nerve-fibers, drops of myelin, pus-corpuscles, and granular fatty cells. The termination of cerebritis is not always in abscess. It is barely possible, before the stage of abscess is reached, for a condition of *yellow softening* to supervene, and the so-called apoplectic cyst may be the final result, or even cicatricial tissue may develop.

The *cerebrum* is involved *four times as often as the cerebellum*, the *left hemisphere* more frequently than the right, and the temporo-sphenoidal lobe more than any other. The cause has something to do with the location: Ear disease places the abscess in the temporal lobe or cerebellum; if in the tympanum, the cerebrum rather than the cerebellum; if the mastoid cells and labyrinth, the cerebellum.

**Symptoms.**—While inflammation of the brain is spoken of as acute and chronic, more strictly speaking it is rather primary and delayed, the symptoms of the so-called chronic form being essentially the same as those of acute cerebritis, but characterized by their late appearance after the cause which precedes them. In acute cases the symptoms develop rapidly and may run their course in a few days, while in the forms known as chronic the symptoms are scarcely less rapid after they once set in, which may be weeks, months, and even longer, after the operation of the cause.

These symptoms are the result of pressure—direct or indirect—of destruction of the brain substance, or of poisoning by absorbed putrid matter. They are much the same as those of meningitis, with which, indeed, abscess is often associated, especially if there is injury. The most striking are *headache*, often severe and persistent; *vomiting*; *vertigo*; *mental dullness*, succeeded sometimes by *delirium* and sometimes by *coma*. *Convulsions* are often present, and are epileptoid in character. *Optic neuritis* is also one of the symptoms. Other cranial nerves beside the optic are sometimes involved.

There is usually *fever*, as shown by elevation of temperature. At other times the temperature is normal or subnormal. The *pulse* is usually slow—from 60 to 70. The symptoms may set in with a *chill* after the latent period. The toxic symptoms are those usual to toxic states—viz., chill, irregular fever, prostration, emaciation, exhaustion. *Paralysis* in the form of hemiplegia sometimes occurs. The paralysis, however, is not always hemiplegic, and may be limited to the arm and face, especially in abscess of the temporo-sphenoidal lobe, which may compress the internal capsule. If on the left side, there may be *aphasia*.

When the abscess is in the parieto-occipital region, there may be *hemi-anopsia*. It is especially in abscess of the cerebellum that *vomiting* occurs, and *staggering* if the middle lobe is affected.

Of the *chronic* form it has already been said that the symptoms, though long delayed, are the same as those of the acute form. Such delay, however, does not always cover all symptoms, since during the latent stage the patient may have headache or vertigo in a mild degree, and especially may he be irritable and depressed, while he may even have a convulsive seizure during this preliminary period. It occasionally happens that there are no symptoms at all, and cases have occurred, more particularly of abscess in the frontal lobe, in which there were no signs or symptoms before death.

*Phlebitis* of the superior petrosal and lateral sinuses is especially common when the abscess is caused by disease of the ear, since the former receives a vein from the internal ear, and the latter receives the mastoid veins. *Edema about the ear and neck and hardness of the jugular veins* should suggest phlebitis, while *rigidity* of the neck and *cranial nerve paralysis* even more unerringly point to meningitis.

**Diagnosis.**—This is easy in acute cases, being substantiated by the history of injury, rigor, and fever, followed by the brain symptoms described. Almost as certain is the diagnosis when such symptoms follow chronic ear disease or localized putrid lung disease. It is to be remembered, that general cerebral symptoms may be produced by pus in the middle ear. These should be treated by puncture of the tympanum, and should the symptoms persist, after puncture abscess may be suspected. In like manner *meningitis* and *abscess* may be confounded, and with reason, because, in the first place, meningitis may be produced by the causes that produce abscess; and, second, meningitis may be caused by abscess, and both may occur together. Meningitis, however, affects the cranial nerves more than abscess, unless the abscess is seated in the pons, and usually meningitis succeeds more promptly upon its cause. It is to be remembered that

*tumor of the brain* may produce symptoms identical with those described. The chief distinctive symptom in abscess is the presence of fever.

**Prognosis.**—This, unless we admit a curable form described by Strümpell, is always ultimately fatal unless we have the rare good fortune to reach it by operation.

Acute cases last from eight to 14 days, rarely 30 days; the delayed cases may not show their first symptoms for months. In the curable form referred to, Strümpell says pronounced symptoms of focal disease exist for a time and suggest a tumor, but after some months or even a longer time they gradually abate, and recovery is complete. The nature of the symptoms is such as to suggest a seat in the cortex, for there is usually paresis of some part of the body, often associated with symptoms of motor irritation and impairment of speech.

**Treatment.**—A certain prophylaxis may be exercised in the proper treatment of disease of the ear, for it is often the neglect of this which leads to the abscess. Such prophylaxis includes measures which secure free discharge and antisepsis. Beyond this the only treatment for abscess which promises anything toward a favorable result is operation, on which account the surgeon should be promptly associated in the treatment of the case. The use of the trephine has saved a few cases. For the details of the operation the student is referred to text-books on surgery.

**ENCEPHALITIS WITHOUT ABSCESS.**—When, on the one hand, inflammation of the surface of the brain accompanying meningitis is eliminated, and, on the other, softening of the brain, formerly thought to be the result of inflammation, but now known to be due to the arrest of blood-supply, a number of cases of encephalitis without abscess remain, in some of which a necropsy was obtained.

## CHRONIC HYDROCEPHALUS.

**Definition.**—A collection of serous fluid either between the meninges or in the ventricles of the brain. The former constitutes intermeningeal hydrocephalus, or *hydrocephalus externus*, or *hydrocephalus ex vacuo*. The latter is ventricular hydrocephalus, or *hydrocephalus internus*. The seat of effusion in hydrocephalus externus may be either in the subdural space—*i. e.*, between the dura mater and the arachnoid—or in the subarachnoid space. The first was formerly regarded as the most frequent; later its occurrence came to be denied, but more recently, by means of frozen brain sections, it has been demonstrated. Since the subarachnoid space communicates with the ventricles of the brain, the two forms of hydrocephalus may coexist. Both external and internal hydrocephalus may be diffuse or circumscribed. When circumscribed there result in the case of the former cystic spaces in the membranes, and in the latter distention of portions of the ventricles.

**EXTERNAL HYDROCEPHALUS** occurs in connection with atrophy of the brain, and is not of much clinical importance.

## INTERNAL HYDROCEPHALUS

This is divided into congenital and acquired.

*Congenital Hydrocephalus.*

This pre-exists birth, and may be present to such a degree as to retard the birth of the head. More frequently it is not recognized until some time after birth.

**Etiology.**—This cannot be said to be certainly known. Virchow early ascribed it to inflammation of the ependyma; Rindfleisch rather to an obstruction to the circulation in the choroid plexus. Drunkenness and syphilis in parents, and accidents in pregnancy, are held responsible; occasionally, also, tumors of the brain. More than one child in a family is sometimes affected.

**Morbid Anatomy.**—The head is characterized externally by its spherical shape and large size, its smooth eyebrows and protruding eyes, the last being due to depression of the orbital plate of the frontal bone. The protrusion is often so great that the eyelids cannot close over the eyes. The size of the head thus obtained is often enormous—from eight to ten inches (20 to 25 cm.) in diameter in a child of three or four years. On the other hand, the face appears very small. On closer examination the cranial bones are found separated and exceedingly thin, at times almost as thin as paper. In the membranous interspaces are often found Wormian bones. The veins may be seen beneath the skin, and fluctuation may sometimes be obtained through the scalp. On incising the brain a variable quantity of limpid fluid passes out. The quantity is sometimes enormous, reaching 20 pounds (40 kilos) or more. The cerebral cortex is greatly thinned, the thickness on the convexity being reduced to but a few millimeters. The gyri and the basal ganglia are compressed, and the ventricles are dilated. The commissures are stretched and even torn. The foramen of Monro is a wide opening, and the third ventricle is dilated and sometimes also the fourth. The ependyma is thickened, the choroid plexuses are vascular, sometimes little changed.

**Symptoms.**—These consist largely of the external morbid states just described, but in addition there is *slowness of physical and mental development*. The child learns to walk late and is very feeble and likely to be mentally deficient, although it is sometimes bright. The weight of the head is sometimes so great that it inclines to fall to the side or backward or forward, and must be supported by the hands of the patient. Other symptoms may, at times, be decidedly delayed, and the child may make some progress in studies. Signs of *mental imbecility* sooner or later make their appearance, manifested first, perhaps, by absence of development, but progressing until the child lives an almost vegetative existence, having to be fed and cared for like an infant, even though several years old. At times there is early headache. There may be *convulsive contractions, tremors, ataxic gait, paresis, and paralysis*; in fact, all the symptoms which succeed on irritative and destructive lesions of the nervous system. So, too, if life is sufficiently prolonged, the symptoms of tumor of the brain may be quite closely simu-

lated, especially when the cranium does not enlarge with the growing distention of the ventricles. There may be *choked disk*, *atrophy of the optic nerve*, and *total blindness*. This is more true of acquired hydrocephalus. There may be prolonged attacks of *drowsiness*, or *coma*, with *slow pulse*, while *sudden death* is not uncommon during epileptiform convulsions or apoplexy.

**Diagnosis and Prognosis.**—The rachitic head may be mistaken for the hydrocephalic, but the latter has not the broad forehead with prominent frontal eminences; it is rather spherical and smooth. A child with congenital hydrocephalus rarely lives to be more than four or five years old, though it may attain adult life

### *Acquired Hydrocephalus.*

**Etiology.**—This is also commonly ascribed to some inflammatory process, although it is said to be sometimes idiopathic. Especially is it a consequence of suppurative and tuberculous meningitis, when it is spoken of as acute acquired hydrocephalus, though chronic inflammatory processes may also cause it. Derangements in the circulation in the choroid plexus and in the ependyma of the ventricles may, however, be responsible. Especially may a tumor in the third ventricle, at the base of the brain, pressing upon the venæ Galeni or on the straight sinus of the dura mater, be a cause; or closure of the foramen of Monro, by which the ventricles communicate with the membranous spaces. Even lung or heart affections and growths in the mediastinum and neck may produce the needed obstruction.

**Morbid Anatomy.**—In cases of acquired hydrocephalus, even though beginning tolerably early in life—say the seventh year—as well as in adults, the skull does not necessarily expand, and the head may not enlarge. Indeed, the head may even be smaller than natural, as in cretins. In these instances the brain substance must yield, and is reduced in thickness, at times to a few millimeters only. In other cases the skull yields, its plates become thin, the fontanels grow larger, and an appearance like that of congenital hydrocephalus may result.

**Symptoms.**—The symptoms of acute acquired hydrocephalus are never distinctive, on account of the rapidity in the course of the disease which produces and obscures it.

Of chronic acquired hydrocephalus as of congenital the most striking symptom is, as a rule, the *marked distortion in the size and shape of the head* already described.

Other symptoms are those of congenital hydrocephalus influenced by the greater age the patient may attain.

Spontaneous evacuation of the fluid sometimes takes place by the nose, mouth, ear, or orbit.

**Diagnosis.**—This is commonly easy. It is only in cases in which the cranium does not expand that the symptoms of *brain tumor* may lead to a diagnosis of the latter condition instead of hydrocephalus.

**Prognosis.**—This is usually unfavorable. Generally the child lives from two to five years, though it may perish in a few months or live for from 10 to 15 years, or, as in a case of Bright's, to 29 years, or even longer. It has happened that spontaneous recovery has followed the evacuation of

fluid previously described. The absorption of small amounts of fluid is also possible.

**Treatment.**—This consists primarily in the treatment of the disease which is responsible for the hydrocephalus if it can be discovered; secondly, in the treatment of the symptoms which may arise, and next, in attempts to cure the malady. Some favorable results have followed the removal of the fluid by puncture of the ventricles, although there has been failure in the majority of instances. Measures should be taken to make the removal gradual, if possible, thus attempting to imitate the spontaneous efforts of nature, which have occasionally been followed by recovery. To this end the slow removal of the fluid—by puncture of the subarachnoid space between the third and fourth lumbar vertebræ—has been recommended and practiced by Quinke. At this point, too, the spinal cord is not very likely to be injured. It is more particularly in congenital hydrocephalus that operation is indicated.

If operation is deemed undesirable, attempts may be made to get rid of the fluid by diuretics and purgatives, although with little prospect of success. Iodid of potassium may be tried, with the faint hope that the hydrocephalus is due to a syphilitic tumor which might thus be melted away. Blisters may also be applied.

## GENERAL AND FUNCTIONAL DISEASES—NEUROSES.

The term neuroses is applied to nervous affections in which there are functional disturbances corresponding to which there is no known anatomical lesion.

## ACUTE DELIRIUM.

SYNONYM.—*Bell's Mania*.

**Definition.**—An acute and violent febrile delirium of unknown cause and undetermined lesion, running a course of from two to three weeks, and usually fatal.

**Historical.**—The disease was first described in 1849 by Luther Bell, of the McLean Asylum.

**Symptoms.**—These set in suddenly and consist in violent, active *delirium*, in which the patient talks and moves incessantly, with a speech that is incoherent and unintelligible and movements which are aimless and irresistible or rhythmical as though with a purpose. This is kept up for hours and hours, notwithstanding the use of the most powerful anodynes, until the patient becomes exhausted, the whole presenting a picture which is at once revolting and pitiable. At times sleep is obtained for an hour or two, but immediately on waking the active movements and delirium begin. The rhythmical movements may be like those of the salaam convulsions, up and down, as of one chopping wood or working a pump-handle. Throughout there is *high fever*, the temperature ranging from 102° to 104° F. (38.9° to 40° C.).

The tongue is dry, the pulse rapid and feeble, the skin, in like manner, dry and often covered with petechial spots or pustules and bullæ or bruises, the result of the violent acts of the patient. There seems, however, no pain or tenderness other than is due to these causes.

**Morbid Anatomy.**—As stated in the definition, there is nothing definite. There may be venous engorgement of the meningeal veins and of the cerebral cortex, with perivascular exudation and cellular infiltration of the lymph sheaths and perivascular spaces. There is often engorgement of the bases of the lungs, and deglutition pneumonia has been found.

**Diagnosis.**—At first the disease may be mistaken for any of the acute fevers which sometimes begin with violent delirium, especially for *typhoid*, but the course of the temperature and absence of other distinctive symptoms soon eliminate any doubt.

The same may be said of forms of *puerperal mania*, and more rarely *pneumonia* of the meningeal type and of *cerebral meningitis* itself. The *incessant* violence is, however, peculiar to Bell's mania.

**Prognosis.**—This is almost always fatal.

**Treatment.**—This must consist of measures to control the mania, of which hypodermic injections of morphin are almost alone efficient, and these often only feebly so. Chloroform or ether must sometimes be em-

ployed, because of the dangerous doses of morphin which seem necessary. Blood-letting has apparently been of service in some cases, and there certainly is no contra-indication to it in the early stage of most cases, the patients at this stage being commonly very strong and vigorous. The cold bath may be employed, but is not an easy treatment to carry out, because of the difficulty in controlling the patient.

### ACUTE CHOREA.

SYNONYMS.—*Chorca minor*; *Mild Chorea*; *Sydenham's Chorea*; *St. Vitus' Dance*.

**Definition.**—A disease chiefly of the young, characterized by irregular, involuntary muscular contractions, associated at times with psychical disturbance, often with rheumatism and endocarditis. The term chorea is derived from the Greek *χορεία*, dancing.

**History.**—The term *chorea Sancti Viti* was first applied by Paracelsus (1493–1541) to an affection of a totally different nature, a sort of hysterical dancing mania which prevailed in epidemic form in the fourteenth, fifteenth, and sixteenth centuries in Germany and the Netherlands, for which the subjects sought relief by pilgrimages to certain shrines, among which was that of St. Vitus, in Zabern, whence the disease was called St. Vitus' dance. From other shrines it received other names, as St. John's and St. Anthony's dance. Chorea minor was first recognized by Sydenham in the sixteenth century, and was also called by him St. Vitus' dance, though a widely different affection from the St. Vitus' dance of Paracelsus.

**Etiology.**—The disease, though not confined to children, occurs far more frequently among them, notably from the time of the second dentition—the sixth or seventh year—to the 15th year. More than three-fourths of the entire number of cases occur during this period. Among adults it is relatively more frequent from the 15th to the 24th year. Occasionally it occurs in old age, when it is known as *chorea senilis*. Chorea is about twice as frequent in the female sex as in the male if all periods of life are considered, but below the period of puberty the difference in the sexes is not so striking. Heredity has always been an acknowledged factor in its causation, but is probably less significant than was once supposed. It has even been claimed that the disease is sometimes congenital in the offspring of a choreic mother. It is more frequent in neurotic families. As to temperament, it is well known that high-strung, excitable, nervous children, as contrasted with the dull and phlegmatic, are especially liable to the disease. It is principally in these that overstudy is seen to have a predisposing effect. Psychical influences are undoubtedly potent; thus, fright causes a large number of cases, while grief causes many, and even joy some.

The so-called Huntington's chorea, which is hereditary, is not the same as Sydenham's chorea, although Charcot did not make this distinction. Sydenham's chorea affects children of all social grades, but is more common among artisans and the lower classes. It is rare in the negro. Wharton Sinkler, who has especially investigated this point, has seen but one case in a full-blooded negro, while William Osler, at the Johns Hopkins Hospital,

out of 175 cases found five in the negro race. It is apparently unknown among Indians in their natural state.

The season of the year appears to have an undoubted influence. Morris J. Lewis, whose studies have been most thorough in this direction, finds that the fewest attacks occur in October and November and the greatest number in March and April. Hermann Eichhorst, on the other hand, says that the greatest number of cases occur in the autumn and winter months. The disease prevails more generally in towns than in the country.

Imitation, commonly regarded as an exciting cause, has been shown by modern studies to play a less important rôle than was thought, many cases described as thus originating being really hysteria. Trauma precedes a certain number of cases. Reflex irritation, especially digestive disturbances, and intestinal worms were regarded as potent causes by the older observers; but here again Osler's studies have failed to find any causal relationship. The chorea of pregnant women has been referred to this category. The causal relation of eye-strain to chorea has been emphasized by Stevens, but is practically denied by George de Schweinitz, who concludes, from an examination of more than 100 cases, that, while ordinary chorea and many forms of facial spasm—habit spasm, etc.—are materially benefited by correcting refractive errors and anomalies of the ocular muscles, he does not believe there is any proof to show that eye-strain is of itself responsible for their origin, with perhaps the single exception of habit spasm affecting the orbicularis and adjacent facial area. It may be such chorea which Howard F. Hansell cured in Da Costa's clinic<sup>1</sup> by atropin, paralyzing the ciliary muscle and preventing the effort at accommodation until the habit was broken up.

The association of arthritis and chorea was observed by the earliest students of the subject, and was distinctly recognized in England as early as 1802, but the exact causal relation of the two diseases has, perhaps, not yet been made out. That they are frequently associated and that there is close connection between the two affections is admitted by English and French writers, but the Germans find the association much less frequent. Steiner, for example, found only four cases of rheumatism in 252 cases of chorea. English observers find from 20 to 70 per cent. of cases of associated joint affection, while in this country, where rheumatism is apparently less frequent in children, the range of percentage found by various observers is from 15.5 to 54 per cent. That the arthritis precedes the chorea in a large number of cases is generally conceded, the latter disease developing with the subsidence of the former, or not until convalescence has been well established. Hence that the rheumatism is the cause of the chorea seemed at one time established, but recent views as to the probable infectiousness of rheumatism and the possible infectiousness of chorea changed the conditions. As the nature of the virus of rheumatic fever is unknown, it may be that chorea is caused by a similar poison. This theory is further sustained by the fact that the infectious diseases play an acknowledged rôle in the etiology of chorea. Scarlet fever, diphtheria, measles, typhoid fever, gonorrhea, secondary syphilis, puerperal fever, pyemia, multiple suppurative polyarthritis, have all been followed by chorea; but with the exception of acute rheumatic

<sup>1</sup> Da Costa's "Medical Diagnosis," eighth ed., p. 221. 1895.

polyarthritis and some forms of septicemia, the number of cases thus associated is not large. On the other hand, acute exanthemata developing in the course of chorea usually check the disease. Anemia has been held to be a cause, and probably is a predisposing cause, although frequently also a result. In fact, the studies of Charles W. Burr and others go to show that anemia is less frequently associated with chorea than has been commonly supposed. The relation of hysteria to chorea is interesting from the close resemblance, at times, of the two conditions. It has already been said that the cases of so-called imitation chorea are often examples of hysteria, and, on the whole, the association of the conditions is rather coincidental than causal, but some cases may be truly imitation in children not hysterical. Poisons are acknowledged causes in a few instances. Carbon dioxid and iodoform are among those which appear to have caused acute attacks of chorea of short duration.

**Morbid Anatomy.**—There is no definitely ascertained morbid anatomy for chorea, and the lesions which have been found are the result of the complications or are incidental. The most constant of these associated lesions are endocarditis, in 85 per cent. of Osler's cases; pericarditis, 26 per cent.; combined heart lesions, 90.4 per cent.; pneumonia, 12 per cent.; less numerous were acute pleurisy, pyemia, and phlebitis, also noticed. As to the nervous system, the symptomatology would lead us to expect the essential lesions in the cortex of the brain, and C. L. Dana has analyzed the recorded autopsies, of which there were only 39 in which the state of the nervous system was accurately described. In 16 there were intense cerebral hyperemia, periarterial exudation, erosions, softened spots, minute hemorrhages, and occasional emboli. The changes were most marked in the deeper parts of the motor tracts, particularly in the lenticular nuclei and the thalami. These changes are the same as those described by W. H. Dickinson in 1876. Essentially similar were the lesions found in two of Osler's cases. In two reported by Bevan Lewis there was apoplexy, one cerebellar and one cerebral and extraventricular. The so-called chorea corpuscles described by Ellischer are in no way characteristic. The same may be said of the swelling and turbidity of certain of the large pyramidal cells in the deeper layers of the cortex in the Rolandic region described by F. C. Turner. The changes in the ganglion cells of the spinal cord described by H. C. Wood in canine chorea have been found also by Triboulet, but he agrees with others who hold that canine chorea is a very different disease from human chorea.

**Nature of Chorea.**—This, it must be admitted, is as yet unknown. It has been intimated that the symptoms are of a kind which would naturally result from lesions in the motor cortical area. No constancy in such lesions is demonstrable. A cerebral seat for chorea is rendered likely by the existence of hemichorea, the association of chorea with mild psychical derangements, and by the fact that choreiform movements are sometimes symptoms of undoubted brain lesions—*posthemiplegic hemichorea*. The embolic theory which was suggested by Senhouse Kirkes, and supported by him, Hughlings Jackson, Broadbent, Tuckwell, and others, was based upon the presence of foci of embolic softening found in a few instances in connection with endocarditis, but has gained few supporters.

The theory which is at the present day naturally attracting most attention is the infectious theory, but the limits of a text-book do not permit its developmental consideration. Suffice it to say that Pianese, of Naples, has apparently isolated from the nervous system of a choreic patient a bacillus which he was able to cultivate successfully, and the cultures from which caused death in animals; also that while the acuter forms present many, if not all, of the conditions necessary to the conception of an infectious disease, the course of the milder forms, their etiology, notably their negative morbid anatomy, seem to demand that the disease be regarded for the present as a neurosis—that is, a disease of functional derangement without known anatomical basis.

**Symptoms.**—*Premonitory* symptoms, both motor and psychical, usually precede the onset of chorea. They include *restlessness* and inability to sit still, and an *altered disposition*, manifested by irritability and perversity. These symptoms, often misunderstood by parents, are sometimes the occasion of reproof and even severe punishment to the child—a course which accelerates and aggravates the disease.

A close study of the symptoms permits of their division into three separate groups, determined chiefly by their severity:

1. A *mild* form, including the majority of cases in which the affection of the muscle is slight, the speech scarcely involved, and the general health slightly disturbed.

2. The *severe*, in which the choreic movements are general, power of speech is lost, and the patient is unable to go about and help himself.

3. The *maniacal*, or *chorea insanicens*, characterized by intense cerebral excitement.

It is, however, unnecessary to separate the symptoms of each variety.

The *motor phenomena* are those first observed. They consist in peculiar jerky movements which begin most frequently in the upper extremities, especially in the right hand, rarely in the legs. They may even be general from the first, though the earliest symptoms often escape notice. *Speech* is affected, sooner or later, in one-fourth of the cases. The extent varies greatly from slight hesitancy to incoherency—the difficulty being in the muscles of articulation rather than in phonation. As a rule, the movements cease during sleep, though they sometimes persist even then. It is not generally believed that the movements extend to the muscles of organic life, though associated irregular and rapid action of the heart has been ascribed to choreic spasm of the papillary muscles. As the disease continues *muscular weakness* becomes manifest in a general want of strength rather than paralysis, though the weakness may be distributed hemiplegically or even monoplegically. It may even precede the jerking movements. Very rarely the pulse may be slow in the feeble state that follows chorea.

*Sensory symptoms* are less conspicuous than motor. Pain is rare, though its presence has been characteristic enough in some cases to obtain from them the name “painful chorea” from Weir Mitchell. Painful points over the sites of emergence of spinal nerves have been pointed out, though they must be rare. *Numbness, tingling, and prickling* sensations are occasionally met, and may be a part of the phenomena of multiple

neuritis sometimes present. *Headache*, sometimes very severe and paroxysmal, may occur, while *epileptiform seizures* are also a rare symptom, and when they occur are probably not a part of the chorea. The *reflexes* are variously affected, the knee-jerk being normal in about half the cases, in the remainder increased or absent. Trophic lesions are almost unknown. *Mental symptoms*, in the majority of cases, are not very conspicuous, though there are in some severe cases extreme manifestations, including melancholia, hallucinations, and even mania, which have their climax in *chorea insanicns*.

Most important are the *symptoms of cardiac disease*, in regard to which William Osler makes the startling statement: "There is no disease in which endocarditis is so constantly found postmortem as chorea. It is exceptional to find the heart healthy." The symptoms which are, therefore, to be always carefully sought include a *systolic apex murmur*, *palpitation*, and *irregular heart action*, although the child rarely complains of the latter or of pain about the heart. It is further important to note that in a majority of these cases the endocarditis is independent of acute arthritis, unless we hold with Bouillaud that in young subjects the heart acts as a joint. Organic *murmurs at the base* are very much more uncommon, most of the murmurs here being functional. They are heard with greatest intensity in the area of the pulmonary artery, but are audible sometimes in the aortic area as well. In a large proportion of all cases in which a murmur is heard at the base or along the left margin of the sternum in the second, third, and fourth interspaces it is functional, but a soft systolic murmur in this area with systolic pulsation in the cervical veins may be caused at the tricuspid orifice.

On the other hand, *endocarditis* sometimes occurs *without symptoms* or physical signs, while the disappearance of physical signs does not prove that endocarditis was not present. A *presystolic murmur* is also at times present, indicating mitral stenosis—in 19 per cent. of Osler's cases. On the other hand, the comparative rarity of simple aortic valve involvement is conspicuous, this being more uncommon than combined aortic and mitral disease, or even combined mitral and tricuspid disease. The tricuspid valves may alone be attacked.

A to-and-fro murmur, indicating *pericarditis*, may be present in from 8 to 25 per cent., and in more than half of these it is associated with endocarditis. It is to be remembered that both forms of organic heart disease, and especially endocarditis, may occur in chorea without rheumatism—*e. g.*, in 66 per cent. of Osler's cases—also that such endocarditis may lay the foundation of permanent organic disease.

W. S. Thayer, in his studies of 689 cases at Johns Hopkins Hospital or Dispensary, found evidence of cardiac involvement in 25.4 per cent. of the cases, and in the wards of the Hospital 50 per cent. The cardiac involvement occurred with somewhat greater frequency in cases where there was acute polyarthritis than where such history was absent.

Cardiac involvement was commoner in cases of chorea with frequent recurrences than in those in which there was but a single attack.

In 110 cases treated in the wards there was fever of moderate degree in almost every instance, and where there was high fever there was

evidence of cardiac involvement. There is good reason for the belief that the presence of fever in otherwise uncomplicated chorea is in a large proportion of cases associated with complicating endocarditis.<sup>1</sup>

Occasional *skin affections* make their appearance in chorea, the larger proportion being due to the prolonged administration of arsenic, so much used in the treatment of this disease. The forms for which the arsenic treatment is more or less responsible are erythematous and papillary eruptions, herpes, and the pigmentation frequently resulting from the prolonged administration of this drug. Eruptions also occur independent of arsenic administration. They are usually purpuric and associated with arthritis, similar in form to the purpura so often associated with rheumatism, and include some of the forms of multiple erythema—as erythema nodosum, purpuric urticaria, or simple purpura. C. H. Brown<sup>2</sup> has reported a remarkable case of subcutaneous nodules composed of young granulating tissue in a case of chorea in a boy of 11.

*Fever* is a rare symptom in chorea, except as the result of complications, of which arthritis is the most common, but endocarditis and pericarditis may also cause fever. The rare instances are cases of *chorea insaniens*, in which the temperature may rise to 105° F. (40.5° C.).

**Diagnosis.**—This is usually easy. *Simple tremor, athetosis, paralysis agitans*, as well as *alcoholic, senile, saturnine*, and *mercurial tremor*, are not likely to be confounded with the movements of chorea. The symptomatic choreiform movements due to cortical irritation by *meningitis, tubercle, hemorrhage, softening, tumor*, or *parasites*, are attended by other symptoms which distinguish them from chorea. In multiple and diffuse *cerebral sclerosis* the so-called *chorea spastica* movements may be very similar, but the early onset—usually in infancy—impaired intelligence, increased reflexes, rigidity, and chronic course of the disease characterize it. *Friedreich's ataxia* might be mistaken for chorea, but it is easily recognized by the lost knee-jerks, the slowness and inco-ordination of movements, talipes, nystagmus, and family distribution. Huntington's chorea is characterized by its hereditation, its limitation to adult life, and ultimate gradually developing dementia.

**Prognosis.**—Except in *chorea insaniens*, which is always fatal, recovery is the rule in from eight to ten weeks. It happens, too, sometimes that the severest cases of the ordinary forms are intractable, and rarely that they terminate fatally after a few days' illness, it may be from exhaustion or it may be from the complicating heart disease. Chorea of the pregnant woman is more serious than the chorea of children.

The *duration* of the disease may be from eight to ten weeks for the ordinary cases and from three to six months for the very severe ones. *Remissions* occur, and *relapses* as well, pointed out by Sydenham. A disposition to vernal recurrence has been noticed.

**Treatment.**—All cases should be carefully examined for causes of reflected irritation, which should be removed; then rest is essential. It is not necessary that the very mildest cases be put to bed, but they should be withdrawn from school and guarded from excitement and the curious gaze of

<sup>1</sup> "Journal Am. Med. Assoc.," Oct. 27, 1906.

<sup>2</sup> "Journal of Mental and Nervous Disease," August, 1893.

friends and strangers, for the movements almost invariably increase when the patient is under observation. More serious cases should be put to bed—a more thorough exclusion as well as rest is thus secured. Not only is recovery thus facilitated, but a diminished liability to heart complication is also attained.

Of drugs, *arsenic* and *iron* hold the first place. The former is given in slowly ascending doses of Fowler's solution until its physiological effect is produced, after which the dose should be gradually diminished. Some one of the preparations of iron should be given continuously in moderate doses. The bromids are also indicated, especially when there are restlessness and want of sleep, when chloral may also be added, and in severe cases may be given continuously. Opiates should, however, never be employed. An old remedy in this country is black snakeroot or *cimicifuga racemosa*, first recommended by the late Hiram Corson, who wrote me that he had used it for 50 years without a failure. I have sometimes used it in the shape of the infusion in mild cases, with apparently satisfactory results, in doses of 1 or 2 fluidounces (30 to 60 c.c.). Modern remedies are antipyrin and physostigma. The former is given to adults in doses of from 7 to 15 grains (0.5 to 1 gm.), much reduced for children. Physostigma has been given in doses of from 1/70 to 1/35 grain (0.0094 to 0.0188 gm.) hypodermically. Hyoseyamin in doses of 1/100 grain (0.00065 gm.), three times a day, has apparently been followed by good results. The oxid of zinc, valerianate of zinc, nitrate of silver, and sulphate of copper, formerly much recommended, have fallen into disuse. In consequence of the close relations between chorea with its attending arthritis and rheumatic arthritis it is reasonable to expect that the salicylates might be useful, but such expectation has not, as yet, been realized.

Montrose Graham Tule attaches great value to apomorphin. He administered in a desperate case, a girl of 15, hypodermically 1/40 grain (0.0016 gm.) which allayed the spasms in three minutes. This was followed up by 1/20 grain (0.0033 gm.) by the mouth every three hours, followed by prompt recovery. Chloralose has also controlled the spasms in an acute case in my hands.

### CHOREIFORM AFFECTIONS.

There remain to be considered some forms of convulsive contractures several of which are included under the term "habit spasm" or "habit chorea," or "tic." The term *tic*, as originally understood, means *facial spasm*. It has, however, been extended by the French school (whose lead in these affections seems at present acknowledged) to include "an habitual, conscious, convulsive movement, resulting in the contraction of one or more muscles of the body, reproducing, most frequently in an abrupt manner, some reflex or automatic action of common life" (Guinon). It is characteristic of these motions that they are more or less under the control of the will, in which respect they differ from the contractions of chorea minor.

## I. SIMPLE TIC.

SYNONYMS.—*Habit Spasm; Habit Chorea.*

Simple tic may be localized or general.

*Localized tic* begins usually in young persons, most frequently in girls from seven to 14 years of age, and may persist through life. The spasm is confined to a single muscle, a group of muscles, or a group of associated muscles, *most frequently the muscles of expression*. The mild forms are looked upon as simply peculiarities of the individual; but the more severe forms, in which nearly all the muscles of the face are affected and even the depressors of the jaw and the tongue are often thrown into action while speaking, are manifestly pathological. It differs from the *idiopathic facial* spasm of adults in that the latter is rarely seen until after the 40th year, and is, moreover, slower than the habit spasm of the facial muscles. It is possible for the simplest forms of habit spasm to be a childish trick perpetuated; such may be a blinking of the eye or the act of sniffing. In other simple forms there is a drawing aside of the mouth or a jerking of the head to one side, or a simple shaking of the head, while the eye is winked at the same time; or there may be shrugging of one shoulder. More rarely the contraction occurs in the legs, as in the very characteristic "string-halt" tic, in which at times the leg is suddenly drawn up. Localized tic may be transient, gradually disappearing after a few months. The French school has devised a method of treatment of these localized tics, consisting of educational movements of the affected muscles.

*Generalized Tic, Electric Chorea* (Henoch).—In this there is sudden electric-like spasm of the muscles of the trunk and limbs, but especially of the neck and shoulders, causing an instantaneous start, which affects the patient for an instant only, when it passes off and leaves him quiet and motionless. The contraction is like that produced by a galvanic shock. It may be associated with facial spasm. It occurs especially in children, but also in adults, particularly in women, and may persist for years.

*Paramyoclonus Multiplex; Myoclonia*.—This term was applied by Friedreich in 1882 to a disease first observed by him, in which there are clonic convulsions in symmetrical muscle groups in the arms and legs without loss of consciousness. It occurs usually in males, and follows emotional disturbances like fright. In addition there is a considerable increase in the tendon reflexes. In order that a case may be one of true paramyoclonus it is necessary that the contractions in the single muscles should be sudden—lightening-like. The muscles affected are commonly those of the trunk and extremities. The contractions are usually bilateral, and vary from 50 to 150 a minute. There are no sensory symptoms. Between the attacks there may be tremors. These cases are allied, on the one hand, to the electric chorea just described, and, on the other, to the different forms of convulsive tic, clonic facial cramp, and clonic cramp of the neck muscles. Some cases of so-called paramyoclonus are really cases of hysteria. This view is sustained by Arthur Conklin Brush<sup>1</sup>, who reports three cases and reviews several.

<sup>1</sup> "The Nature of Paramyoclonus Multiplex," "American Jour. of the Medical Sciences," December, 1899.

*Dubini's Disease.*—The term electric chorea is applied to an acute infectious disease occurring in Lombardy, and known as Dubini's disease, in which there are sudden contractions, first usually in the arm, but passing thence into all the extremities, followed in several weeks or months by paralysis and muscular atrophy, occasionally by epileptiform convulsions and fever. No morbid anatomy has been determined.

## II. TIC WITH EXPLOSIVE UTTERANCES, COPROLALIA, ECHOLALIA, FIXED IDEAS, ETC.

SYNONYMS.—*Maladie de la tic convulsif; Gilles de la Tourette's Disease.*

**Definition.**—In addition to motor spasm, this form of tic is characterized by explosive utterances of certain words and sounds, such as "fire" "murder," "hah," "bow-wow;" or profane words, such as "God damn," "Jesus Christ;" or filthy and obscene words, when it is known as *coprolalia*. There may also be mimicry of words, when it is called *echolalia*, or mimicry of action, *echokinesis*; or the patient may be possessed of a fixed idea of the variety known as *arithmomania*, *délire du toucher*, *onomatomania*, and *folie pourquoi*. In *arithmomania* almost every action is preceded by performing a certain number of acts, as in a patient of Osler's, who before she went to bed had to tap her heel upon the bedstead a given number of times; before drinking a tumbler of water, to rotate the glass nine or ten times, and the same thing when setting it down; before opening a door a certain number of knocks had to be given, and the greatest difficulty was experienced in getting her to brush her hair, as it took so long to count before she began. In the *délire du toucher* there is the constant fear of contamination from contact with objects; in *onomatomania* to repeat over and over again names which arise, and in the *folie pourquoi* to demand a reason for every one of the simplest acts. In other instances the patient imagines that some one is talking to her. All these are in addition to the convulsive acts.

The involuntary movements themselves vary greatly from trifling tic in any one or more of the muscles of the face to contractions involving all the muscles of the body. This condition, which is neither chorea nor habit spasm, is at times mistaken for both. It is commonly easy of recognition, and although of uncertain prognosis, recoveries take place.

## III. COMPLEX CO-ORDINATED TIC.

**Definition.**—This includes a number of forms of habit movement differing from ordinary tic in the more complex nature of the actions performed. It includes tricks and habits, such as those of one who in writing stops at every few words and looks intently at his finger tips; the "head nodding" of children (not to be confounded with the *epilepsia nutans* of children), "thumb sucking," "rocking in bed," and similar actions. Of the same nature is the so-called "head-banging," in which the child, asleep or awake, while in bed, will turn over and bang the head violently into the pillow, repeating this act five or six times or for two or three hours at a time;

or the child may strike the head repeatedly with the fist—*krouomania*; or it may rotate the head violently from side to side, balancing or gyrating the body with great rapidity. This practice is sometimes communicated from one child to another. These movements are met especially in feeble-minded children, in whom it may be accompanied by nystagmus, and is sometimes the result of injury after birth. When these phenomena do not occur in the feeble-minded or after injury early in life, the prognosis is said by Gee and Haden, who have especially studied the subject, to be favorable.

#### IV. SPASM OF THE MUSCLES OF RESPIRATION AND DEGLUTITION.

**Definition.**—The spasm affects the muscles of respiration and phonation, the muscular contraction being accompanied by more or less noise, as a “sniffle” or “hiccough” during inspiration, or some noisy or explosive sound during expiration. Such spasms are sometimes part of a hysterical state. Among those described as thus occurring is a sort of rumbling which comes from low down in the abdomen, passes up the stomach, and out of the mouth as an explosive loud noise—something like belching, but louder. In another instance there was a peculiar clucking noise in the throat accompanying motions, particularly those of swallowing, which disappeared only during sleep. Again, there may be a loud inspiratory cry preceded by three or four deep inspirations and followed by a deep, hoarse, expiratory sound.

#### V. CHRONIC PROGRESSIVE CHOREA.

**SYNONYMS.**—*Huntington's Chorea; Chronic Hereditary Chorea.*

**Definition.**—A disease of adult life, commonly hereditary, characterized by irregular movements, deranged speech, and ultimate dementia gradually developing.

**Historical.**—The affection was first described by C. O. Waters, of Franklin, N. Y., in Dunglison's “Practice of Medicine,” in 1812; again in the “American Medical Times,” 1863, by Irving W. Lyon; fully in 1872 by George Huntington, of Ohio, in the “Medical and Surgical Reporter,” in whose paper the following three marked peculiarities were presented and dilated upon:

1. Its hereditary nature.
2. A tendency to insanity and suicide.
3. Its manifesting itself as a grave disease only in adult life.

Subsequent to Huntington's description little is found in literature until 1884, when C. A. Ewald reported two cases in Germany, and 1885, when Clarence King, in this country, reported another family. Then followed numerous reports; and finally, in Paris, in 1889, the monograph of Huet, and another by Osler, in 1894, in which the history of two families is detailed. Numerous cases were reported between 1889 and 1894.

**Etiology.**—Its frequent hereditary origin has been mentioned. Indeed, heredity is one of its most striking features, 25 per cent. of certain families having been victims, and even more than 50 per cent. of the adults in families. It is especially when both parents were affected, and seriously, that one or more of the offspring almost invariably have the disease if they live to adult age. The two sexes are about equally affected, though in some families males are oftener affected. It is further characteristic that if a generation is skipped, the disease never manifests itself again in that family,

and that it *rarely* presents itself *before 30 years* of age. Huet has, however, collected seven cases of earlier onset. It is said, also, that it is not invariably hereditary, being sometimes due to emotional causes. In all the families in which this choreic tendency has been found the nervous temperament prevails.

**Morbid Anatomy.**—This is somewhat more definite than that of chorea minor. At least, there has been found at necropsy quite frequently a condition of *pachymeningitis* and *hematoma* of the dura mater with atrophy of the cortex, and less frequently a disseminated *encephalitis*, evidenced by sub-cortical foci of round cells. Nothing has, however, been found which can in any way be regarded as peculiar or as accounting for the disease occurring at a certain age or for its affecting certain individuals, though the lesions do explain the motor phenomena. It should be stated that Charcot and his pupil Huet do not separate this chronic progressive chorea from chorea minor, but all other writers do.

**Symptoms.**—The *onset is gradual* in hereditary cases, although it may be sudden in cases arising otherwise. As in chorea minor, *motor symptoms* are the first to appear: first usually in an unsteadiness of the gait or slightly irregular movements of the hands. Occasionally only the *mental symptoms* are the first to appear, not usually manifesting themselves until the motor are well established. Motor symptoms include also *spasm* of the muscles of the face. The movements differ from those of chorea minor in being *slower* and by *absence of co-ordination*, strikingly manifested in walking. The station may be good, except for a slight swaying of the trunk, but an attempt to walk is followed by an unsteadiness characterized by marked lateral deviation from the straight line, by swaying of the body, and sometimes by precipitate falling movement from which the patient may, however, recover himself—in brief, a typical drunkard's gait. This unsteadiness ultimately makes locomotion impossible, and the patient takes to his bed. Yet before this stage is reached, although ataxic, he may be able to walk long distances. While at rest the movements cease altogether. They are aggravated by emotion and excitement, while in the beginning they may to a degree be influenced by the will. Thus, a patient said to me lately: "If I put my mind to it, I can stop it."

*Speech* is affected in most instances, being at first slow and hesitating and interrupted by interjections; later it is indistinct. The handwriting is likewise involved, the letters being irregular and badly formed, running into one another and off the line, and ultimately writing becomes impossible. Sensation and the special senses remain intact, as does the muscular sense, until the disease is advanced. The reflexes are usually increased.

The *tendency to insanity and suicide* has been referred to as an acknowledged symptom. Beginning as a simple irritability or moodiness with depression, it passes slowly over into feeble-mindedness. The suicidal impulse is sometimes carried out.

**Diagnosis.**—This is easy in the hereditary cases only. *Friedreich's ataxia* resembles it slightly, but begins earlier. *Idiopathic double athetosis* also occurs in elderly persons, but in it the movements are associated with rigidity and are of a peculiar character, and the gait is also spastic, while neither rigidity nor spastic gait plays any part in progressive chorea.

**Prognosis** is ultimately fatal. The progress of the disease is progressively and irresistibly from bad to worse.

**Treatment** is of no avail.

## VI. CHOREA MAJOR.

**SYNONYMS.**—*Pandemic Chorea; Automatic Chorea; St. Vitus' Dance; Rhythmical or Hysterical Chorea; Lata; Miryachit; Jumpers; Jerkers; Holy Rollers.*

I prefer to include under this heading all the different varieties of saltatorial spasm of which the historical St. Vitus' dance of Paracelsus, prevalent in the fourteenth, fifteenth, and sixteenth centuries, is the most familiar illustration.

All are varieties of tic, in which strong contractions take place in the leg muscles when the patient attempts to stand, causing a jumping or springing action. All are endemic neuroses, illustrated by the "jumping Frenchmen" of Maine and Canada, the subjects of which are liable, on any sudden emotion, to jump violently and utter a loud cry or sound and obey any command or imitate any action without regard to its nature. The jumping prevails in certain families. Similar were the "jerkers" who appeared during the religious revivals in Kentucky in the early part of the present century; and the "holy rollers," in New Hampshire and Vermont. The disease known as *lata* among the Malays, and *miryachit* in Russia are similar. In the true St. Vitus' dance, chorea major, or *chorea Germanorum*, the paroxysm arises spontaneously; so, also, in the salaam convulsions of children, in which the muscles of the abdomen are affected, and in which there is a bowing forward of the head and body as many as a hundred times or more. The paroxysms may occur several times a day, lasting from a few seconds to as many minutes. In the others, as the American jumpers, etc., it is in response to some external impression. During the paroxysm the affected person sings, dances, jumps from the ground, rolls from side to side, hammers with his hands, stamps with his feet, or whirls madly around until he falls exhausted to the ground.

## VII. POSTPARALYTIC CHOREA AND POSTCHOREAL PARALYSIS.

**SYNONYM.**—*Posthemiplegic Mobile Spasm* (Gowers).

**Definition.**—By this are meant choreiform movements which are the result of cerebral disease, most frequently hemorrhage. They may immediately precede or follow the stroke.

**History.**—Weir Mitchell<sup>1</sup> first called attention in 1874 to certain choreiform movements which sometimes occur in partially paralyzed limbs after an attack of hemiplegia. Later, Charcot recognized the condition and described it.

Posthemiplegic chorea, on the other hand, ordinarily appears in the limbs previously paralyzed, at the time when they again begin to be capable of motion. It is generally sudden, and either continues throughout life or disappears gradually. Often it is associated with contractures. Not infre-

<sup>1</sup> "American Jour. of the Medical Sciences," October, p. 342, 1874.

quently the affected side of the body is anesthetic, and even the organs of special sense may take part in the hemianesthesia, in which cases it is probably a hysterical hemianesthesia.

The movements are more frequent in the hand than in the leg, though sometimes they occur in both, most marked in the fingers and toes, and diminish toward the shoulders and hips. They are really more athetoid than choreic, but quicker, consisting mainly in inco-ordinate gyrations of the fingers and thumbs, flexion and extension of the wrist and elbow, shrugging and other movements of the shoulder. They always cease during sleep. Charcot considers posthemiplegic chorea as identical with athetosis.

**Symptoms.**—The prehemiplegic form is rarer and more serious in significance. The movements vary greatly, and the milder degrees can be recognized only on close examination. In this form the symptoms precede, usually by a few days, the apoplectic stroke, and cease as soon as paralysis appears.

The lesion causing these symptoms is regarded as cerebral, and in that portion of the cerebrum within the internal capsule in which the fibers of the pyramidal tract pass between the lenticular nucleus and the optic thalamus. Sometimes, however, similar phenomena are associated with disease elsewhere, as in the pons or even in the spinal cord; but under any circumstances it would seem to be necessary that there should be irritation of the pyramidal tracts somewhere in their course.

## EPILEPSY.

**SYNONYMS.**—*Morbus caducus sive sacer; Morbus divinus; Falling Fits.*

**Definition.**—Epilepsy is a chronic paroxysmal disease, characterized in its typical form by sudden loss of consciousness and by violent general convulsions (grand mal); but both unconsciousness and convulsions may be so fleeting as to be barely recognized (petit mal); while convulsions may be localized and unattended by loss of consciousness (Jacksonian or cortical epilepsy); finally, seizures may be substituted by conditions of uncontrollable violence or somnambulistic acts (psychical epilepsy).

Epilepsy is, strictly speaking, a syndrome or group of symptoms of which the morbid basis is not always the same. Formerly it was considered essential to the diagnosis of epilepsy that the convulsions should not be toxic, reflex, traumatic, the result of previous brain disease, or heart failure. At the present day toxic convulsions, which are essentially covered in actual practice by uremic convulsions, are not regarded as epileptic, nor are pure reflex convulsions which are due to such causes as teething, constipation, worms, and other forms of peripheral irritation. On the other hand, certain convulsions due to cortical brain lesions, which will be further considered, are acknowledged to be epileptiform. For most cases of epilepsy no anatomical basis has as yet been discovered.

**Etiology.**—From one to six persons out of every 1000 have epilepsy. The tendency of modern studies is to diminish the importance of heredity, formerly so conspicuous as a supposed cause of epilepsy. Gowers' statistics,

which may still be regarded as representing the older pathology, drawn largely from his own practice ascribe to heredity a percentage of 35, while the range in the older statistics is from 9 to 40. Osler's observations, on the other hand, on cases at the Infirmary for Nervous Diseases in Philadelphia, and in the Institution for Feeble-minded Children at Ewlyn, Pa., give the percentage in the two institutions as a little over 1 per cent., and in five cases out of 435 in which the epileptics were children of epileptic parents it was traceable to the mother in every instance. The comparative unimportance of heredity as a cause is upheld by the modern French school, notably by Marie. On the other hand, the disease is of frequent occurrence in neurotic families, including those subject to insanity, hysteria, and neuralgia. So, too, vices of constitution and vicious habits in parents, especially alcoholism and syphilis, are acknowledged causes. The intermarriage of relatives is also an element. More certainly responsible is local disease of the brain *cortex*, including tumors and traumatic disease, such as are produced by fractures, and the conditions described as causing the cerebral palsies in children.

All of these are causes which may be both essential and exciting. Among the more purely exciting causes are fright, irritation by worms in the intestinal tract, dentition, constipation, and the like, all of which may provoke attacks in an epileptic. Some would regard the reflex epileptiform attacks excited by these causes as true epilepsy, and call it reflex epilepsy. But at present these cases should not be called epileptic, since they do not recur after the exciting cause is removed. Such were the two striking cases in my own experience, one of which disappeared entirely after the removal of a tapeworm in a girl of 18, and another after the cure of constipation in a young man of 20. These are very different from others in which attacks are brought on by like exciting causes, but occur also independently of these causes.

True exciting causes are infectious diseases, alcoholism, and syphilis. The influence of infectious diseases is thus shown: Given an epileptic who is subject to seizures once a month, who acquires typhoid fever, the prodromal symptoms are almost always sure to include frequently-recurring epileptic seizures. *Masturbation* is included among the true causes, but is probably only an exciting cause. *Ocular and aural irritations* are exciting causes. *Cardiac epilepsy* is a variety in which there is disturbance of the heart's action, either palpitation or slowing, prior to attacks; but such derangements are symptoms rather than causes, or they may be a mode of manifestation of the aura to be presently described.

Epilepsy is pre-eminently a disease of childhood and youth, and after 20 it is most unlikely to arise. Most cases begin between the ages of 10 and 16. Yet idiopathic epilepsy may occur after 60. It seems to be slightly more frequent in boys than girls, although all statistics do not point this way, whence it may be concluded that the numbers in each sex are nearly equal.

**Morbid Anatomy.**—The cortical lesions described as causing the cerebral palsies of children and some resulting from trauma are found in connection with most cases of Jacksonian or focal epilepsy. *Tumors*, especially those involving the motor layer of the cortex, are among these

causes; so are localized *syphilis*, *pachymeningitis*, and *tyroma* or tuberculous tumor, and sometimes tuberculous meningitis, pointed out by J. Hendrie Lloyd. Lloyd would, however, exclude the gross deformities, such as por-encephalia; and diffuse processes, such as lobar sclerosis, which manifest themselves by idiocy and arrested development, and are not infrequently provocative of epileptic seizures.

*Sclerosis* of different parts of the brain and medulla oblongata is also found in cases of epilepsy. This is especially true of the hippocampus major, this being probably a conspicuous local focus of a more diffuse lesion. Similar sclerosis is sometimes found in the cerebellum. A *nuclear degeneration* and vacuolation of the cells of the second layer of the cortex has been claimed by Bevan Lewis as a distinctive lesion of epilepsy. Many cases of so-called idiopathic epilepsy are still without a demonstrable morbid anatomy.

**Mechanism of the Convulsion.**—The epileptic seizure itself is regarded in the light of our present knowledge as an explosion or *discharge of nerve force*, the seat of discharge, in the severe seizures, at least, being the large motor cells in the deeper layers of the cortex, the function of which is to store up and discharge nerve force. The same mechanism exists in sensory and psychical epilepsy. The explanation is not entirely satisfactory.

**Symptoms.**—These vary in the four varieties known as grand mal, petit mal, Jacksonian, and psychical epilepsy.

1. *Grand Mal.*—In a large number of cases the epileptic attack is preceded by what is known as the *aura*, a peculiar sensation which differs greatly in different individuals. Occasionally it is like what the word literally means, a breath of air, which starts from a particular part of the body, as the extremities or a single finger or toe or a part of the surface of the body, such as the neighborhood of the stomach or the heart. At other times the aura is a simple epigastric sensation, a sense of discomfort or uneasiness emanating from the stomach or the feeling of a ball arising therefrom, and this is not a very uncommon form. It may be a flash of light, which may be of different colors; an object, as a face or faces, and even a coffin—as in one of M. Allen Starr's cases. Auditory auræ are manifested through the sense of hearing, and may be subjective sounds of any kind, including musical tones or even voices. Gustatory and olfactory auræ include subjective tastes and smells, mostly of an unpleasant character. Auræ are represented also by tingling, numbness, or simple flushing or chilliness anywhere in the body. "Intellectual auræ" so called by Hughlings Jackson, are certain mental conditions, such as the "dreamy state," and the consciousness of a certain algebraic formula, which always presented itself to a patient of Starr.

In other cases there is a more prolonged *prodrome*. For several hours or for a day the patient may be the subject of sensations. He may feel generally miserable, dispirited, timid, irritable, or dizzy, or he may be pale or quiet, and wait patiently for the dreaded event, known to him rather by its consequences than its phenomena, of which he is unconscious. There is pathetic sadness often in this patient expectation. *The aura is by no means always present*, indeed, perhaps in the majority of cases of epilepsy there occurs no warning of the attack. The aura may be substituted by certain movements, such as running rapidly for a few minutes either forward or in

a circle—the so-called *epilepsia procursiva*—or the patient may stand on his toes and rotate with great rapidity.

Following the aura or independent of it occurs the *convulsion* or “fit,” of which the initial event is often the *epileptic cry*. This is succeeded by the *fall*, which may be sudden, as if the patient were shot, while serious injury may be a consequence. Following this the phenomena of the fit may be quite sharply divided into *three stages*, that of tonic spasm, of clonic spasm, and of coma.

(a) *The Tonic Spasm*.—In this the head is drawn back or to the right and the jaws are fixed; the arms are flexed at the elbow, the hand is flexed at the wrist, and the fingers are clinched into the palm, while the legs and feet are extended. The muscles of the chest are involved and respiration is suspended, and the face becomes dusky, livid, and swollen, contrasting with the initial pallor. The muscles of the two sides are not equally affected, so that the neck is twisted and the spine curved. This stage lasts but a *few seconds* and is succeeded by clonic spasm.

(b) *The Clonic Spasm*.—Now the muscular contractions become intermittent. At first tremulous and vibratory, they soon become strong and general, until the arms and legs are thrown about in the most violent manner, sometimes so violently as to produce dislocation, usually of the shoulder. The muscles of the face are also involved in distorting contractions, while the eyes roll and the lids open and close. The jaw muscles contract violently and the tongue is apt to be caught and bitten. A frothy saliva, often blood-stained, escapes, and the patient is said to “froth at the mouth.” There may be involuntary discharge of feces and urine. The lividity supervening in the first stage diminishes somewhat during this stage. The temperature rises  $1/2^{\circ}$  to  $1^{\circ}$  F. ( $0.28^{\circ}$  to  $0.55^{\circ}$  C.). Very soon the contractions become less violent, finally abate, and this stage terminates, in *one or two minutes*, in the stage of coma.

(c) *Coma*.—In this the limbs are relaxed and there is profound unconsciousness, but the breathing is noisy and stertorous. The face remains congested, but is no longer cyanotic. The patient may, after a time, be aroused, but if left alone, commonly sleeps several hours, awaking after a time in a remarkably natural state, feeling bruised and aching, but otherwise quite himself; or there may be some mental confusion and even headache.

These are the phenomena of the attack in the vast majority of cases of grand mal. There may not be another attack for several days or a month or more. In severe cases, on the other hand, there may be daily recurrence, though not until the disease has lasted for several years. In a few instances the attacks may follow one another in rapid succession without a return of consciousness, lasting from 12 hours to a day or more, producing the *stat epilepticus*, in the course of which the patient may die from exhaustion. In this state there is often decided fever. In some instances the Jacksonian form of epilepsy may appear as status epilepticus.

After the attack the *reflexes* may be increased and ankle clonus may be obtained; at other times the reflexes are absent. The urine is also often increased, and a small amount of albumin is quite common after the fit. There is also sometimes an increase in the amount of uric acid in the urine *after* the convulsion in *grand mal*.

Inequality of pupils (anisocoria) has been considered a symptom of epilepsy. This symptom,<sup>1</sup> however, occurs in healthy individuals, and too much value should not be attached to it.

2. *Petit Mal*.—The symptoms in minor attacks vary somewhat, but commonly the patient stops in the midst of what he may be doing, the eyes become staring and fixed, the pupils dilated, the countenance pale, there may be some twitching of the facial muscles or the limbs, and consciousness is lost, but there is no convulsion. Anything that is in the hand may be dropped, but in a minute or two consciousness returns and the patient resumes what he has been doing as though nothing had happened. Here, too, though rarely, there may be auræ of various kinds and even an epileptic cry; also forced movements—procurive epilepsy. There may be dizziness without unconsciousness, and the patient may fall. An increase of uric acid in the urine is said also to be quite frequently associated with this form of epilepsy. As the disease continues the attacks of *petit mal* generally become *grand mal*, or the two forms of attack may alternate.

3. *Jacksonian or Partial or Cortical Epilepsy*.—In this, *consciousness is retained*, though it is thought by some that there is always a momentary period of unconsciousness while convulsions occur, though circumscribed to a single group of muscles or to a single limb. It is almost always symptomatic of some focal lesion in the cortical motor area, which may be a tumor, an injury or inflammatory process in the membranes or brain substance, softening, hemorrhage, abscess, or sclerosis. It is especially likely to be a sign of a growing tumor. Hence it is also called symptomatic epilepsy. Previous to the twitching there may be a numbness or *tingling in the part to be involved*, which has been called the "signal symptom" by Seguin, because it ushers in the attack. It may remain during the attack, and is of value in determining the seat of the lesion, and therefore the place for operation. Its seat is usually the same in the same patient in all the attacks.

The spasm or convulsion begins uniformly in one part—it may be the face, the thumb, the toes—thence slowly invades an entire limb. It continues sometimes for three or four minutes or longer. The movement is tonic and clonic, extending from the part in which it begins to other parts in a definite order of extension. Thus, if it begins in a part of the face, it extends thence to the whole face, then to the shoulder, arm, forearm, and hand, and possibly the leg from the trunk down to the toes; or it may start in the fingers and go in the opposite direction. Jacksonian epilepsy also occurs in uremia and progressive paralysis of the insane, and it has already been spoken of as following the hemiplegia of children. After the convulsion, the parts convulsed and especially that in which the spasm begins may be partially paralyzed and awkward in movement, and quite often the numbness and palsy continue for some time, with a moderate degree of tactile or thermal anesthesia. More rarely this paresis is permanent, when it is evidence of changes in the cortex such as may be caused by a growing tumor. Rarely the opposite side of the body is affected, and if this occurs, consciousness may be finally lost.

4. *Psychical Epilepsy*.—This occurs either as a later symptom following the more common forms of *grand mal* and especially *petit mal*, or as an

<sup>1</sup> See a paper by Wendell Reber, "The Pupil in Health and Epilepsy," "Med. News," August 24, 1895.

independent state or as what is known as a "psychical epileptic equivalent," where the usual seizure is substituted by a somnambulistic state in which the patient performs various acts, sometimes of great complexity, including driving, walking, and the like, of which he is totally oblivious after he passes into the natural condition. Some striking instances of psychical epileptic equivalent are related by M. Allen Starr in his book on "Familiar Forms of Nervous Disease." Other manifestations of psychical epilepsy are represented by violent maniacal excitement and uncontrollable violence, in which criminal acts, including even homicide, are committed. See also under Prognosis.

*Relative Frequency and Time of Attacks.*—The major form of attack is the most frequent, after this, mixed forms of major and minor, and then minor and Jacksonian; the most infrequent are the psychical forms.

Two-thirds of the attacks occur between 8 A. M. and 8 P. M.; many attacks occur early in the morning after awaking, some between 3 and 5 A. M., and others in the night at unknown hours—nocturnal epilepsy. In true epilepsy the patient generally feels perfectly well between the attacks—indeed, he not infrequently feels better for a time after the spell.

*Diagnosis.*—The epileptic fit is of itself in no way characteristic of the disease. The uremic convulsion is identical, as is also the reflex convulsion due to teething and other causes. Even hysterical convulsion closely resembles it, but there are points of difference. Something more, therefore, than the convulsion is necessary to prove the presence of the disease. The *aura* is distinctive, and when present, is almost conclusive. Scarcely less so is the epileptic "cry" although it is less constant than the *aura*. The *relaxation of the sphincters* belongs rather to the epileptic fit, while the bitten tongue, the dilated pupil, and sudden unconsciousness belong to uremia as well; and it is from *uremia* that it is most important to distinguish epilepsy. The occurrence in the midst of apparent health of a convulsion with the features described, followed by prompt recovery without albuminuria or casts, can hardly be anything but epilepsy. At other times, when other signs of Bright's disease are absent, it may be necessary to defer the diagnosis a little longer in order to examine the urine. Finally, epileptics may have *Bright's disease*, when errors are still more likely and sometimes unavoidable.<sup>1</sup>

The *reflex convulsion* in children is likely to be repeated until the cause is removed, and in this respect the condition resembles the *status epilepticus*, but in the former a little careful searching will probably discover the cause. The isolated reflex convulsion may be more difficult to account for at first, but in these cases immediate decision is less important, and may await time to help us. The very short duration of the *petit mal* separates it sharply from the uremic fit. Nocturnal convulsions, occurring as they do often without the knowledge of the patient, are usually epileptic.

The *hysterical convulsion* sometimes simulates closely the epileptic. But the hysterical patient rarely loses consciousness completely, the fall is not so sudden, the victim rarely if ever hurts herself, and never bites her

<sup>1</sup> See two interesting cases reported by me in the "Transactions of the Association of American Physicians," vol. vi., 1891.

tongue; nor is there any rise of temperature, while even the pulse and respirations commonly remain quite normal. There is rigidity, but it is unlike that of epilepsy—it is not more conspicuous in the beginning of the attack. Opisthotonos, or arching of the back, does not occur in the epileptic convulsion. Finally, the hysterical convulsion is of longer duration, lasts 10 minutes or more, while the duration of the epileptic fit is not usually more than three or four minutes.

The *petit mal* is most frequently mistaken for *fainting*, but after two or three occurrences it should be recognized. The vertigo of *Ménière's disease* and of attacks of *indigestion* resembles it, but in the former there is deafness, while in neither is there actual unconsciousness, as is always the case in *petit mal*.

Jacksonian epilepsy is *sui generis* and is not simulated by any except the rare instances of *circumscribed uremic convulsions* and similar spasms in *general paresis*; however, it has been described as occurring in hysteria. A further study of each instance must quickly dissipate the error. While the approximate *seat* of the lesion may be inferred in many cases of Jacksonian epilepsy, the precise *cause* cannot generally be determined, because all sorts of lesions produce the same symptoms. Recurring epilepsy in persons over 30 is probably due to organic causes, and in nine cases out of ten, according to H. C. Wood and also Fournier, is due to syphilis.

The highest refinement of diagnosis in the study of epilepsy attempts to determine from the character of the aura the seat of beginning cortical irritation. Thus, a visual aura, it is claimed, might indicate that the nervous discharge began in the occipital lobes; a vertigo might indicate that it began in the cerebellum; a sense of numbness, the sensory area of the cortex. The "intellectual auræ," as they are called by Hughlings Jackson, are regarded by him as affording evidence of a nervous discharge from the highest cerebral centers.

**Prognosis.**—The true epileptic rarely gets well. I believe I have seen two cases of recovery in my experience. In such statement epileptiform attacks due to peripheral irritation are rigidly excluded as not being true epilepsy. These invariably get well with the removal of the irritation, while true epilepsy, in which attacks are readily excited by such irritation, is benefited but not cured. The chances of recovery are said to be greater in the young, and in the male sex than in the female. One of my cases of apparent recovery was a man who had his last fit after 40; the second a woman who had no attack after 14. Both live. C. L. Dana places the recoveries at from five to ten per cent., which appears to me large. Even in cases of combined *petit mal* and *grand mal*, in which the prognosis is most unfavorable, recovery is said to occur. The prognosis of *petit mal* is more unfavorable than that of *grand mal*; of the mixed forms still more unfavorable, and posthemiplegic epilepsy most unfavorable of all.

On the other hand, an epileptic rarely dies of his disease. He may fall in the water during an attack and drown, may choke to death if attacked while eating, or may be smothered by the bed clothes. Death sometimes occurs from exhaustion in the *status epilepticus*, but this is not frequent. The health of epileptics usually deteriorates slowly, and life is shortened.

accordingly, few surviving the age of 40 or 50. They rather frequently die of tuberculous phthisis. Especially frequent is mental deterioration; indeed, it may be said to be the rule when the patient lives long enough, and about ten per cent. become demented or insane. Changes begin with loss of self control succeeded by confusion of intellect. Delirious and passionate outbreaks precede and follow the convulsive seizures during which criminal acts are committed. Much may be done by treatment to control the number of attacks, and the less numerous they are, the less serious is the effect upon the health. Many epileptic persons earn a living, and more could if properly helped.

The more infrequent the attacks, the better the prognosis. Pure nocturnal epilepsy and the pure diurnal form are each more easily cured than the mixed forms. Cases, too, which arise after 20 years of age are more likely to get well.

**Treatment.**—No fact in therapeutics is better established than that the *bromids* control epilepsy in varying degree—it may be completely, it may be simply to render infrequent the seizures. There is probably no important difference in the efficiency of the various preparations, but the bromid of potassium has been most extensively used. The bromid of sodium is preferred on account of its greater solubility. Bromid of ammonium is slightly more stimulating. More recently bromid of strontium has been highly recommended. Causes of *peripheral irritation* should first be sought, and if possible *eliminated*. Gastro-intestinal irritation should be removed. Phimosis should be cured. The possible practice of masturbation should be inquired into. These eliminated, the bromid treatment may be commenced. The doses required vary greatly and must be determined by trial. Scarcely less than 15 grains (1 gm.) four times a day are required for adults, and from this point the dose may be increased until the desired effect is produced. The massive doses sometimes given, amounting to ounces in a day, are ultimately harmful, but doses of a dram (4 gm.) are sometimes necessary and well borne, but if long continued are likely to produce bromism. It is sometimes of advantage to combine the various bromids of sodium, potassium, and ammonium. Greater efficiency is secured if the drug is given on an empty stomach, half an hour before meals or two hours after, and smaller doses suffice when thus administered, and the omission of sodium chlorid from the diet is believed to lessen the amount of bromid necessary and to increase its efficiency. Bromism, shown by drowsiness, mental torpor, gastric and cardiac distress with acne, sometimes results. It is doubtful whether it can be obviated in any way except by omitting the drug. The bromid eruption may sometimes be averted by combining arsenic, but this does not always succeed, and on this account, too, the drug must be omitted. In a few cases the bromids are absolutely useless, more especially in cases in which they produce gastro-intestinal derangement, perhaps in about five per cent. of cases. *Chloral* adds to the efficiency of the bromids, and is sometimes necessary to produce the desired effect. It may be given in doses of from 10 to 30 grains (0.66 to 2 gm.).

Of late dechloridation or elimination of chlorine from the food has been recommended as an adjuvant to the treatment of epilepsy by the

bromids. It is accomplished by substituting sodium bromid for sodium chlorid in the food of epileptics. Sodium chlorid is not wholly eliminated but enough bromid is added to the food to make each patient take about 15 grains a day. It is claimed that the bromid is rapidly absorbed and becomes part of the body tissue when thus given, and that only one-half the usual quantity is necessary to produce the sedative effect. Arthur Morton<sup>1</sup> concludes that this method controls the convulsions and has little if any effect upon the nutrition, although it is likely to cause constipation and does not furnish enough salt to satisfy the patient. He says it may be advantageously employed in intelligent epileptics but useless in middle grade epileptics, as they have neither desire nor will to carry it out.

Flechsig claims for the associated use of opium and bromid superior results, but the possibility of an opium habit will restrain the cautious physician from adopting its use.

To treatment by the bromids should, of course, be added proper hygienic measures. Suitable food, especial attention to the bowels, fresh air, and outdoor life are indispensable. Bathing is important, and cold baths—particularly douches and shower-baths, cold sponge-baths or wet packs should be judiciously used. Vasomotor tone and circulation are thus strengthened.

Of other remedies recommended may be mentioned *antifebrin* and *antipyrin*. A trial of the former in the Vanderbilt Clinic in New York, by M. Allen Starr, was unsatisfactory. On the other hand, in the hands of Charles S. Potts, at the Dispensary of the University of Pennsylvania, it was apparently useful. Especially efficient at the latter proved a combination of antipyrin and bromid of ammonium, suggested by H. C. Wood. For adults a dose of 6 grains (0.39 gm.) of the former and 10 grains (0.66 gm.) of the latter, three times a day, in a number of cases averted the seizure for months. Continuous exhibition seems necessary. These drugs at least merit a trial where the bromids are for any reason unsatisfactory. *Monobromated camphor* has been recommended by Hasle. The best mode of administration appears to be in a capsule or emulsion, the dose being 2 to 5 grains (0.13 to 0.32 gm.).

Starr has also used the *tincture of simulo* (*Capparis coriacea*) at the Vanderbilt Clinic with the effect of reducing the number of attacks in *grand mal*, but to no purpose in *petit mal*. It was used in doses as large as 1/2 ounce (13.5 c.c.) daily. In *petit mal* the same observer found *nitro-glycerin* the only remedy of any service. He appears to have used it in doses of 1/100 grain (0.00065 gm.) three times a day. In my experience this regulation dose fails in a large number of cases to produce the physiological effect, and larger doses—from 1/50 to 1/25 grain (0.0013 to 0.0026 gm.)—may be given. It is to be remembered that epilepsy is one of the diseases which are nearly always influenced for a time by new remedies. The preparations of *valerian* may also be tried in the event of failure with the bromids. Others which have been used are borax, iodid of zinc, and sulphonal. Chloretone is sometimes of great service in doses of 3 grains once or twice daily.

<sup>1</sup> "Boston Medical and Surgical Journal," No. 24, p. 698, 1905.

The *nitrile of amyl* has been employed to abort the attack in cases where there was an aura, and in a certain number of cases—about 25 per cent. in Starr's experience—has proved efficient.

*Operation*, usually trephining, is increasingly practiced, and many successful cases have been reported, chiefly of Jacksonian epilepsy. When a well-defined lesion can be located, operation should promptly be done. Even in doubtful cases operation may be justified, as with modern surgical precautions it is attended with much less risk. It should be remembered, too, that operation *per se* has proved curative—that is, cases have apparently recovered after trephining where no lesion was found after removing the disk.

Food should be simple and easily assimilated, overeating should be especially avoided. Stale bread, wheaten grits, and similar foods, rice, potatoes, fresh succulent vegetables like string beans, peas, and tomatoes, with an abundance of milk, are suitable. Water should be freely drunk by the patient, and a glassful is advised between meals and at bedtime. Constipation must be avoided.

*Asylum Provision.*—It is exceedingly important that some systematic provision should be made for epileptics either by the State or by private charity. They are, as a rule, unwelcome inmates of hospitals because of their incurability and the disturbance they occasion. Doubtless the neglect to which they are subjected at home aggravates in many instances their condition, while it makes even more unhappy their lot. Provision should be made to enable them to pursue some vocation, the tendency of which has been shown to be curative. A hospital with such provision has been inaugurated near Philadelphia, and similar institutions exist in some other States. The mind should be kept occupied; nothing is more baneful to the epileptic than idleness, and it is said that cures have been effected by giving the patient something to do.

*Treatment of the Convulsion.*—Of no small importance is the treatment of the eclamptic attack. The first measure is to secure protection against biting the tongue. Unfortunately, this is often the initial event in the convulsion. The end of a towel may be twisted and inserted between the teeth, or a suitable piece of wood or a clothes-pin may be similarly used. A small object like a cork is unsafe, as it may be swallowed or drawn into the larynx and cause death by suffocation. Some patients carry such an appliance ready for use. The patient should be controlled sufficiently to protect him from injury.

Given a case that under the bromids has yielded to treatment, what course shall be pursued as to its interruption? The most experienced clinicians urge that the drug should be continued at least two years after the fits have disappeared, and Seguin even advises that there should be no reduction in the bromids until three years have elapsed without symptoms. My own practice has been to continue a dose of from 15 to 20 grains (1 to 1.32 gm.) at bedtime for an indefinite period after cessation of the fits. The friends of the patient should be impressed with the importance of such a course, as he himself is almost sure to grow indifferent after the long absence of attacks.

## REFLEX CONVULSIONS OF CHILDREN.

SYNONYMS.—*Infantile Convulsions; Eclampsia; Epilepsia Acuta.*

**Definition.**—Convulsions due to peripheral irritation in children.

**Etiology.**—There is some confusion in the use of the word eclampsia. Some would use it as simply synonymous with the word convulsion, an application, I think, altogether the best. Others apply it to convulsions due to peripheral irritation only; others seemingly to puerperal convulsions only; others, notably Hermann Eichhorst and C. L. Dana, define eclampsia as acute epilepsy. Eichhorst further says: "Epileptiform convulsions, which have the same genesis as true epileptic attacks, are excited by irritation of the cortical motor brain areas." He then names, among the causes of these, toxic agencies, including uremia and lead-poisoning, but also says he will treat only under eclampsia of the convulsions of infants (5 to 20 months), among the causes of which he names heredity; psychical causes, as fright or anger; but most frequently reflex irritation, as of the skin or gastro-intestinal tract (dentition, intestinal worms, inflammation, and the like); foreign bodies; fecal accumulation; stone in the bladder, etc; and finally, the infectious fevers and rickets. This class of cases I have taken great pains to exclude from the epilepsies, and prefer to include at present under the heading of Reflex Convulsions of Children. The convulsions which attend diseases of the brain are a part of the symptomatology of these affections, and do not require separate consideration.

Debility and malnutrition may be considered as predisposing causes of the form of convulsion under consideration.

**Symptoms.**—These demand no detailed consideration, since the convulsion is epileptiform and has been described. It is much more often partial than the typical fit of true epilepsy, but it has the same stages of the tonic and clonic spasm followed by drowsiness. It is most frequently single, but the fits may follow one another in rapid succession, and though rarely, terminate fatally. As in epilepsy, the temperature rises slightly during the fit. It may come on suddenly without warning, or be preceded by restlessness and fever. It not infrequently occurs during sleep.

**Diagnosis.**—This is usually easy, the convulsion coming on suddenly in the midst of health, yet traceable to some such event as the ingestion of some indigestible food, to teething, or to some other source of peripheral irritation.

The convulsion is distinguished from that of *infantile hemiplegia* by the absence of hemiplegia. A transient paresis does, however, sometimes follow the reflex convulsion.

These convulsions most frequently occur between the fifth and twentieth months, and toward the end of the second year, though they may occur as late as the fifth year. Convulsions occurring after this period are more likely to be true epilepsy.

**Prognosis.**—Cases of infantile convulsions are always alarming, yet most get well, and doubtless many cases among the poor recover

which do not come under the notice of the physician. On the other hand, not a few deaths are caused by them—according to Morris J. Lewis, 8.5 per cent. of all deaths in children under 10; and according to West, 22.35 per cent. of all who die under one year. Cases of infectious disease ushered in by convulsions are almost always serious, but the convulsions themselves are rarely fatal. Convulsions due to gastric derangement are generally followed by recovery.

**Treatment.**—The first step in the treatment must always consist in finding and *removing the cause*. If it be undigested food, an emetic and an enema are indicated; if dentition is at fault, the lancet should be promptly applied to the gums. The next step is immersion in a *warm bath*, say at 95° F. (35° C.), increased to 100° F. (38.8° C.), to which mustard may be added. At the same time *cold* should be applied to the head by means of an ice-bag or cold water. To control the convulsion, *chloral* is the remedy *par excellence*, but while waiting for its effect, it may be necessary to permit the child to inhale a few drops of chloroform. The dose of chloral should be sufficient—2 1/2 to 5 grains (0.165 to 0.33 gm.) to a child of one year, frequently repeated until the effect is produced. It may be given in enema in double this dose, the buttocks being compressed until it is absorbed. The *bromids* may be given in combination with chloral, but they are altogether too feeble to be relied upon alone. Should these measures fail, *opium* may be used and even morphin, hypodermically, in minute doses; but these drugs should be used only as a last resort. Generally, the attack is relieved the moment the peripheral irritation is removed.

## MIGRAINE.

**SYNONYMS.**—*Sick Headache; Bilious Headache; Hemicrania; Megrin; Migrän; Paroxysmal Headache.*

**Definition.**—Migraine is an intermittent, sensory neurosis, of which headache, commonly hemicranial, is the most invariable symptom. Almost as constant are aggravated nausea and vomiting, to which may be added other sensory symptoms, especially deranged vision. Ophthalmoplegic migraine is a rare form, in which paralysis of ocular muscles occurs.

**Etiology.**—This is obscure. The disease is more common in females—apparently three times as frequent as in males. It begins early in life, commonly at puberty, and even earlier—as early, in fact, as at two years. It affects vigorous and strong as well as nervous and anemic subjects. Exciting causes are fatigue, mental and physical, including eye-strain, digestive derangements, and menstrual disorders. What is known as the uric acid diathesis plays an undoubted rôle in certain cases. As often none is discoverable.

It is usual to speak of migraine as a vasomotor disturbance, because there are symptoms which point to involvement of the sympathetic system, but this is a matter of inference rather than demonstration. The attacks are characteristically paroxysmal. It appears to be more frequent in

the winter season in this climate, when it is not infrequently associated with a gouty or rheumatic attack. Caries of the teeth and nasal troubles are a cause in children.

**Morbid Anatomy.**—No lesions other than those described as causal are found. The precise seat of the pain is not known, but is believed to be in the meninges of the brain.

**Symptoms.**—The attack is often ushered in without any warning, at others with *prodromal* symptoms familiar to the patient. They are various and not distinctive of the disease, but so characteristic for each case that the individual foretells the attacks on their approach. They include general discomfort, vertigo, a sense of pressure, tinnitus, spots before the eyes, chilliness, and the like. Hemianopsia and scotoma may be among them.

Then the *pain* starts in suddenly and is continuous, usually in one side of the forehead, but it may also be in the occiput, whence it extends to the half or whole head. It is extremely severe, sometimes described as blinding, at others sharp and boring or shooting. It is sometimes attended by flashes of light. Light and noise aggravate it, and a darkened room is always sought. Hemianopsia is not infrequent.

Along with pain there is generally total want of appetite, and intense *nausea* succeeded by *vomiting*. The vomited matter includes first the contents of the stomach (if the stomach is empty, mucous matter), and later yellow and bitter bile, whence the term “bilious headache.” If the stomach happens to be full, the pain may be relieved by the vomiting.

The *vasomotor* symptoms are conspicuous in some cases, and are assigned by some an important rôle in the causation of migraine. From this standpoint two subdivisions are made, *angiospastic hemicrania* and *angioparalytic hemicrania*. In the first form, described by Dubois-Reymond from observations on himself—some of the best descriptions have been by sufferers—the forehead and ear on the affected side are pale, the skin is cool, the temporal arteries are contracted, the *pupil is often dilated*, and the secretion of saliva is increased—in a word, there are the symptoms of irritation of the sympathetic. In hemicrania angioparalytica, described by Möllendorff, also from observations on himself, the face is reddened on the affected side, it feels warm, the temporal arteries are dilated and pulsate strongly, there is sometimes unilateral sweating of the face, with the *pupils contracted*—symptoms suggestive of paralysis of the sympathetic. By no means all cases are capable of being thus classified, and mixed forms are met.

The frequency of the attacks varies greatly; usually they do not occur oftener than once in two weeks or once a month. They may, however, occur every ten days or even weekly.

The duration of the attack varies. Very often the patient goes to bed at night, and in the morning, or at the end of 12 hours, is relieved; or the attack may last 24 hours or even two or three days. the attacks continue over a period of many years, sometimes ceasing in women after the climacteric is passed, and in men after 50.

Further speculation as to the true nature of migraine would be unprofitable here, though mention should be made that the arteries on the

affected side sometimes become the seat of arteriocapillary fibrosis, a condition giving some force to the view of vasomotor origin.

**Diagnosis.**—The symptoms of *brain tumor* sometimes closely simulate migraine. One case of supposed migraine under my observation turned out to be brain tumor. Ophthalmoscopic examination may discover papilloedema in cases of brain tumor and thus settle the diagnosis. Such examination should always be made.

**Prognosis.**—This is favorable so far as life is concerned, but it is not always easy to prevent the attacks or diminish the frequency of their occurrence. It often happens that they cease after middle life.

**Treatment.**—Before treatment is instituted every case should be thoroughly investigated with a view to discovering causal conditions. Should such search be successful, their elimination may result in a cure. Such accessible causes are eye-strain, affections of the nose, mental and physical fatigue, and indiscretions in diet.

The attack itself is more likely to be warded off the earlier the treatment for it is instituted. Sometimes a dose of salts, taken as soon as the first symptoms appear, wards off an attack, or the attack may be relieved by vomiting. *Phenacetin* in from 10 to 15 grain (0.66 to 1 gm.) doses relieves some attacks. Byrom Bromwell in a very impressive paper recommends 30 grain (2 gm.) doses of this drug as curative. After the first dose it may be continued in smaller doses. *Antipyrin* and *antifebrin* are similarly successful, and I am informed by apothecaries that many women purchase these drugs regularly to relieve their attacks. Such practice should, however, be discouraged.

Sometimes a hypodermic injection of *morphin*, even so small a dose as 1/8 grain (0.011 gm.), acts magically, and on the whole it is the most reliable remedy, although it is one to be put off if others succeed. *Caffein* is a less efficient remedy, but may be used in conjunction with morphin or immediately after it to counteract the unpleasant effect of this drug. It may be given in 3 to 5 grain (0.2 to 0.33 gm.) doses, and is sometimes administered hypodermically in the shape of caffein-sodio-benzoate in the same dose. *Salicylate of caffein* is also recommended in like doses. *Cannabis indica* is a remedy much recommended, but is unfortunately of uncertain strength. We may begin with 1/4 grain (0.016 gm.) and increase rapidly. *Bromids* may be tried. *Guarana* is more efficient in from 30 to 60 grain (2 to 4 gm.) doses of the powder and similar doses of the fluid extract.

If the spastic form can be distinctly recognized as present, *nitrite of amyl* may be expected to be serviceable—3 to 5 drops by inhalation. In the opposite or paralytic form *ergot* has been advised, and may be given in doses of from 10 minims to 1 dram (1 to 4 gm.). *Nitroglycerin* in doses of from 1/100 to 1/50 grain (0.00066 to 0.0013 gm.), and *nitrite of sodium* in doses of from 3 to 5 grains (0.2 to 0.33 gm.), may be useful in the class of cases benefited by nitrite of amyl. Cold to the head is sometimes grateful, and when there is nausea, cracked ice or cold carbonated or apollinaris water or small doses of iced champagne are sometimes efficient.

*Electricity* is said to have been useful in a few cases, but I have had

no experience with it. It is recommended that in the spastic form the anode should be applied to the sympathetic, and in the paralytic form the kathode, the other pole being applied to the cervical cord as high as possible on the occiput.

*Preventive Treatment.*—General treatment between attacks should not be neglected. When there is anemia, the judicious use of *iron* and *arsenic*, continued for some time, has occasionally been followed by a disappearance of the tendency to the disease.

The urine should be carefully examined, and if concentrated and tending to deposit uric acid or oxalates, diluents and the alkaline mineral waters are indicated. In a few instances in my practice the daily use of natural Vichy water, to the extent of a bottle a day, had the effect of diminishing, and in one instance of eliminating, the attacks. The conditions of a healthful life, bathing, fresh air, and simple wholesome food, should be observed. Many persons are totally free from attacks while traveling. A course at Contrexville, Vichy, or Carlsbad may be of service in averting attacks,

## OCCUPATION NEUROSES.

SYNONYMS.—*Professional Spasm; Copodyscinesia.*

**Definition.**—A term applied to a group of diseases characterized by symptoms excited by an effort to perform some oft-repeated muscular act, commonly one involved in the occupation of the patient. The most usual symptom is cramp or spasms in the muscles concerned, whence this word is preceded by that of the various occupations, to indicate its special variety. Thus we have writer's cramp or scrivener's palsy, telegrapher's cramp, pianoforte-player's cramp, typewriter's cramp, seamstresses' cramp, milker's cramp, etc.

### WRITER'S CRAMP.

SYNONYMS.—*Graphospasmus; Cheiropasmus; Mogigraphia; Scrivener's Palsy.*

**Definition.**—The professional neurosis of clerks and scriveners. It is the most frequent of the occupation neuroses and may serve as the type for all.

**Historical.**—The first notice of writer's cramp appears to have been by Bernhart Ramazini in 1746. It was first fully described by Sir Charles Bell in 1830, and called scrivener's palsy by Samuel Solly, who published three admirable clinical lectures in "The Lancet" in 1864-65. Other monographs are those by G. V. Poore, in "The Practitioner," in 1872-73 and 1878, also in his "Text-book of Electricity," 1876, and "Med-Chir. Trans.," vol. lxi., 1878; W. H. Erb's article in "Ziemssen's Cyclopaedia," 1876, and O. Berger's article, "Beschäftigungsneurosen," in Eulenberg's "Real-Encyclopädie," first edition, 1880, third edition, 1894.

**Etiology.**—There is no predisposition to sex, the disease being more frequent in men in occupations where more men are employed, and more frequent in women in occupations where more women are employed; and it is likely that since an increasing number of women have become tele-

graph operators, more cases may be expected among them, in whom, perhaps, also, the neuropathic temperament may favor it. The majority of all cases occur between 20 and 50—154 out of 177 cases collected by Berger from Gowers, Poore, and himself. Predisposition is caused by previous injury and a neurotic disposition, while even heredity is said to predispose. An especially important factor is a faulty method of writing, while cases have occurred which were apparently independent of the usual exciting cause. Steel pens are said to be responsible for an increased number of cases since their introduction. The disease is becoming less frequent as clerical exactions grow less.

**Morbid Anatomy and Pathology.**—No distinctive anatomical changes have ever been discovered in writer's cramp. Three theories are held regarding its nature. According to the *first*, it is essentially a local disease: weakness in certain muscles permitting overaction on the part of their antagonists, an overaction which increases to spasm. According to a *second* theory, the spasm is reflex and due to an irritation of the sensory nerves concerned in the act of writing. The *third*, and usually accepted theory, makes the affection primarily and essentially central, due to deranged function in the centers concerned in the act of writing, and therefore in the central nervous system.

The only discoverable morbid change is an occasional atrophy of muscles concerned.

**Symptoms.**—*Spasm* is almost always the initial disturbance, commonly affecting the forefinger and the thumb; but the onset is gradual, and the first effect is an awkwardness in which the pen does not move quite as intended. It is irresistibly grasped too tightly, yet the forefinger has a tendency to slip off, the pen passing between it and the middle finger, while an attempt to mend matters by taking a new hold only increases the difficulty, and the hand labors as if tied down. It feels tired, and there is often an aching pain throughout, extending even to the arm. The writing is irregular and uneven. These symptoms may continue, with more or less difficulty in writing, lasting for weeks or months, coming earlier, however, after each effort, and with gradual increasing severity until the intolerable spasm sets in. This may be so violent in a combined movement of flexion and adduction in the thumb that the pen may be wrested from the grasp and thrown to a distance, or there may be a lock spasm, described by S. Weir Mitchell, in which the pen is firmly locked between the fingers. The spasm is almost always tonic in character, although it may now and then be varied by a slight start or jerk. It is sometimes associated with *tremor*. Rarely tremor occurs alone, and it may be the premonitory symptom of *atrophy*. The spasm may be limited to the act of writing, while other actions are well performed; but absolute limitation to this act is seldom met in severe cases.

Special difficulty attends the performance of acts requiring delicate co-ordination of the muscles. Sometimes a patient can write with a pencil, but not with a pen. *Paresis* and *paralysis* may occur with spasm or alone. On the other hand, the strength of the hand may be quite unimpaired. Such loss of power varies greatly, being sometimes trifling, at other times considerable.

*Sensory symptoms* are almost always present in various degrees. They may even exist alone, producing a sensory form. They are manifested at first by the distressing fatigue alluded to, or by dull pain often referred to the bones or joints, very often to the metacarpal bones or to the wrist, ceasing with cessation of writing. Sometimes there is local tenderness or a tingling sensation. Again, the pain is more severe, neuralgic in character, and distributed along the course of the nerve, induced at first by the act of writing, later by any muscular act of the part. There may also be tenderness in the course of the nerve.

*Vasomotor* disturbances are seen in severe cases, manifested by hyperaesthesia, a glossy, shining skin, or a cyanosed, chilblain-like appearance; or the hand may become blue and hot on attempting to write.

In the beginning the *electrical reactions* are normal, but in advanced cases there is a diminished faradic and sometimes increased galvanic irritability of the motor nerve endings distributed to the muscles. It is to be remembered that the radial, ulnar, and median nerves all supply muscles employed in writing.

**Diagnosis.**—This is usually easy, the initial limitation of the symptoms to the act of writing sufficiently indicating the nature of the case. More frequently other paralytic and painful affections of the arm and hand are mistaken for writer's palsy. Among these may be included *hemiplegia* of gradual onset, *commencing insular sclerosis*, early *tabes dorsalis* affecting the arms, or *pressure palsy of the musculo-spiral nerve*.

In most of these cases, however, other symptoms are present or are soon added. More frequently nervous persons *imagine* they have writer's palsy. In some cases the condition is really one of *muscular rheumatism*.

**Prognosis.**—A well-established case of scrivener's palsy rarely gets well. There are, however, exceptions, even under the most unfavorable conditions. The prognosis is more favorable when sensory symptoms predominate. Relapses are prone to occur when the patient returns to work.

**Treatment.**—*Prevention*, as usual, is much more effectual than curative treatment. The disease is confined almost exclusively to those who write in a cramped manner, and is said to be unknown in those who write from the shoulder. The curative treatment consists essentially in *rest* promptly adopted—a long rest being often sufficient to effect a cure, while no other treatment can take its place. Various *mechanical devices* to aid in writing while the cure is going on have not accomplished much, and the patient may learn to write with the left hand, although the disturbance may occur in this hand also. Typewriting is, as a rule, as easily learned with the affected hand as before disability. The devices referred to may be such as a very thick penholder which can be directed by the whole hand; or a pen attached to a ring, which is slipped over the index or middle finger, and the thumb is thus permitted to rest. The typewriting machine has, however, rendered all such devices of less consequence. The usual nerve tonics, such as strychnin, may be given. Hygiene of the part, including hydrotherapy, frictions, especially massage, and sometimes electricity are useful.

The important position assigned by all neurologists to the *electrical*

*treatment* of writer's cramp demands some special consideration, especially as the methods advised are by no means uniform. The preference given to the galvanic current over the faradic is, however, almost unanimous, and unless the latter is especially mentioned, the former is intended. Berger recommends a *stabile* current—*i. e.*, a current in which the electrodes are not moved about—with the positive pole in the neck and the negative partly in the fossa supraclavicularis, partly on the affected nerves and muscles of the arm; the length of sitting, from five to ten minutes daily, or every other day.

Benedict recommended galvanization along the spinal column, with especial reference to sensitive vertebræ, but also localization of the galvanic current, as recommended by Berger; duration of sitting, three to four minutes, current strong enough to be easily felt. He also found subsequent faradization to the muscles most affected useful. Eulenberg also advised galvanization of the muscles affected with chronic cramp and of the involved nerve-trunk with the positive pole. In cases with tremor and rapid exhaustion the negative pole is to be applied to the spinal column and the positive on the peripheral nerve-trunks and muscles affected. Erb advised galvanization of the cervical vertebral column, with ascending *stabile* and *labile* currents combined with peripheric galvanization. In several cases it appeared to him that transverse and longitudinal currents through the head were followed by favorable results.

Onimus used an ascending current through the affected arm, with the negative pole in the neck and the positive pole upon the muscles of the forearm, especially the ball of the thumb, in addition to a current of moderate strength along the cervical vertebræ. M. Meyer employed a *stabile* galvanic current with the anode to the tender spots on the vertebral column when these were present, and the kathode on the sternum. Althouse sought to reach the cervical cord by placing the anode upon the cervical spine and the kathode on the depression between the angle of the jaw and the sternocleidomastoid muscle—a position corresponding to the superior cervical ganglion of the sympathetic. The current should be mild, uniform, and uninterrupted for from three to five minutes at a time. The method should not be reversed. In cases of paresis of certain muscles it is sometimes of benefit to have the patient make voluntary movements of these muscles simultaneously with the closing of the galvanic current applied to the nerve innervating these muscles.

Testimony is united to the effect that the galvanic treatment must be kept up for a long time, even for months continuously, with a current of moderate strength, say a maximum of four milliamperes, and section electrode of about three qcm.

Faradization is recommended only in cases where there is demonstrable paresis and anesthesia, and then in weak currents. In anesthesia the brush may be used. Erb found that many of his patients were benefited by wearing on the arms, for several hours daily, a simple galvanic element, such as a zinc and copper plate, united by wire, and under it a moist piece of linen.

Gowers has much less confidence in electricity, especially in the spasmodic form of the disease, and is probably right when he says if the patient

goes on writing electricity has not the slightest influence on the disease. My own experience with electricity has not been very encouraging.

The position accorded to *gymnastic exercise* of the arm and hand muscles is scarcely second to that of electricity—indeed, it is preferred by some. Especially efficient appears to be that of a German writing-master, Julius Wolff. The gymnastics are of two kinds: First, active, in which the patient moves the fingers, hands, forearms, and arms in all directions possible, each muscle being made to contract from six to twelve times with considerable force, and with a pause after each movement, the whole exercise not exceeding 30 minutes, and repeated two or three times daily. Second, passive, in which the same movements are made as in the former, except that each one is arrested by another person in a steady and regular manner. This may be repeated as often as the active exercise. Massage is practiced daily for about 20 minutes, beginning at the periphery; percussion of the muscles is considered an essential part of the massage. Combined with this are peculiar lesions in pen-prehension and writing. Priority for this method is claimed by Roman Vigoroux and Th. Shott. The testimony of some of the best authorities in Europe is given in behalf of this method. Poore secured good results by combining gymnastic exercises with the use of electricity. Tenotomy and nerve-stretching have been attempted and abandoned as useless.

## HYSTERIA.

**Definition.**—Hysteria is a morbid state of the nervous system in which may be manifested every variety of nervous symptoms due to deranged function of the cerebral, basal, and spinal centers, associated with lowered will-power and exaggerated emotional tendencies.

**Etiology.**—Hysteria is a disease of civilization and of certain races. It is unknown in the barbarian, and is more rare in Northern races, while the volatile Southern temperament favors its development. Thus, the French and Italians of the Latin race furnish many subjects, while it is rarer among Germans, English and Americans. The disease is also frequent among Hebrews.

The sexual organs of women have been held responsible for hysteria in the female, and the name hysteria is derived from *ὑστέρα*, a womb; but this conception is erroneous. In males the disease assumes more the form of hypochondriasis, but in them also convulsions, contractures, and paralysis occur. It is found in boys as well as in adult males, especially in alcoholic males. About half of all cases occur in the second decade, especially after puberty, though it may also occur earlier; one-third between 20 and 30; while boy subjects are commonly under the age of puberty. Masturbation and adherent prepuce are held responsible for many cases in boys. Heredity plays a certain part, while the neurotic constitution especially favors hysteria.

Among the exciting causes are included diseases of the generative organs in women, but their influence as compared with other illnesses may simply grow out of their frequency. Ovarian disease has been held

responsible, and tenderness in the ovarian region is undoubtedly a frequently associated symptom, but it is questionable whether this tenderness is of ovarian origin. Association with others similarly affected is an undoubted factor, and it is not unusual for the disease to spread itself from one to a number of girls living under the same roof. Various diseases other than those mentioned also predispose to hysteria. Even local affections, including injuries, may thus operate, and hysterical joint affections may follow trauma of a joint. Strümpell relates an instance of a girl who, from having inhaled smoke, acquired hysterical paralysis of the vocal cords. General disease of an exhausting kind, such as fevers, nervous diseases, functional and organic, predispose to hysteria. Hysteria is common in prostitutes. Cerebral tumors, tuberculous meningitis, multiple neuritis, chorea, infantile hemiplegia, often cause conspicuous hysterical phenomena. Diphtheritic paralysis may pass into hysterical palsy, while Gowers has known hysterical convulsions to attend the onset of embolic hemiplegia, as shown by autopsy. Among psychical nervous causes are fright, such as attends a runaway or a fire; an angry scene; the constant operation of trifling mental causes, including worry and anxiety.

**Symptoms.**—An idea of the number and variety of the symptoms of hysteria has probably been obtained from the definition given—a variety which belongs to no other disease, and which may include almost all symptoms excited by any of the numerous nervous diseases. The hysterical patient is, however, characterized by certain general, corporal, and mental peculiarities which should be first considered. Such persons are emotional, irritable, capricious, sensitive, often willful, sometimes because of indifferent early home training and overindulgence. They exaggerate every illness, and demand an inordinate amount of sympathy. If women, they are at times disagreeable and petulant or doggedly silent, while at others they are charming and fascinating. They are often intellectually bright. Hysteria does occur, however, among intellectual degenerates. Other hysterical cases present no mental peculiarities. As to physical development, the hysterical patient is by no means always delicate; indeed, some of the most stubborn cases are those which appear in blooming health, rosy, and well nourished.

The symptoms of hysteria are conveniently arranged in five divisions: 1. Derangements of sensation. 2. Derangements of motion. 3. Vaso-motor derangements. 4. Visceral derangements. 5. Convulsive seizures. 6. Joint symptoms. 7. Mental symptoms.

Some of these symptoms are so common in hysteria and so peculiar to it, that of themselves they are of decided diagnostic value, and as such have received the name of "hysterical stigmata." Among the most important of these are:

1. DERANGEMENTS OF SENSATION.—The symptoms in this category are, as a rule, only elicited by the special examination of the physician, being rarely discovered by the patient. They include, especially, alterations of cutaneous sensibility, manifested by anesthesia or hyperesthesia. Most striking is insensibility to painful impressions, known as *analgesia*. It is usually tested by thrusting a pin deeply into the flesh—an act which

is often totally unfelt. Less invariably is there failure to appreciate the sharp irritation of the electric current. Such analgesia may be confined to definite parts of the body, half the body, or may be general. It may extend to the mucous surfaces as well, and even to the deeper tissues, as those of the muscles and joints. While analgesia is the most common manifestation of deranged sensibility, there may be absence of the sense of temperature, of pressure, and even of the muscular sense.

*Hyperesthesia* is almost equally characteristic. The areas involved may be exquisitely sensitive or but slightly so, requiring, sometimes, considerable pressure to develop the tenderness, while at other times it is elicited by the slightest touch. The hyperesthesia is especially noticeable when the attention of the patient is directed to it by such remarks as, "This will hurt you very much when I touch you." The sensitive areas may also be limited or extended and anywhere—on the head, thorax, limbs. Inguinal tenderness is especially frequent on the left side. Even more characteristic is the hyperesthesia of the spinal column,—the so-called "hysterical spinal irritability"—which affects the column as a whole or in segments, not infrequently a single vertebra. The sensitiveness may be so extreme that the slightest contact may cause the patient to cry out, while strong pressure may be necessary to cause it. Of special interest also are the hysterical zones, to be again referred to.

The *special senses* are variously involved. There may be simple dimness of vision or narrowing of the field, due to anesthesia of the peripheral part of the retina. There is often total amblyopia, but never hemianopsia. The cases of so-called hysterical hemianopsia are rejected by some competent observers. Hysterical achromatopsia is not infrequent. According to Charcot, the loss of the appreciation of violet is the most common, then of green, and, lastly, of blue and yellow. Loss of hearing is not infrequent, and still more frequent is anesthesia of taste and smell, even bitter substances, like quinin, or pungent ones like vinegar, producing no impression or but a trifling one.

2. DERANGEMENTS OF MOTION.—The most striking of these is *paralysis*. It commonly comes on suddenly, apparently as a result of fright or other suddenly acting cause. It may, however, be gradual, and take weeks for its development. It is most frequently hemiplegic, but may be monoplegic, rarely diplegic, while every form of organic paralysis may be simulated. Hemiplegia is more usual on the left side—according to Weir Mitchell, four times as frequent as on the right. The face is not usually affected, the neck and arms rarely, the legs oftenest. The patient can sometimes move the legs in bed or even when sitting up, while all attempts at walking are unsuccessful; or she may be able to move the arms when the eyes are open, but not when they are shut. It is a paralysis of the will. Sometimes one leg only is paralyzed, giving rise to a peculiar gait, the free leg making long strides while the paralyzed one is dragged along with a shuffling noise, and not swung outwardly in a circle as in true hemiplegia. Sometimes there is ataxia with paresis. Paralysis may be either flaccid or spastic. Though far more frequently a symptom of hysteria in women, it may be as striking in men. Paralysis of the vocal cords is one of the most frequent symptoms of hysteria, giving

rise to *aphonia*. The paralysis is easily demonstrable by laryngoscopic examination, because of anesthesia of the pharynx. It may be so marked that the vocal cords actually open with an attempt at phonation. Anesthesia and motor paralysis are commonly associated.

*Contractures* and *spasms* are a form of motor derangement; they may occur alone or with anesthesia and paralysis. They exhibit every variety, and may attack any group of muscles; they may be tonic or clonic, and sudden or gradual in development. The tonic contracture is most usual in the arm, which is flexed at the elbow and wrist, while the fingers grasp the thumb in the palm tightly. In the feet, also, flexures predominate, the feet being inverted and the toes flexed. In the larger joints, on the other hand, the extensors are involved, as a rule. Rarely extensor contractures occur in the small joints; all disappear with chloroform narcosis unless they have persisted a long time and shortening of the muscles, ligaments, etc., has occurred. The reflexes may be very much exaggerated and the condition closely resemble spastic paraplegia. Extreme emaciation may occur in connection with these contractures, as witness a remarkable case related and illustrated by Weir Mitchell in the "Medical News," August 24, 1895.

Even hysterical trismus may occur, and a very striking result of abdominal contracture is the *phantom* tumor, which is found usually just below and in the neighborhood of the umbilicus, often simulating a firm and solid growth. The mechanism of its production, according to Gowers, is a relaxation of the recti and spasmodic contraction of the diaphragm, together with inflation of the intestines and an arching forward of the vertebral column. Women have even been prepared for surgical operation on such tumors when the delusion was dissipated by the anesthetic, and the abdomen has been opened for purely hysterical conditions. Such tumor is not infrequently associated with symptoms of spurious pregnancy—*pseudocyesis*. Visible tremor may be present, rarely hysterical athetosis.

3. VASOMOTOR DERANGEMENTS.—A striking *pallor* is often present, at other times hyperemia, and even a hot skin. *Hemorrhage* from internal organs, especially the stomach and lungs, often alleged, is usually at least apocryphal. Commonly, the blood is derived from the gums, and its amount is never considerable. Yet such symptoms have been the basis of a diagnosis of pulmonary disease or gastric ulcer. Hemorrhages into the skin are also alleged, but are very rare.

*Hysterical fever* belongs also to vasomotor symptoms. A temperature of 106° F. (41.1° C.), and even more, has been reported. Such temperatures are characterized by their irregular occurrence. Actually they are extremely rare, being in most instances traceable to deception, and many doubt their existence.

*Anomalies of secretion* include profuse and scanty perspiration, the latter resulting in a peculiar dryness of the skin; the salivary secretion is similarly influenced, and modifications in the urinary secretion are some of the most characteristic phenomena of hysteria. They include *ischuria*, but especially *polyuria*, the patient passing a large amount of very light-colored urine of low specific gravity. *Excessive thirst* is also frequent,

further augmenting the polyuria. The chemical composition of the urine is altered in many severe cases; thus, the phosphates and urates have been found diminished, while the ratio of earthy to alkaline phosphates may be changed to one to two or one to one, instead of one to three. Such changes are held by Charcot's school to be diagnostic of convulsive hysteria as contrasted with epilepsy.

4. VISCERAL DERANGEMENTS.—The *digestive system* is especially disturbed by simple indigestion, depraved appetite, flatulence, and gastric pain. Not infrequently there is spasm of the esophagus, causing difficulty in swallowing; in some instances expulsion of food before it reaches the stomach. Hysterical vomiting is very common, and alleged vomiting of impossible substances is one of the most characteristic symptoms. An antagonism to food is sometimes present, so extreme that death by starvation has been barely averted; indeed, is said to have occurred. Constipation is a frequent and troublesome symptom. Much more rare is the opposite condition of diarrhea.

*Cardiovascular* and *pulmonary* symptoms exhibit every variety, including irregularity of the heart's action, tachycardia and bradycardia, precordial oppression and sense of suffocation, with extreme frequency of breathing and deranged rhythm. Laryngeal spasm, hysterical cough, and hysterical hiccough are frequent symptoms. *Hysterical cries* with inspiration or expiration, and imitation of the sounds produced by various animals are described by the French neurologists.

5. JOINT AFFECTIONS, purely hysterical, were early studied by Sir B. Brodia, and later by Sir James Paget. They involve the knee and hip and consist of fixation, tenderness, and even swelling.

6. The MENTAL SYMPTOMS are a prominent feature of hysteria, and vary greatly in their manifestations. Irritability and capriciousness of temper, maniacal excitement, hallucinations, and even insanity may occur. The hysterical trance is a well-known condition. It may come on spontaneously, but more frequently it follows one of the forms of hysteroid attacks to be later described. The cataleptic state may be associated with this symptom.

7. CONVULSIVE SEIZURES.—Hysterical convulsions are a recognized symptom, while in some they are the only manifestation of the disease. Their severity varies greatly; but two degrees are described, a milder or minor, and a severer or major.

(a) *Minor Form*.—This may come on suddenly or be preceded by a *prodromè*, including hysterical behavior, such as laughing and crying; a sense of constriction about the throat, or that of a ball rising in it (the so-called *globus hystericus*); a feeling of anxiety with shortness of breath with pain and discomfort in the chest or abdomen (*pseudo-angina*).

In the *actual seizure* the *patient falls*, with this striking feature: that she rarely fails to find a soft spot, such as a sofa or bed, to receive her. The convulsion consists in clonic contractions of a disordered and irregular kind, in which all four extremities and even the trunk may take part. Though seemingly unconscious, the patient still gives to the careful observer the impression of a certain method in her madness. The convulsion lasts usually a few minutes, when it passes off spontaneously, or the patient

may be aroused by some powerful impression, such as the dashing of cold water in the face, or by a sharp galvanic shock. She may remain emotional for a time, but the period of torpidity, so characteristic of the epileptic fit, is rare.

(b) *Major Form (Hysterical Epilepsy).*—This has become widely known, more particularly from the graphic descriptions and vivid pictures furnished by the French school of neurology. It is much less common in this country; indeed, it is rare outside of hospital walls, where prostitutes are the usual subjects. The attack may be preceded by prodromata similar to those that precede the milder attacks. The convulsion is described by French writers as having four distinct stages:

1. The epileptoid state, closely simulating a true epileptic attack, with apparent unconsciousness, tonic spasm, even opisthotonos, grinding of the teeth, livid face, succeeded by clonic convulsions, relaxation, and coma; lasting rather longer than the true epileptic attack.

2. The period of "contortions and grand movements," called by Charcot "clownism," characterized by emotional display, striking contortions, or cataleptic poses.

3. The period of spastic positions and passionate attitudes, including those of ecstasy, fright, beatitude, or eroticism.

4. The return to consciousness and a stage characterized especially by manifestations of delirium with extraordinary hallucinations and by hypnotic "suggestibility." In it visions are seen, voices heard, and conversations carried on with imaginary persons. Imaginary events are related as actually true. These hallucinations sometimes persist even after recovery. These periods are not sharply separated from one another.

*Suggestions and Hypnosis.*—At this point it is suitable to say something of these conditions, so closely associated with the hysterical state and which have attracted much attention of late. By suggestibility is meant the susceptibility of a person to the production of a definite psychical or physical state dependent upon the arousing of corresponding ideas in the mind. It is really a further development of the hysterical mental constitution already referred to, in which the patient permits himself to be dominated by his imagination. Suggestion is merely the artificial fostering of the psychical peculiarity. It is most easy during the part of the hysterical attack when the patients speak, hear, and answer. At such times a definite direction may be given to the patient's ideas. If he is told in an emphatic, convincing manner that he is in a certain situation, be it one of a pleasurable kind or a state of suffering or danger, he believes it, and at once, by behavior or expression, shows that he believes it, and is actually experiencing the conditions named. Physical states may be similarly suggested, such as paralysis, contractures, and anesthetics, while severe pain may be inflicted without exciting sensibility. After the attack is over the subject is totally ignorant of what has transpired, but during another attack may remember the events of the previous one, or, what is still more strange, supposed events, furnishing thus an instance of double consciousness.

*Hypnosis* is closely allied to suggestion. It is regarded by many

as nothing more or less than the intentional production of a hysterical attack, or a hysterical psychosis by suggestion. As Strümpell graphically puts it, "Hypnosis is an artificial hysteria." This view, however, is not held by all. The French school makes four principal forms of the hypnotic state with many transitions:

1. The cataleptic state, in which the limbs retain all the positions artificially given them.
2. The state of suggestion or artificial hallucination, in which patients are induced to eat tasteless and unnatural food with a gusto.
3. The lethargic state: a state of apparent unconsciousness, with the eyes closed, the muscles relaxed, yet with a markedly increased excitability in the muscles and nerves, in which a light tap on a nerve like the facial is sufficient to put all the muscles supplied by it into a tetanic contraction far outlasting the irritation.

4. A state of hysterical somnambulism, in which the patient, while remaining half unconscious, still answers automatically questions put to her, obeying orders or giving them, and sometimes exhibiting certain sensory hyperesthesias. It will be seen that each of these corresponds with one or another of the different manifestations of the hysterical attack.

*Hysterogenous Zones.*—In this connection some further reference should be made to the so-called hysterogenous zones already alluded to. These are hyperesthetic areas especially studied by Richet, on which persistent pressure will sometimes excite a hysterical attack. While the submammary areas, especially the left, and the inguinal region are favorite hysterogenous zones, the zones may be in any part of the body: as, for example, the sides of the trunk. Pressure in such a zone may cause an existing attack to subside. Hysterical spasm may be localized or limited to groups or muscles.

In the above description of hysteria the views long prevalent have been retained. Within the past few years an entirely different conception of hysteria has been promulgated by Babinski.<sup>1</sup>

He defined hysteria as a neurosis made up altogether of symptoms which are produced by *suggestion*, and are capable of cure solely by *persuasion*, either directly or indirectly. He therefore suggested the name pithiatisme, derived from two Greek words *πειθα*, meaning *persuasion*, and *iaōs*, *curable*, curable by persuasion. He regards his conception as a further exemplification of the old nosological adage *naturam morborum curationes ostendant*, the cure indicates the nature of the disease. At greater length he defines hysteria as a special psychical condition manifested principally by certain symptoms which are primary and others which are secondary or accessory. The primary symptoms may be produced by *suggestion* in certain subjects with rigorous exactness and may be made to disappear under the exclusive influence of *persuasion*. They include anesthesia, paralysis, contractures, crises, mutism, etc. The secondary symptoms are those strictly subordinate to the primary. The muscular atrophy in the hysterical person is the type of these. It never appears primarily; suggestion cannot cause it. It is secondary to hysterical paralysis or con-

<sup>1</sup> J. Babinski: *Ma Conception de l'Hystérie et de l'Hypnotisme (Pithiatisme)*. Conférence faite à la Société de l'Internat. des Hôpitaux de Paris, June 28, 1906.

tracture, and never precedes them. It slowly disappears when the muscular function is restored.

Hypnotism he defines as a psychic condition rendering the person who is found susceptible, subject to the will of another. It manifests itself by phenomena which suggestion may produce and persuasion cure, and which are identical with those incident to hysteria. On the contrary, to declare to a patient affected with a psychic paralysis that the symptom with which he is affected is cured, be it by a simple act of the will or by electrotherapy or any other treatment, is not suggestion, for the idea given out is reasonable; it is persuasion.

The word suggestion in the medical sense is employed to express an action by which one tries to make acceptable to another an idea manifestly absurd. For example, to say to someone at a time when it is clear and dry that the heavens are overclouded and it is raining, constitutes a suggestion, for this allegation is in flagrant discord with the truth. To say to an individual whose muscles are functioning normally that he is hemiplegic or paraplegic is also a suggestion, because it is contrary to common sense. If these assertions are accepted, if the visual hallucination or the paralysis is realized, one can say that the person under consideration has been suggestionized or hypnotized.

**Diagnosis.**—This is not usually difficult. There is something indescribable in the bearing and appearance of a hysterical patient which enables the experienced physician often to recognize the disease at a glance. While, as stated, every phenomenon of any organic nervous disease may be present, yet the essential symptoms of organic lesion are still wanting and there are symptoms which are peculiar to hysteria alone. The anesthetics are peculiar in their area of distribution, and hysterogenous zones are nowhere else found. The hysterical convulsion is quite *sui generis*, the throat and pharyngeal symptoms are not found elsewhere, and the emotional symptoms are tell-tale. Cases occasionally occur in which the diagnosis between hysteria and organic disease is very difficult.

**Prognosis.**—This is very rarely serious, though the course and duration of the disease vary greatly. The milder cases may be of very short duration, while the more serious may last for weeks or years, often, however, with intermissions and changes. Only in very rare instances does a fatal result occur, and reports of death from hysteria demand very critical examination.

**Treatment.**—A proper prophylactic treatment, so commonly overlooked, would prevent many cases of hysteria. The counteracting of all that is mentioned under the head of predisposition constitutes such treatment. Wholesome discipline or training in youth, the inculcation of self-denial as contrasted with overindulgence and the gratification of fancy, and careful exclusion from the companionship of hysterical persons make up the sum of these.

The successful curative treatment of hysteria also more frequently depends upon the individuality of the physician than on the remedies employed. Indispensable, however, is the removal of the causes which predispose to the disease, whether they be of the nature of moral influences or bodily ailment. Among the most difficult to eliminate of the former

are those which arise from the fondness and sympathy of relatives who have, from long habit, become almost slaves to the fancies of the hysterical subject, and with whom, in consequence, firmness has become impossible. It is in consequence of such difficulties that the isolation plan of treatment, which has become inseparably associated with the name of Weir Mitchell, has been so successful. Originated for neurasthenic cases, it is as applicable to the hysterical in whom neurasthenia is likewise often present, while hysteria also often forms a large factor in the neurasthenic state. Whenever possible, the patient must be removed from her previous surroundings, her family, and even her friends. This accomplished, the details of management largely depend upon the peculiarities of the case, but in a general way the Weir Mitchell plan may be said to be as follows:

First, and indispensable, is the care of an intelligent and sensible nurse. Under her charge the patient is put to bed and kept in a condition of absolute rest, even reading being prohibited, and also at first self-feeding. Massage is used daily, at first for short periods, which are gradually lengthened, until an hour is thus consumed. With massage is associated electricity, the faradic current with slow interruptions being usually preferred. Thus, with a small electrode, the motor nerve points can be picked out, and the contraction of individual muscles produced. Massage and electricity both have for their purpose the substitution of exercise, to which end the former is by far the most useful and important. Both are discontinued during menstruation. The food at first is milk, which has been usually skimmed, but in my own experience good milk unskimmed and diluted with one-fourth its bulk of water, or aerated water, answers the purpose better. The proportion of casein is less, and the oil, which is so valuable for the nutrition of the patient, is retained in more nearly its normal quantity. At first from four to six ounces of milk are given every two hours. After a week or ten days a chop or a few raw oysters are added at luncheon, with a cup of coffee or tea, and later at breakfast an egg, bread and butter or biscuit with the milk, the latter being continued at two-hour intervals. The patient should have a thorough sponge bath daily at the hands of the nurse. It is convenient to make out a schedule including the hours for nourishment, massage, and electricity, of which the last two should be separated by several hours. Massage should be followed by a full hour's rest. Under this forced feeding the patient gradually fattens, and concurrently with this the excitability of the nervous system usually grows less. In a month or six weeks the patient is allowed to sit up, at first for a few minutes only, but each day a little longer, until the whole day is thus spent, interrupted by periods of rest. Later she is taken out to drive, and then to walk for gradually increasing distance, until, in the vast majority of instances, she is enabled to perform enormous amounts of physical exercise without fatigue. I have known patients bedridden for months and even years, women whose relatives had been worn out with nursing, who, after a few weeks of this treatment, acquired the most vigorous health, walking many miles a day and presenting an appearance of health and strength which would be considered absolutely impossible by one unfamiliar with the results of this mode of treatment. As a rule, three months should be asked for

its fulfillment. As has already been said, the individuality of the physician has much to do with the success of the method. One who has a firm, earnest, yet gentle manner will do more with such cases than one who is vacillating and disposed to yield to the caprice of the patient. An element of "suggestion" must perhaps be acknowledged in the power of the physician thus constituted, yet the full application of this principle of treatment by hypnotic suggestion is to be deprecated. The nurse in charge must be similarly constituted, and it not infrequently happens that a nurse otherwise excellent is totally unadapted for the management of a case of this kind.

As to medicines, the number that are useful are few. Iron and arsenic, in very moderate doses, are the only ones which are actually curative. The various nervous sedatives, including valerian, asafetida, the bromids, the milder hypnotics, such as phenacetin, rarely chloral, may be used as occasion requires; morphin should never, or almost never, be given. A convenient form in which to use asafetida is the suppository; 10 grains (0.66 gm.) may be put in a single one.

The paralysis and contractures generally require some time to overcome, and in some cases are persistent in spite of all treatment. Cure is accomplished mainly by manipulation aided by electricity, under the use of which the symptoms gradually disappear and the patient, induced at first to walk for a few steps, will slowly acquire full power of locomotion. Anesthesia is best treated by faradization and the electrical brush. Paralysis of the vocal cords is also best treated by electricity, suitable electrodes having been devised for that purpose.

Allusion should be made to metallotherapy, a treatment instituted by a French physician named Burq, who years ago ascertained that by laying plates of metal upon a cutaneous surface affected by hysterical anesthesia, sensation is sometimes at once restored not only in the immediate region, but also sometimes in a much larger area. The cases so treated were, for the most part, hysterical hemianesthesias. Iron is the metal most frequently efficient, but sometimes copper, zinc, or gold are employed. The process of determining the metal essential to each individual case was called *metalloscopy*, and Burq held that this metal would also have the same effect if given internally. A committee of the Paris Society of Biology tested these statements in 1876 and confirmed them, except as to the internal administration of the metal. A similar discovery was that of Charcot, also substantiated, that the return of sensation to an anesthetic area as the result of applying a metal plate is accompanied by a simultaneous development of anesthesia upon the opposite side previously normal and in an exactly corresponding place. This is known as transfer. Other hysterical symptoms than anesthesia have been found to exhibit analogous phenomena. Thus, transfer can sometimes be observed in hysterical amblyopia, achromatopsia, deafness, loss of the senses of smell and taste, contractures, and paralysis, while such transfers may be induced by other means than metal plates, known as esthesiogenous remedies. They include large magnets, feeble galvanic currents, static electricity, vibrating tuning-forks, and sinapisms. It must be plain to any thinking person that these phenomena are merely

the result of suggestion produced by ideas similar to those already described. Their career will doubtless end like that of Perkins' tractors. Hypnotism has also been employed of late for the treatment of hysteria, and has acquired some popularity in France, where it has been especially practiced by the school at Nancy. Wonderful cures have doubtless thus been accomplished, but based as it is upon mysticism and imagery, and being already much abused by charlatans, it is to be hoped that its fate will be that of metallothrapy and Perkins' tractors.

### NEURASTHENIA.

SYNONYMS.—*Nervous Exhaustion; Nervous Weakness; Encephal-esthenia; the American Disease.*

**Definition.**—A term originally suggested by George M. Beard, in 1879, for a complexus of symptoms without anatomical basis, in which muscular weakness, nervous irritability, and pain are variously manifested. Beard defined nervousness as "Deficiency of nerve force, manifested chiefly by undue sensitiveness to external impressions," and neurasthenia as "A sign and type of functional nervous disease" evolved out of this general nervous sensitiveness. The line of demarcation between neurasthenia and hysteria is not always definite. Not only do the two conditions sometimes merge, but certain cases of neurasthenia are in no way distinguishable from the minor forms of hysteria. The condition is called *spinal*, *cerebral*, *cardiac*, or *gastric*, according as the symptoms dependent on one or the other of these systems predominate, but the line of demarcation is not sharp.

**Etiology.**—The same class of persons who are predisposed to hysteria are predisposed to neurasthenia, and such predisposition may be inherited or acquired. So, too, many of the exciting causes of the former become the exciting causes of the latter. Among these are overstrain of mind and body, overwork, especially overwork associated with care and anxiety. It is distinctive of neurasthenia as contrasted with hysteria that it is more frequent among men, on whom business care and financial worry fall more severely. It is well known that men differ greatly in their power to bear the mental strain incident to the struggle for existence or business success. From the special prevalence of this disease in America it has been called "the American disease," and is reasonably ascribable to the fact that mental and physical strength in this country is more taxed than in any other.

**Morbid Anatomy.**—Although Beard took great pains to prove that neurasthenia is a physical and not a mental state, and that these phenomena do not come from emotional causes or excitability, but from nervous debility and irritability, there has been found no distinctive morbid change associated with its complexus of symptoms any more than with hysteria. It is barely possible that the investigations of C. F. Hodge and others, demonstrating changes in nerve-cells during functional activity, may result in some further knowledge in this direction.

**Symptoms.**—It has already been said that the symptoms of the minor

forms of hysteria are the symptoms of many cases of neurasthenia. The *appearance* of the patient may be that of perfect health; less frequently he looks worn and worried. In the *spinal* form motor phenomena are the most conspicuous. Of this and, indeed, of all forms, the most constant symptom is *muscular weakness*, as a result of which the patient complains of being tired and weary, even too weak at times to keep out of bed. Such weakness may affect the gait, making it uncertain and trembling, and the acts performed by the upper extremities may be similarly embarrassed. There may be *hyperesthesia* and *paresthesia*, and even the special senses may be affected, especially *vision* and *hearing*. The latter is more frequently oversensitive, and vision may be obscured by the presence of scotomata or muscæ volitantes. In the *cerebral* form especially characteristic is a low-spiritedness or *despondency*, often painful to witness, and which may alternate with *irritability* or *moodiness*. Another symptom is *sleeplessness*, though many patients sleep well; indeed, there is occasionally an irresistible disposition to sleep. A disposition to seek *solitude* is characteristic, while at other times the patient fears to be alone. Again, he is *restless*, unsettled, and impelled to move about from place to place, while there is sometimes a pronounced disposition to *suicide*. *Confusion of mind*, and especially a difficulty in dealing with figures, is a very common symptom, sometimes an initial symptom, the simplest arithmetical problems being quite impossible with one so affected.

The *cardiac* form is characterized by *palpitation* and frequent irregular action of the heart and *precordial pain*, which give rise to the belief in the patient's mind that he has cardiac disease, arteriocapillary fibrosis, or "hardening of the blood-vessels," as it is called by the laity. Of vasomotor phenomena there may be *flashes* of heat, *sudden sweats*, even night-sweats, and a relaxed state of the peripheral blood-vessels to an extent which may cause the "*water-hammer*" and even *capillary* pulse, similar to that of aortic regurgitation. *Epigastric pulsation* is often an annoying symptom in women. In the *gastric* form are, especially, *gastric pain*, the distinctive symptom of "nervous dyspepsia," but there are also distention and discomfort after eating, or a constant noisy motion of gases—*borborygmus*. *Polyuria* is a conspicuous symptom. A slight degree of glycosuria and even intermittent albuminuria have been reported. The opposite condition of urine—a dark hue and high specific gravity—is more rarely present. *Hoarseness*, *aphonia*, and very frequent breathing are regarded as symptoms of neurasthenia as well as of hysteria.

**Diagnosis.**—This is generally easy, and is arrived at by the exclusion of the objective symptoms of organic disease and by the etiology, for it will be observed that all of the symptoms which have been narrated are subjective in character. The so-called *spinal irritation* is a condition which resembles neurasthenia, and probably some of the cases so named which are not hysteria are cases of nervous exhaustion. Sensitiveness of the vertebræ is not apt to be present in neurasthenia, whereas it is the most distinctive symptom of spinal irritation.

**Prognosis.**—Recovery from neurasthenia may be confidently promised to almost every patient who is in a position to meet the indications of a successful treatment, which, unfortunately, are likely to be expensive,

though the modern hospital affords to even the poorer classes an asylum where the treatment may be successfully carried out.

**Treatment.**—The first essential condition of a successful treatment is *removal of the causes* which are responsible for the illness. To this, in the case of women, and sometimes of men, the most successful adjuvant is the *rest treatment* of Weir Mitchell, the technic of which has been already described under the treatment of hysteria. After this and, in the case of men, often even before this, *removal from the scene* and surroundings which attended the development of the disease is most useful. *Travel* away from home, especially in foreign countries, a sojourn at a sanitarium or health resort, the seaside, the woods, the mountains, for prolonged periods, have always, in my experience, sooner or later been followed by recovery. For the poor, the rest-cure as carried out in hospitals may be substituted for the more expensive methods of home treatment.

The treatment of the *insomnia* of neurasthenia calls for brief special consideration, and what is said here may apply to the treatment of any form of simple insomnia, by which I mean insomnia not the result of pain. Modern therapeutics has added to our resources a number of drugs which are more or less efficient to this end. The best of these, considered from all standpoints, is *sulphonal*. Not less than from 10 to 15 grains (0.66 to 1 gm.) should be given to an adult, while twice as much may be given if needed. I prefer to give this dose and repeat it in an hour if no effect follows. It is bulky, soluble with difficulty in cold water, but readily so in any hot menstruum, and especially suitable is hot milk. It should be given an hour or two before sleep is desired, but associated quietude is necessary to secure its effect. Nearly the same may be said of *trional* in the same doses. It is rather more conveniently administered, and may be placed dry on the tongue and washed down with a mouthful of water. *Paraldehyd* is an excellent remedy, but very disagreeable, and is more prompt in its action than sulphonal or trional, and should be given in dram (4 gm.) doses. *Chloralamid* is also a good hypnotic; its dose is 30 grains (2 gm.). It should be dissolved in alcoholic menstruum diluted to 1/2 ounce (13.5 c.c.). *Phenacitin* may be used in doses of from 15 to 30 grains (1 to 2 gm.). *Chloral*, as a simple hypnotic, is better, perhaps, than any of those named, although it has yielded its former high place to those just mentioned because of their harmlessness. It has the further disadvantage of sometimes causing drowsiness the next day, and occasionally it is exciting. From 10 to 30 grains (0.66 to 2 gm.) should be given at a dose. It is especially useful when combined with morphin, making a much smaller dose of this drug efficient, but morphin should not be used if it is possible to get along without it. *Chloralose*, a modified chloral, is often efficient in doses of 5 grains (0.33 gm.) to an adult. It often acts magically but sometimes a second dose excites. Hydrobromate of *hyoscin* may be used in doses of 1/100 grain (0.00066 gm.) if the drugs named fail. Sometimes it acts like a charm, at other times it produces the opposite effect—exciting the patient. One trial suffices to settle the question.

It is true of all the drugs named that their effect is apt to wear off, and increasing doses must be used, and the hypnotic habit is easily formed.

It is, therefore, desirable to obviate the necessity of their use as early as possible, and, if possible, substitute other measures. Often the patient simply needs a start to put him in the way of sleeping, while sometimes the simple feeling that there is something at hand which he can use if he wishes gives him the needed confidence and he goes to sleep at once. A warm *bath* before retiring, or even at times a cool bath or cool sponging, and again a hot bath, promote sleep. To persons residing in cities sleep is often favored by a sojourn at the seaside, many being able to sleep there when they cannot do so at home. The same is true of the country or the mountains.

It is important, too, in our efforts to secure sleep for our patients to investigate the various functions, derangement of any of which may keep a neurasthenic patient awake. Irregularities of digestion and circulation should receive attention. An undigested meal or a loaded bowel often keeps one awake, while an excited heart, by its ceaseless beating, repels the restful sleep without which life is wretched. Often a light meal or a single glass of wine seems to furnish the brain-cells the right amount of stimulus to enable them—

"To shut the banging doors and windows wide  
Of restless sense."

## TRAUMATIC NEUROSES.

SYNONYMS.—"*Railway Brain*"; "*Railway Spine*"; *Traumatic Hysteria*;  
*Erichsen's Disease*.

**Definition.**—A neurasthenic or hysterical state, the result of shock from railroad accident or accident of similar alarming character.

**Historical.**—The condition was first studied by Erichsen in 1868 to 1875, under the designation of "railway spine." Erichsen regarded it as an inflammation of the spinal meninges. Leyden, in 1875, made important contributions to the literature of the subject in treating of spinal concussion. Spitzka, in a review of "Spinal Injuries as a Basis of Litigation," in 1883, referred the symptoms to the category of spinal irritations. J. J. Putnam and G. L. Walton, in 1883, first pointed out the hysterical nature of the affection, a view which is commonly accepted to-day. H. W. Page, an English railway surgeon, published in 1885 a considerable volume directed against Erichsen's view. There still remain a few, and among them S. V. Clevenger, in a work on "Spinal Concussion," published in 1889, and Gowers in his 1892 edition, who hold that railway spine is something more than a purely mental condition. W. A. Hammond suggested an anemic origin.

**Etiology.**—Profound nervous shock, however induced, by railroad accidents, shipwreck, boiler explosions, and the like, even when the sufferer himself is not a victim, but is profoundly impressed by it, is capable of producing this nervous state.

**Morbid Anatomy.**—In the vast majority of cases, anatomical changes are not discoverable; in fact, as most cases recover, there is little opportunity to seek them. In a few, however, morbid alterations have been found in the brain and spinal cord, including *degeneration* of the pyramidal tracts of the cord, demonstrated by Edes in four cases; *multiple sclerotic areas* in the white matter, and *arteriosclerosis* in the vessels of the brain, with scattered areas of degeneration, but the study of concussions in man

has not led to very definite results. The effects of concussions of the brain and spinal cord have been studied in animals, and changes in the nerve-cells and nerve-fibers have been found.

**Symptoms.**—These are not essentially different from those of neurasthenia from other causes. The most remarkable fact with regard to them is that they do not necessarily immediately follow the accident, and there may be some interval of time between the two events—the accident and its result. In some cases the symptoms appear suddenly, in others they are gradual in their invasion. All the symptoms detailed under neurasthenia may be present, especially spinal tenderness and pain in various parts of the body, principally in the back and head; there may be numbness and tingling in the extremities, increased muscular irritability, and increased knee-jerk. The latter varies from day to day, and may be exhausted by repeated stimulation. Extreme depression of spirits is another symptom. Other patients exhibit active hysterical symptoms, including modifications of sensation and motion, hemianesthesia, anesthesia, paresis, and even paralysis.

In the more severe cases in which there is actual concussion the symptoms suggest organic changes, which are, indeed, actually found at times in the shape of pachymeningitis. Such cases exhibit diminished superficial reflexes, with exaggeration of the deep ones. There may be severe pain, variously distributed. Other symptoms are alterations in the temperature sense and in the muscular sense, both of which may be bilaterally distributed. There may also be modification of the special senses, including those of smell, taste, and vision, with inequality of pupils. There may be monoplegia with or without contracture. Symptoms which imply true organic change are optic atrophy, bladder-symptoms, paresis, and exaggerated reflexes. Such cases are sometimes, though rarely, fatal.

**Prognosis.**—Most cases get well. The effect of litigation is often to delay recovery, while successful litigation does not always relieve the symptoms, and when it does, it is by no means always speedily—months and even years elapsing before the cases recover. A few cases, where there is true organic disease, perish.

**Treatment.**—Rest, mental and physical, is the first essential condition of recovery. It may be aided by the measures useful in other forms of neurasthenia, such as massage, electricity, and proper feeding. Medicines avail little, except for their moral effect. Narcotics should be avoided.

## OTHER FORMS OF FUNCTIONAL PARALYSIS.

### ABASIA-ASTASIA.

**Definition.**—Abasia ( $\alpha$  privative;  $\beta\alpha\sigma\iota\varsigma$ , a step) is a term given by P. Blocq, in 1888, to a difficulty in starting the act of walking from a state of previous rest. Astasia ( $\alpha$  privative;  $\sigma\tau\alpha\sigma\iota\varsigma$ , a standing) is an inability to stand, contrasted with integrity of sensation, muscular strength, and co-ordination of other movements of the legs.

**Nature.**—The phenomena are thus far inexplicable in the absence of discoverable lesions, and are usually regarded as hysterical. It is a condition occurring in adults, equally frequent in men and women—as determined by Knapp's study of 50 cases, of which half were in either sex.

**Symptoms.**—These occur in connection with a variety of morbid states, and a large majority of them are doubtless hysterical.

In the "unconscious" variety the patient is without any idea that he cannot walk or stand, when he suddenly finds that he cannot do either. Another variety of abasia-astasia is the "hypochondriacal," in which the patient acts under "conscious" erroneous impression that he cannot walk or cannot stand. It is sometimes associated in the hypochondriacal paranoiac with paresthesia, and in the neurasthenic with abnormally increased sense of fatigue. A third form is associated with some suddenly acting "shock," as fright, which acts inhibitorily on the motions of the patient. Finally there is the "coercion" variety of abasia-astasia, in which the patient, while in the act of walking or standing, is suddenly seized with the idea that he cannot walk or shall not walk. This differs from the hypochondriacal form in that the patient is conscious of the erroneousness and absurdity of the idea, but is nevertheless coerced by it.

These different forms are not always sharply defined. Suddenness is especially characteristic in the "unconscious" form. In other cases the patient may walk a few steps and then suddenly break down. Sometimes he stands rooted to the ground, as it were. At other times the development is slow, requiring even years to reach its acme. Sometimes it is preceded by trembling or staggering, as associated symptoms, the result of the effort of the patient to stand or move forward.

Closing the eyes usually increases the difficulty. On the other hand, sometimes, with the eyes closed the patient can walk in the normal manner, when it is impossible to do so with the eyes open. The latter is especially true of the hypochondriacal variety. In these cases, too, the natural gait is sometimes restored after attempting an unusual method of walking, as walking backward or with the legs crossed or by leaping or in military step. So, also, abasics can walk on all-fours. The morbid state is also influenced by certain surroundings, as broad open surfaces or long narrow corridors or standing without special support. Th. Ziehen refers to a case in which it came on when the patient walked under a tree, the moving leaves of which produced moving shadows. There is sometimes associated tachycardia; at other times evident hysterical symptoms, such as tender spots, hemianesthesia, and the like. In other cases there is epilepsy, paralysis agitans or chorea.

**Diagnosis.**—This is based upon the retention of absolute integrity of sensation, of muscular strength, and of co-ordination of the legs, demonstrable in the recumbent position. From *hysterical paraplegia* it differs in that the power of motion is intact in the recumbent position. From *intermittent lameness* it is distinguished by the fact that in intermittent lameness the inability to walk comes on after the patient has been walking a while, and the power of locomotion is restored after rest. Abasia-astasia has been observed in tumor of the frontal lobe of the brain.

**Prognosis.**—This is regarded as favorable, though relapses occur.

**Treatment.**—The evident hysterical nature of the affection, in the majority of cases, suggests the treatment for such cases. The rest-cure, massage, gymnastics, electricity, gradually increasing practice in walking, are measures which are likely to be useful. Th. Ziehen, to whose article in Eulenberg's "Real-Encyclopädie" I am indebted for much of the information in this section, recommends "suggestion without hypnosis," especially in the hypochondriacal and hysterical forms, as a reliable means of rapid cure; and in the cases in which fear or terror is conspicuous, small doses of opium.

#### FAMILY PERIODICAL PARALYSIS.

**Definition.**—A rare form of hereditary or family paralysis of the voluntary muscles, usually general, except the face, recurring at intervals of from one or two weeks to three months, and confined principally to children. It is attended with a loss of reflexes and electrical reaction, but no mental or sensory disturbance.

The disease is rare. It was first described by Cavaré in 1853 and by Romberg in 1857. Edward Wyllis Taylor<sup>1</sup> collected 25 cases, including two of his own, up to September, 1898, to which John K. Mitchell<sup>2</sup> added a twenty-sixth in 1899.

**Etiology.**—The disease is hereditary and is transmitted through the mother. As many as 12 members of a single family have been affected, though it does not usually affect all the children. Goldflam suggests that the paralysis is due to autointoxication, the poison acting upon the nerve endings in the muscles, while he also found that the urine secreted during the attacks was more toxic than at other times. The view of autointoxication is not accepted by all, and J. J. Putnam has advanced a theory of inhibition. The recent studies of John K. Mitchell on the case referred to, for some time under his observation, tend to confirm Goldflam's view, and also to show that there are two poisons, one of which predominates in one case and the other in another, and according as one or the other predominates the effect is greater on the peripheral nerves and muscles or the spinal center. It should not be omitted that some clinicians, including C. L. Dana, consider the majority of cases hysterical, though he says some may be cases of recurring poliomyelitis.

**Symptoms.**—The disease occurs in *youth* and in the *midst of health, even during sleep*. Beginning as a weakness or weariness in the arms and legs, it is *usually complete in 24 hours*. It is rarely confined to the legs, and may also involve the muscles of the neck, and even those of the tongue and pharynx, while those of the head and face remain intact.

**Sensation** for the most part is *unaffected*, as are also the special senses. The deep reflexes are diminished, sometimes abolished, while the superficial reflexes are feeble. Faradic sensibility of nerves and muscles is greatly lessened, sometimes absent. There is no fever, and sometimes

<sup>1</sup> "Journal of Nervous and Mental Disease," vol. xxv., p. 637, 1898. Dr. Taylor alludes to 53 cases, but does not include cases inadequately reported: as, for example, cases merely mentioned by writers, but not reported in detail.

<sup>2</sup> "Amer. Jour. of the Med. Sci.," December, 1899.

the temperature is below normal, while the pulse is slow. Nothing abnormal has been found in the blood or urine, though the breath is heavy, the tongue is coated, and the urine is relatively diminished during the attack and increased after its termination, as happens in migraine.

The attack recurs at intervals of from one to two or more weeks, in some instances daily. It *begins to abate usually in a few hours or after a day or two*, and ultimately disappears completely, and the patient remains well until another attack sets in.

**Treatment.**—None is of any service, though some of the earlier cases seem to have yielded to quinin, while it is more than likely that these were in some way complicated with malaria.

## VASOMOTOR AND TROPHIC DERANGEMENTS.

### ACUTE ANGIONEUROTIC EDEMA.

**SYNONYMS.**—*Giant Urticaria; Acute Circumscribed Edema of the Skin.*

**Definition.**—Edematous swelling occurring suddenly in various parts of the body, disappearing in a few hours, perhaps to recur again.

**Historical.**—The disease was first accurately described by Quincke<sup>1</sup> in 1882. Strübing<sup>2</sup> proposed the name now adopted, as more appropriate to the symptom-complex.

**Etiology.**—Heredity is sometimes observed, but any other cause is unknown.

**Pathology.**—The condition is regarded by Quincke as a vasomotor neurosis producing sudden dilatation and increased permeability of the vessels. It is, however, one of the derangements which may be said to be of mixed vasomotor and trophic origin.

**Symptoms.**—The *face*, especially the eyelids and nose, is the most usual site, but the swelling may affect any part of the *body*, as the hands, face, or genitalia, including the penis. It may be painful. Even the *mucous membranes* may be invaded, especially the lips, mouth, and pharynx, while a fatal edema of the larynx has occurred. The *onset* is *sudden* and the patient's previous health may have been excellent. *Gastro-intestinal disturbances* manifested by vomiting, colic, diarrhea, and gastralgia, are sometimes associated while they sometimes alternate. They are ascribed to an edema of the mucous membrane. This has been demonstrated from sections of fragment of mucous membrane of the stomach removed by stomach-tube by Roger S. Morris.<sup>3</sup> There are also at times *heat, redness*, and *itching*. While the symptoms arise suddenly, subsiding often as quickly, the disease is likely to be prolonged.

**Treatment.**—Remedies calculated to increase muscular and nervous tone, such as nitro-glycerin, strychnin, quinin, and iron, are indicated. In other respects the treatment is symptomatic, and directed to whatever symptoms demand attention. Morphine is sometimes necessary to re-

<sup>3</sup> "Angioneurotic Edema," "American Journal of Medical Sciences," November, 1904.

lieve pain. Tracheotomy may be necessary to save the life of the patient from death by edema of the glottis.

### RAYNAUD'S DISEASE.

SYNONYMS.—*Local Asphyxia; Symmetrical Gangrene of the Extremities.*

**Definition.**—A vasocontractile disease characterized by three stages, more or less complete—viz.:

1. Local syncope.
2. Local asphyxia.
3. Local gangrene.

**Historical.**—The disease was first described by Maurice Raynaud in 1862. Raynaud's thesis, translated by Barlow, with additional cases and bibliography, is published in volume cxxi., 1888, New Sydenham Society's publications.

**Symptoms.**—The disease is more frequent in women—Raynaud's cases including 20 women and 5 men. It is also a disease of early life; the majority of Raynaud's patients were between the ages of 18 and 30, while five were between three and nine. The first phenomenon noticed is an unusual *pallor or anemia of the part*, resulting in marble-like whiteness and loss of sensation. This is the *local syncope*. Affecting, as it often does, the fingers and toes, these have been called dead fingers and toes. It follows exposure to cold, and to comparatively slight degrees of cold in those predisposed. The condition may disappear under warmth, and then only does pain manifest itself—when the parts are being thawed out, as the saying is. *Local asphyxia* follows, consisting in *engorgement*, the parts previously pale becoming purple and livid. The change is not simultaneous in all the fingers, some being still white while the others are livid.

The local asphyxia may succeed the local syncope, or it may come on independently of it. The tip of the nose and helices of the ears are the parts prone to cyanosis, but in addition to the fingers and toes the hands, feet, and arms and legs may be involved. A peculiar and striking mottling is the result on these large surfaces, produced by an alternation of various shades of purple with intervening lighter-hued spaces. In the darkest areas the capillary circulation is quite stagnant. There are also *swelling*, resulting *stiffness*, and *pain*, the latter often extreme and associated with an intense itching. But in Raynaud's disease there is perhaps more frequently *anesthesia* than pain. These are the phenomena, too, of chilblains, with which so many suffer in this climate with the approach of cold weather. In Raynaud's disease, as in chilblains, these symptoms may pass away in time under the influence of warmth; in fact, for a long time they occur only during the colder weather. A reaction takes place, and the parts assume a bright, red color in which the circulation is very active, and the anemia produced by pressure is rapidly replaced by an active hyperemia. The attacks may keep recurring for years without further effect, though in extreme cases there may be *loss of substance* in the ear-tips and fingers' ends, which in time may become indurated, uneven, and scarred from this cause.

The third stage of *local* or symmetrical *gangrene* is reached in a few cases only. In these the parts affected remain asphyxiated, and the phenomena of dry gangrene make their appearance. The fingers or toes, one or more, become black, dry, and cold, while gangrenous blebs appear in the parts adjacent to the sound tissue, a line of demarcation occurs, and the dead part sloughs away less extensively than at first seemed likely to be the case. Rarely, and only in cases of young children, does a fatal termination occur.

The symptoms that have been described may be said to be essential, but others also may be added of great clinical interest. One of these is *hemoglobinuria*, which is, of course, associated with a corresponding albuminuria. There are, at times, a few blood disks in the urine. Hemoglobinuria, when present, generally occurs at the same time with the cyanosis, and the attack has frequently been preceded by a chill. Other associate symptoms, less common, are scleroderma and edema, probably angioneurotic.

At other times *cerebral symptoms*, including torpor and partial loss of consciousness, are present; at others, epilepsy, mania, delusions, and even temporary hemiplegia. Dimness of vision is a symptom easily explained if we suppose there is a spasm of blood-vessels producing local retinal syncope. Other associated symptoms are peripheral neuritis with tingling and formication—neuritis being regarded as one of the causes of the disease; arthritic swelling; urticaria; erythema; also colicky pains, nausea, vomiting, and diarrhea.

**Pathology.**—Three chief theories have been brought forward to explain Raynaud's disease:

1. That it is due to endarteritis obliterans.
2. That it is caused by peripheral neuritis.
3. That it is the result of vascular spasm.

The intermittent nature of the disease is quite incompatible with its causation by endarteritis, which is progressively increasing in its effects. It is true that some of the results of peripheral neuritis are similar to those of Raynaud's disease, but the frequency of the former affection as contrasted with the rarity of the latter militates, also, against this view.

The theory of arteriole spasm, suggested by Raynaud himself, best explains the symptoms. Its frequency among women and children, whose vasomotor system is so impressible; its occurrence under the influence of cold, which is one of the most powerful excitors of vasomotor spasm; the frequent dimness of vision, which has been shown by ophthalmoscopic examination to be associated with contraction of the central artery of the retina; the occasional precedence of a chill; and the phenomena of hemoglobinuria, all go to show the probability of vasomotor spasm. Since the hemoglobinuria is likely to be associated with hemoglobinemia—which probably arises from the solution of hemoglobin liberated in the asphyxiated parts—such an origin for the hemoglobinuria must be admitted. It will be noticed that the conditions in Raynaud's disease are in some respects similar to those of intermittent hemoglobinuria, and such similarity affords a basis which may ultimately help to explain more satisfactorily the phenomena of both. The relation of Raynaud's disease to chilblains

also affords an interesting field of investigation—in fact, has already been studied by Legroux.

**Diagnosis.**—It is not unlikely that Raynaud's disease and gangrene from endarteritis obliterans have been confounded. Raynaud's disease is limited to smaller areas, as the ends of the fingers, the tip of the nose and the helices of the ears. It is preceded by local pallor. Obliterating arthritis affects larger vessels and limbs, especially the lower limbs, is less apt to be symmetrical, and is more likely to be fatal while Raynaud's disease is rarely so.

**Prognosis.**—This is not altogether unfavorable. Only delicate and feeble children, as a rule, perish, while it is quite possible, under favorable circumstances, to outgrow the tendency.

**Treatment.**—Persons subject to local syncope and local asphyxia should be protected from cold, and when the attack comes on, they should be kept warm, if necessary in bed, the parts being wrapped in wool and subjected to artificial heat. Friction may with advantage be associated. Galvanism and faradism are recommended.

B. B. Cates, of Knoxville, Tenn., has reported the successful treatment of Raynaud's disease by nitroglycerin in doses of 1/100 grain (0.00065 gm.) increased to 1/50 grain (0.0013 gm.) three times a day, and Harvey Cushing has recently reported a case with recovery by the application of the tourniquet or rubber bandage to the affected limbs repeated frequently during the day.

#### PROGRESSIVE FACIAL HEMIATROPHY.

SYNONYM.—*Unilateral Progressive Facial Atrophy.*

**Definition.**—A gradual progressive wasting of the bony, muscular, integumental, and adipose tissue of half the face.

**Etiology.**—That it is a trophic neurosis can scarcely be doubted. In one case—that of Mendel's—which came to autopsy there was the terminal stage of a neuritis in all the branches of the trifacial. In Homen's case, an acute one, and perhaps not strictly to be regarded as an instance of true facial hemiatrophy, a tumor was found pressing on the Gasserian ganglion and trigeminal nerve, but in similar cases of tumor of the ganglion facial hemiatrophy has not occurred. It has been observed in syringomyelia.

The disease usually begins in youth, but in a few cases it did not make its appearance until middle age. It is rather more common in the female sex. Sachs has collected 97 cases.

**Symptoms.**—The atrophy is much more frequent on the left side than on the right. It may begin as a circumscribed spot on the cheek or chin, or diffusely, involving first the subcutaneous tissue, the muscles, chiefly those of mastication, and finally the bones, especially of the upper jaw. In the cases which begin in early youth the muscles remain intact. The tissues of the orbit take part in the atrophy, and the eye appears sunken. The corresponding halves of the tongue and of the soft palate are sometimes involved. The hair on the same side may fall out and appears thin. The

line of demarcation is sharp in the median line. In a few rare instances the disease is bilateral, and in a few cases also the atrophy involves the corresponding shoulder and arm. Sensibility is intact.

**Diagnosis.**—The disease, though very rare, can scarcely be confounded with anything else. The facial asymmetry associated with *congenital*

FIG. 138.—Left Facial Hemiatrophy—(Strümpell).

*wry-neck* alone resembles it. Strümpell mentions a case of facial *hemihypertrophy* in a boy of 10 under his observation. Hypertrophy of one side or of one limb is also a rare condition.

**Treatment.**—A suitable treatment is the application of electricity to the atrophic side, alternated with massage.

#### ACROMEGALY.

**Definition.**—A disease characterized by enlargement of the bones, especially the bones of the hands, feet, and face.

**Historical.**—It was first described by Marie, of Paris, in "Revue de Médecine," 1886. It had, however, been previously described under other names, as "hyperostosis of the entire skeleton" by Friedreich, as general hypertrophy, or "makrosomie," by Lombroso, as "giant growth," by Fritzsche and Klebs. Since then numerous cases have been reported, and the disease was exhaustively described by Arnold, of Heidelberg, in Ziegler's "Beiträge," in 1891.

**Etiology.**—It is a disease of early adult life, usually occurring under 30 and is, perhaps, slightly more frequent in women. Heredity, syphilis, and the specific fevers have preceded the disease, but no necessary relation has been shown.

**Morbid Anatomy and Pathology.**—This consists in a true hypertrophic enlargement of the bones, except the superior maxillary, which contributes

to the enlargement of the face by a dilatation of the antrum, while the lower jaw is simply enlarged. As stated, the enlargement is uniform and symmetrical instead of involving only the shaft as in osteitis deformans, or the ends as in arthritis deformans, and is quite independent of rheumatism. Hyperplasia of the pituitary body has been a striking feature in most cases which have come to necropsy, in every one of 34 collected by Furnival. Marie early sought to make these changes responsible, as disease of the thyroid is for myxedema. Persistence and enlargement of the thymus gland have been found, and atrophy as well as enlargement of the thyroid.

A further study of acromegaly in connection with "giantism," "dwarfism," and "cretinism," go to show that it is at least not improbable that all of these are the result of some deranged function of the pituitary gland. It is well known that giantism may degenerate into acromegaly, while a comparison between the skeletons of a dwarf and a macrocephalic suggests that they are opposite extremes of one and the same process. Of further interest in this connection is the embryonic relation between the pharyngeal tonsil—adenoids in the vault of the pharynx, and the extraordinary influence they have on nutrition—and the pituitary body, which are at one period of development in connection and subsequently separated by ossifications at the base of the skull; while not infrequently in early life they remain connected by a fibrous cord running through the body at the sphenoid.

**Symptoms.**—The most striking features are the *enlarged bones*, especially those of the hands and feet, the appearance of the former being well characterized as spade-like, while the fingers and nails are broad. The *legs* and *arms*, on the other hand, are not elongated early, but late in the disease the forearms and legs may increase in circumference; while the *ends* of long bones, like the femurs, are often prominent. The scapulæ, clavicles, sternum, and the ends of the ribs are also sometimes involved. The proper use of the hands is not interfered with. The *head* and face are *enlarged*, the latter is elongated, while the neck appears short, and the inferior maxilla may project beyond the upper, and the lower lip protrude in consequence. The *ears* are unduly prominent, while the *cartilages* of the nose, eyelids, and larynx are enlarged and thickened, as is also sometimes the tongue. The *spinal column* may be involved, and there may be kyphosis. The *muscles*, on the other hand, are sometimes atrophied, and the genitalia are unusually developed. The skin, though coarse and exhibiting a tendency to perspire, is not thickened as in myxedema.

Among other symptoms are *mental dullness*, a sense of fatigue, and quite severe pain in the head and extremities; *alteration of voice* due to changes in the tongue and larynx, and possibly to paresis of the vocal cords; impairment of special *senses* of taste, smell, and hearing; blindness due to optic atrophy; thirst, shortness of breath, *asthmatic* attacks, *palpitation*, and even *hypertrophy of the heart*. In a number of cases bitemporal hemianopsia has been observed and was due to pressure on the chiasm by the enlarged pituitary body. There are *menstrual derangement* and early cessation of the menses in women. The alterations

in the *thyroid* have been alluded to, and an area of dullness over the manubrium is ascribed by Erb to persistence of the *thymus*.

**Diagnosis.**—This is easy. The difference between acromegaly and *osteitis deformans* and *arthritis deformans* has been mentioned. In *osteitis deformans*, too, as pointed out by Marie, the face is triangular, with the base *upward*, while in acromegaly it is ovoid, with the large end downward. Acromegaly has been mistaken for congenital progressive hypertrophy or "giant growth," but in the latter only one limb is usually involved and the shaft of the bone is affected.

**Prognosis.**—The duration of the disease is long and usually ultimately fatal, although it is sometimes arrested. The fatal cases are probably those with tumor of the pituitary body.

**Treatment.**—None has been found to be of any value. Naturally, one thinks of the possible utility of extract of the pituitary gland, though if the condition be the result of excessive pituitary secretion, but little can be expected from such use. In fact, such has been the result in the few cases in which it has been tried.

#### SCLERODERMA.

SYNONYMS.—*Cutis tensa chronica; Sclerema; Dermatosclerosis; Glossy Skin.*

**Definition.**—A chronic, somewhat diffuse, indurated, hide-bound, and pigmented condition of the skin, trophoneurotic in origin.

**Historical.**—The disease was first described by Alibert, in 1817. A publication on the subject is "Die Sklerodermie," by Lewin and Heller, 1895, in which 508 cases were collected.

**Etiology.**—This is obscure. It is more common in women than in men, and is most frequent in early adult and middle age. In one case under my observation, that of a hack-driver, long exposure to wet and cold seemed a likely cause, and others report similar experience. Rheumatism, especially of the joints, and strong impressions on the nervous system have been regarded as causes.

**Pathology.**—The identity of scleroderma and morphea is claimed by some. I follow Louis A. Duhring in separating them, because both are capable of assuming a variety of forms which present entirely different clinical features at various stages. Scleroderma is much rarer than morphea. In the matured forms, while the epidermis is unaltered, there is increase of pigment in the lower layers of the rete, with a distinct overgrowth of connective tissue in the corium and subcutaneous connective tissue. Contrary to what would be expected, the sweat and sebaceous glands appear to be normal.

**Symptoms.**—The disease appears first in the neck, shoulders, back, chest, arms, and face. It begins usually as a stiffening of the *skin* which passes over into a *hard, tense, unyielding tissue*, resisting motion, and causing fixation and flexion. The patient is literally "*hide-bound*." The hand, with its smooth, glossy surface, utterly without wrinkles, is striking and distinctive. The change may involve the greater part of the body

and even the whole of it. When less general, it is symmetrical. The condition passes insensibly into that of the surrounding healthy tissue. *Pigmentation* is usually a later symptom, but may be an early one.

There is generally *no constitutional disturbance* or other local symptom, such as pain, burning, and tingling, but more rarely these are present. The evolution of the condition is generally slow, requiring weeks and months, and when completed, it is likely to remain unchanged for months or years, or slowly passes away, leaving the skin normal. Rarely, however, an atrophic state may succeed, producing such a shrinking or contraction that the integument is apparently bound to the bones, while over the joints the skin may become so fixed and immobile that ulcers and excoriations are easily produced.

**Diagnosis.**—The diagnosis rarely furnishes difficulty. In some stages it resembles morphea, from which it will be distinguished when that subject is considered.

**Prognosis.**—This should always be guarded, as the disease is often intractable, though recovery sometimes occurs.

**Treatment.**—Treatment of a curative kind is unknown. The patient should be thoroughly protected against cold, as he is exceedingly sensitive. Friction with oil is a rational means for softening the skin, and may give comfort, but does not check the spread of the disease. Cod-liver oil, iron, and arsenic are indicated. The constant electrical current has been recommended in the local forms.

## MORPHEA.

SYNONYM.—*Keloid of Addison.*

**Definition.**—A trophic, asymmetrical neurosis of the skin, characterized by patches of skin firm in texture, white, pale pink, light yellow, or waxy hued, sometimes elevated, at other times depressed.

**Etiology.**—More common than scleroderma, it is also found more often in women, and at all ages. Its etiology is unknown, but its tropho-neurotic origin is more than likely.

**Symptoms.**—The *patches* occur more frequently about the breasts and neck and sometimes in the course of nerves, such as the intercostal or lumbar, or on the face along the branches of the fifth pair. They range from  $2/5$  inch (1 centimeter) to four inches (10 centimeters) in diameter. There may be a *preliminary hyperemia* with itching of the skin and increased pigment deposit, or a milk-white *leukoderma* from the beginning. The *spots* are dry, without perspiration, sometimes scaly. Ultimately there may be *anesthesia*, in pinkish or purplish hyperemic spots or in small linear cicatricial-like areas, which grow rapidly. In fact, the *rapidity of spread* of the spots is one of the most interesting clinical features. In the later stages there are often distinct *atrophy* and *cicatrization* with *pigmentation*. The spots may persist for months or disappear in a few weeks, and though more frequently persistent for a long time, they ultimately disappear spontaneously. The spots seem to be the *direct result* of a *cutting off of the circulation* by a *narrowing of the blood-vessels*. This

may be by compression by an inflammatory exudate, but is more likely to be a vasomotor constriction, probably due to irritation of the vasoconstrictor nerves.

Histologically there is a condensation of the connective tissue of the corium with a shrinkage of the papillary layer.

**Diagnosis.**—Morphea differs from scleroderma in that its lesions are more circumscribed, and in an absence of sclerodermic hardness. Pigmentation and cicatrization usually appear only in the later stages of morphea, while they are seen in the early stages of scleroderma before there is change in structure. Scleroderma is symmetrical in distribution; morphea is not. The atrophic striæ seen in one form of morphea closely resemble the lineæ albicantes of pregnancy or other cause of distention.

**Treatment.**—That recommended in scleroderma may be expected to be useful in morphea, especially arsenic, which is recommended by Louis A Duhring. Here, too, the constant galvanic current is held to be of service, an extended trial being, however, necessary.

### AINHUM.

**SYNONYMS.**—*Ainham*; *Quigila*; *Suhka Pakla*, or *Dry Suppuration*; *Pityriasis athiopijs*; *Scleroderma annulare*.

**Definition.**—A trophic disease, resulting ultimately in the amputation of one or more toes, especially the little toe, confined almost exclusively to male negroes.

**Historical.**—It was first described in 1866 by da Silva Lima, of Brazil, to which country it was at first thought to be limited, but since then cases have been reported from almost every quarter of the tropical and semitropical globe, including the extreme southern United States.

**Etiology.**—It would seem that a moist, sandy soil and warm climate must have some influence in its etiology, but nothing definite is known. Its practical limitation to the colored race has been referred to. The operation of a pathogenic organism has been suggested, and the disease as an amputating leprosy. Traumatism has undoubtedly been associated with it.

**Symptoms.**—Ainhum begins as a furrow or crack at the digitoplantar fold, seen first on the inner side. In a few days the toe will swell and become the seat of a burning, shooting pain, which may extend into the foot and leg, though pain is not constant. The furrow increases laterally and in depth until finally the toe is constricted and the distal end becomes ovoid. The swelling subsiding, spontaneous amputation ultimately takes place, a dry scab forms at the furrow, and the case ends. It is not always confined to one toe, though it is as a rule. Sensation is not usually destroyed, though it may be, and the nail remains unchanged. There are no constitutional symptoms.

The histology of the process has been studied by C. H. Eyles, who concludes that there is an ingrowth of epithelium with corresponding depression of surface, due to a hyperplasia that strangles the papillæ

and cuts off the nourishment of the epithelium and causes it to undergo horny change. The bone changes are those of a rarefying osteitis, proceeding from the periosteum inward. According to Collas, it is an amputating leprosy.

The **diagnosis** is easy. There is no disease which resembles it.

The **prognosis** is favorable as to any danger to life. The duration of the disease is from two to four years.

**Treatment** is unnecessary.

## SYPHILIS OF THE NERVOUS SYSTEM.

SYNONYM.—*Syphilis of the Brain and Spinal Cord.*

**Definition.**—A term applied to the condition and symptoms resulting from invasion of the nervous system by syphilitic disease.

**Etiology.**—Any one of the various lesions which arise in the tertiary stage of acquired syphilis or are the result of inherited syphilis may invade the nervous system. More frequently they are the result of acquired syphilis, but a gummy tumor may develop in the brain of the fetus *in utero*. The phenomena of syphilis of the nervous system present themselves usually a year or more after the primary infection. Exceptionally only do they present themselves before the end of the first year, but may appear a few months after the infection. Occasionally from 10 to 30 years may elapse after the infection before symptoms of syphilis of the nervous system appear.

Age and sex have a bearing only as they influence the distribution of the disease. The same conditions which predispose to the development of other brain affections predispose also to the implantation of the syphilitic poison. Such is the inherited nervous disposition, or vulnerability acquired in any way, say through traumatic or septic agencies. Such predisposition favors the earlier operation of the syphilitic poison as well as of other causes of nervous disease. For evident reasons also nervous syphilis is more frequent in the male than in the female sex.

**Morbid Anatomy.**—As stated, any of the tertiary syphilitic lesions may be the cause of nervous syphilis. While the fundamental process in each instance is the same, it may be quite definitely subdivided into two—

1. Extravascular syphilitic new formations.
  2. Syphilitic disease of the blood-vessels.
1. Extravascular syphilitic new formations include—
- (a) Specialized new formations, the syphiloma or gumma.
  - (b) Simple inflammatory products.

(a) The *syphilitic gumma*, or syphiloma, is a circumscribed yellow or grayish-yellow mass often caseated in the center. It may occur as a single focus or in multiple foci. Its most frequent seat is in the dura mater or the subarachnoid space, whence it invades the brain substance and adjacent vessels and nerves. More rarely it starts *ab initio* in the substance of the brain, whence it sometimes closely resembles the tyroma

or solitary tubercle. The tendency to degeneration, which results in the caseation referred to, is the characteristic feature of the gummy tumor, but it is associated with another property of extreme importance, a fibroid change at the periphery, which produces the appearance of a capsule about the tumor, although no distinct capsule exists. Such fibroid change may also interpenetrate the tumor itself.

(b) Of even greater clinical importance is the *simple inflammatory luetic neoplasm*, which starts in the meninges—*meningitis gummatosa*—most frequently at the base of the brain, especially in the neighborhood of the optic chiasm, but also in the fissure of Sylvius and on the convexity. In these more diffuse areas one often finds, alongside of each other, the different stages of young granulation tissue, cheesy foci, and contracting connective or scar tissue. Either of the two membranes, the dura mater or pia mater, may be involved.

2. *Syphilitic disease of the blood-vessels* includes *intravascular syphilitic growth*.

Starting from the endothelial cells of the intima, it produces a firm connective tissue which differs from atheroma in being thicker and more translucent, but which, after internal administration of iodid of potassium, becomes thinner and more opaque, in fact, more like simple atheroma, for which it is, then, often mistaken. Thickening of the adventitia is also sometimes superadded. It is to be remembered that this intravascular and perivascular formation presents no distinctive histological features, any more than does syphilitic meningitis. The vessels affected are those of the base of the brain, especially the middle cerebral artery and its branches.

The possible results of such intravascular growth are (1) *occlusion*, with resulting necrotic softening or induration of the cortex, especially in children; or (2) *intracranial aneurysms* of the larger arteries. Of these, Gowers says: "We know two other causes of such intracranial aneurysms: one, very rare, is traumatic arteritis. The other is embolism 'imperfectly occluding the vessels,' probably the cause of two-thirds of such aneurysms before the degenerative period of life. In the remainder, in which there is no history of injury and no evidence of embolism, there is a history of syphilis in so many cases as to justify the opinion that most of them are due to this influence. Often the history is imperfect, because the aneurysm has been unsuspected until the final rupture, and syphilis has not been inquired for. When we consider how great is the amount of new-growth in the walls of a diseased artery, and how prone are the new elements to change into extensible fibroid tissue, the wonder is that aneurysm is not a more frequent occurrence. Probably the explanation is to be found in the common persistence of the elastic layer, which affords the chief safeguard against permanent dilatation."

(3) A third effect of syphilitic vascular disease is *hemorrhage* within the substance of the brain, and small hemorrhages are not uncommon within the brain and spinal cord.

In the *spinal cord*, syphilis frequently produces chronic inflammation of the dura mater—spinal pachymeningitis. Its effect is mainly seen on the spinal and bulbar nerve-roots, although the cord also may be invaded

by sclerotic fibrous tissue. The pia mater may be invaded in association with the dura mater, especially in diffuse inflammation, and sometimes is more involved than the dura mater. The most common syphilitic manifestation in the spinal cord, however, is meningo-myelitis. Gummata visible to the naked eye are seldom found in the spinal cord.

The *cranial nerves* may suffer from compression by tumor or chronic meningeal inflammation, or may be invaded by an inflammation involving the sheath and interstitial tissue.

**Symptoms.**—Of fundamental importance in studying the symptomatology of nervous syphilis is the fact that the symptoms due to syphilitic disease are in no way distinctive. They are essentially the same as those of tumor or meningitis or occlusion of blood-vessels from other cause. This being admitted, it might seem scarcely necessary to make a separate subject of syphilis of the nervous system. It, however, affords opportunity for a somewhat more systematic classification of the lesions and a review of the symptoms caused by them.

These symptoms vary with the seat of the lesion, of which sometimes quite a close diagnosis can be made. The specific nature of the lesion may be inferred to a degree from the symptoms, but most largely from the history. From the grouping of the symptoms may be inferred the most important of the local processes, as originally suggested by Huebner. They are:

1. *Basal Brain Syphilis or Basal Gummy Meningitis.*—The symptoms are to a certain extent those of a tumor in this section—viz., *general cerebral and focal symptoms*, due to the local effect of the growth.

*General symptoms* are intense headache, often worse at night, apathy, loss of memory, somnolence, and tendency to stupor, all of which characterize more or less the typical tumor of the brain. Maniacal excitement, ultimate imbecility, and physical weakness may supervene.

The *compression or focal symptoms* due to basal syphilis are also the same as those due to tumor. The nerves concerned are especially the optic and oculomotor (third), and to a less degree the trochlear (fourth) and abducent (sixth) of the eyeball. The symptoms include narrowing of the field of vision, hemianopsia, and even total blindness, alterations in the pupil and defects in the movement of the ball and eyelids. In syphilis these effects are irregular and seldom bilateral. There may also be optic neuritis and even choked disk, but the latter is less frequent than in other varieties of brain tumor. Syphilomata always cause a rapid and severe form of optic neuritis, so that chronicity in a neuritis is presumptive evidence against its syphilitic origin. Especially characteristic of syphilis is variation in the severity of the symptoms, due to variation in intracranial pressure the result of contraction of the new formation; and especially characteristic is amelioration, the result of properly timed specific treatment. Other nerves which suffer are the auditory, facial, olfactory, and trigeminal. Gummata on the nerve-trunks furnish no symptoms distinct from those of inflammation.

The course of syphilitic lesions is subacute or subchronic, never acute or chronic. Marked improvement, arrest, and even cure may result from proper treatment. On the other hand, involvement of the blood-

vessels by syphilitic disease may lead to hemiplegia, epilepsy, and bulbar symptoms, of which there can only be one eventual termination, and that a fatal one, but the patient may live a long time.

2. *Gummy Meningitis and Syphiloma of the Convexity and Neighborhood of the Fissure of Sylvius.*—In this more rare seat of localization the same prodromata may precede the severer symptoms, sometimes for a considerable time. These severer symptoms include, first, *general or local epileptiform convulsions*, which are sudden and succeed one another at longer or shorter intervals. They are of great diagnostic value, it being true of them, as originally said by Fournier, that, occurring in subjects over 30, if not due to uremia or alcoholism, in nine out of ten cases they are caused by syphilis. They are rarely preceded by an aura. Other cortical symptoms are hemiplegic or monoplegic paresis, cortical derangements of speech, such as motor aphasia and the like, and imbecility. These cases are often fatal. The convulsions continue, consciousness becomes deranged, coma supervenes, and death ensues. Even here, however, a judicious treatment is often of great service.

Syphilitic meningitis is more common at the base of the brain than at the convexity, though gummy tumors are more common in the latter situation. In either place the symptoms of the local meningitis are such as indicate a surface lesion, at the base by implication of the cranial nerves, at the convexity by causing motor phenomena. The signs always point to a superficiality of situation and become thus of value in a topical diagnosis, but they do not indicate that lesions more deeply situated are absent.

3. *Syphilitic Disease of the Walls of the Arteries.*—The characteristic symptoms are those of a sudden focal lesion, and are due to the sudden closure of a vessel by *thrombosis*. The most frequent symptom is *hemiplegia*. *Convulsions* are exceedingly rare. *Hemianopsia* may sometimes be present, indicating disease in the *posterior cerebral artery*, while lesions may occur in parts of the brain in which there can be no focal symptoms. Disease of the basilar and vertebral arteries, sufficient to cause definite symptoms, is seldom survived. In 19 cases out of 20, according to Gowers, the Sylvian artery and its branches are the vessels invaded.

Cerebral embolism causes the same symptoms, but it seldom occurs before 45, or the age of tendency to degeneration, unless there is valvular heart disease or endocarditis. In the absence of these, therefore, we can infer syphilis with considerable certainty. Except embolism and injury, sudden hemiplegia occurring between 25 and 45 is very seldom due to any other cause than syphilis. The course of the disease and extent of the paralysis vary as greatly as when caused by embolism. It may be slight and transient, or severe and lasting. All of the symptoms may not occur instantaneously, some hours or days being required to develop them. On the other hand, the phenomena of embolism are more likely to be suddenly complete. In thrombosis one stroke may succeed another at short intervals, and this is rather characteristic of syphilis. So is the fact that *consciousness is seldom totally lost*. Giddiness and vomiting sometimes precede it, more often does severe headache—in fact, in more than half the cases. The headache may be general

or chiefly on the side of subsequent lesion. It may precede the threatened lesion by only a few days, or a week, often for several weeks, rarely for two or three months. There may be tingling in the side about to be paralyzed. In severe cases death takes place promptly, ordinarily with high temperature.

4. *Cases of Combined Cerebral and Spinal Syphilis.*—Under these are included cases illustrating any one of the three forms considered, associated with symptoms of a more widespread syphilitic disease. Thus there may be a combination of the cerebral symptoms described, with spinal symptoms, the latter especially often as the result of *meningitis of the cervical cord* producing paraplegia, hemiplegia, or arm paresis alone, and pain in the course of the spinal nerves, or the cerebral symptoms may be associated with those of tabes dorsalis or progressive paralysis, and if so, there is scarcely a limit to the complex of nervous symptoms which may thus arise.

**Diagnosis.**—A gumma of the cortex and glioma in the same region may produce identical symptoms. So, too, the symptoms due to occlusion of an artery by syphilitic disease may be identical with those due to embolism—in fact there are no symptoms or combinations of symptoms that are not produced by other causes. How, then, shall we know the syphilitic origin? Having first made the topical diagnosis, we notice any modification of the usual symptoms of meningitis or brain tumor or arterial occlusion, or such additional symptoms as may be due to syphilis. What are these? We have seen that the very sudden onset of symptoms is not usual in syphilis except from occlusion of a blood-vessel. At least a week is usually necessary for their development. On the other hand, they are very seldom chronic. We have seen that there is great variation in the severity of the symptoms. We have seen that convulsions occurring after 30 not due to uremia or alcohol are in nine cases out of ten due to syphilis; that localized spasms, unilateral or more limited, ocular palsies, morbid somnolence, point to syphilis; that hemiplegia in persons under 45 years and not due to cardiac embolism is likely to be due to syphilis. Persistent headache, worse at night, either alone or associated or preceding the palsy, is characteristic of syphilis. Of value in diagnosis is the therapeutic test—the effect of treatment—but it must be remembered that lesions not syphilitic—glioma, for example—may be improved by antisymphilitic treatment. The symptoms are usually relieved by specific treatment. Above all, though not conclusive, is the knowledge of the presence of syphilis learned from the anamnesis, from ocular discovery of lesions, from miscarriages in women, and the presence of syphilids. Multiple sarcomatosis of the brain and spinal cord may cause symptoms almost exactly like those of syphilis, but fortunately the former is a very rare condition.

“Wasserman's reaction” in the diagnosis of syphilis is the application of the phenomenon of the deviation of the non-specific complement from the hemolytic series to the specific syphilitic series; *e.g.*, when the washed erythrocytes of sheep are brought together in suspension with definite quantities of the heated serum of a rabbit, previously immunized with washed erythrocytes of the sheep, and complement in the form of fresh

guinea-pig serum, solution of the corpuscles, or hemolysis, occurs. These three elements are spoken of collectively as the hemolytic series, the corpuscles as the *antigen*, the rabbit's serum as the *amboceptor*, and the guinea-pig's serum as the *complement*. Theoretically, a similar process takes place in syphilis as occurs in the immunization of the rabbit, *i.e.*, amboceptors are formed. If, therefore, the cause which excites the human organisms to the production of these amboceptors is brought into contact with them and a complement containing serum, anchoring will take place in a manner similar to that seen in the hemolytic series. If anchorage of the three elements in such a mixture does occur, it can be demonstrated by subsequent addition of the hemolytic antigen and amboceptor when no hemolysis or only that degree of hemolysis will take place in proportion to the amount of complement unabsorbed.

The method is as follows:

The syphilitic antigen is prepared from a syphilitic fetal liver either by shaking small pieces of the organ in salt solution containing 1 per cent. carbolic acid for several hours and then filtering, by making an ethereal extract, or by desiccation of the organ in vacuum and making a solution of the residue in salt solution.

The hemolytic antigen is prepared from defibrinated sheep's blood washed several times in isotonic salt solution, a 5 per cent. suspension of corpuscles being recommended.

The hemolytic amboceptor is prepared by immunizing rabbits with intraperitoneal injections of the suspension of sheep's erythrocytes collecting the serum and heating it to 50° C. for 30 minutes to destroy the complement.

The test is carried out as follows:

Varying amounts of the syphilitic antigen and the heated serum from a syphilitic subject is mixed with a definite quantity of guinea-pig's serum and placed at incubator temperature for an hour. A mixture of 5 per cent. suspension of sheep's erythrocytes and a definite quantity of hemolytic amboceptor serum is added to the tubes and shaken. This final mixture is placed at incubator temperature for an hour and then centrifuged. If the complement has been absorbed in the first series then no hemolysis will take place; if, however, the tested serum was non-syphilitic, then the same degree of hemolysis should take place as found in the controls of the hemolytic series alone.

Hideyo Noguche has modified this reaction as follows:

He prepares the antigen by extracting a lipid substance from the liver and heart of dogs and cows.

Instead of using sheep's corpuscles in the hemolytic series, he employs human corpuscles, owing to the fact that a certain percentage of human sera tested produced hemolysis of the sheep's corpuscles.

In his test, therefore, he obtains the hemolytic amboceptor by immunizing rabbits with washed normal human corpuscles.

Another important improvement in the technic is the preservation of the specific antigen and the hemolytic amboceptor, which rapidly lose their strength in solution, in a dried form by soaking measured strips of filter-paper (.5 mm. square) with each.

His test is carried out as follows:

A strip of antigen filter-paper is brought in contact with a definite quantity of the human serum to be tested and fresh guinea-pig's serum added, the whole being suspended in isotonic salt solution. This is allowed to stand at incubator temperature and then the hemolytic series added by taking a strip of the hemolytic amboceptor paper and a definite quantity of washed normal human blood corpuscles.

**Prognosis.**—Much benefit may be obtained by a timely and appropriate treatment of syphilis of the nervous system, though some cases do not respond to treatment. It is to be remembered, when there is actual destruction of nervous tissue, as in old cases of syphilis of the nervous system or in forms of degenerative disease due to syphilis, no medicines can be of much benefit. It is only the syphilitic lesion itself which is amenable to treatment, and with its removal comes relief to the pressure and irritation which cause so many of the symptoms of nervous syphilis.

**Treatment.**—It is evident from what has been said that treatment, to be efficient, must be prompt and early; whence the importance of an early diagnosis. Mercury and the iodid of potassium are almost the sole drugs needed, and at first they should be united. The most effectual way to bring about the mercurial effect is by inunction, although some prefer the hypodermic use of bichlorid of mercury. The method of inunction, using from 30 to 90 grains (2 to 6 gm.) daily, and beginning with the axilla, has been described on page 214. Simultaneously the iodid of potassium should be administered, beginning with 10 grains (0.66 gm.) three times a day, rapidly increasing until some effect is produced. As soon as this effect is noticed the dose may be held at a sufficient amount, usually a dram (4 gm.) a day. It is well known that very large doses of iodid of potassium are borne in syphilis without producing iodism.

The mercurial inunction should be kept up for a couple of weeks after the symptoms have commenced to yield, or it may be substituted by the bichlorid of mercury in  $1/12$  grain (0.0055 gm.) doses three times a day, which may be further reduced and finally omitted. The iodid of potassium should, however, be kept up for an indefinite time in such doses as are well borne. Such remedies should be given as are indicated to relieve special symptoms, as phenacetin, antipyrin, and opium to relieve pain. A prompt bleeding is undoubtedly of service at times in apoplectic cases, and is harmless in any case. It should, therefore, be used tentatively in all cases in which it is not contraindicated by debility, the quantity of blood drawn being regulated by the effect on the symptoms and on the pulse.

Should it happen that the symptoms are totally relieved by treatment, what should be our course thereafter? Certainly not to allow the patient to believe he is permanently cured. For almost inevitably the symptoms will return if such a course is pursued. Doubtless the advice given by Gowers in his admirable Lettsomian lecture is good, that every syphilitic subject, for at least five years after the date of his last symptoms, should have a three weeks' course of treatment twice every year, taking for the time 20 to 30 grains of iodid of potassium a day. But it is questionable whether the period should be limited to five years.

Better is it to continue the intermittent treatment for the remainder of his days. Especially likely are the symptoms to return in the second half century, when the natural tendency to tissue degeneration sets in.

#### LEONTIASIS OSSEA.

An affection in which there is undue enlargement of the bones of the cranium and sometimes of the face, causing resemblance to the face of the lion. M. Allen Starr has reported such a case. He has called the condition megalcephaly. Putnam says the disease begins in early life and is often traumatic in origin.

#### MICROMEGLY.

A condition, the opposite of acromegaly, defined by Jonathan Hutchinson and Hastings Gilford<sup>1</sup> as a "mixed premature and immature development." Gilford says "it is a disease of that part of the nervous system presiding over nutrition, manifested by smallness and immaturity of some parts or functions, and a relative or actual enlargement or prematurity of others."

<sup>1</sup> *Lancet*, vol. ii., p. 1227, 1896.

## SECTION X.

### *DISEASES OF THE MUSCULAR SYSTEM.*

#### MYOSITIS.

##### RHEUMATIC MYOSITIS, ACUTE AND CHRONIC.

These have been treated in connection with the subject of rheumatism.

##### INFECTIOUS MYOSITIS.

**Definition.**—A rare form of acute or subacute inflammation of striated muscle, due to unknown infectious agencies.

**Morbid Anatomy.**—Several cases have come to necropsy. The conditions found have been firmness, fragility, and fatty degeneration of the muscle substance, with serous infiltration and hyperplasia of the interfascicular connective tissues. In another case there was hyaline degeneration in varying degree without involvement of the intermuscular tissue.

**Symptoms.**—The parts usually involved are the extremities, but the disease may also invade the trunk-muscles and heart. There is swelling with slight edema, hardness, and stiffness, making motion painful and difficult. Instead of pain there is rarely paresthesia. The symptoms resemble those of trichiniasis, insomuch that it has been called pseudo-trichiniasis. In addition to the symptoms named an erythematous rash, irregularly scattered over the trunk and extremities, is regarded by Löwenfeld as characteristic. It is sometimes followed by slight pigmentation. There sometimes succeeds an atrophy of groups of affected muscles, and Wagner suggested that some of the cases may be examples of acute progressive muscular atrophy. Such cases are hardly fair examples of infectious myositis. The duration of the disease is from three months to three years.

Another form of infectious myositis is acute purulent myositis, sometimes associated with pyemia.

##### PROGRESSIVE OSSIFYING MYOSITIS.

This is a rare form of myositis, in which the muscles undergo progressive calcification, localized or extending over widespread areas. The disease is more common in males, and usually begins about puberty. It occupies many years in development, and consists in a preliminary inflammatory process, followed by more or less extensive deposits of bony plates throughout the muscular system, and at times in ossification of entire muscles, with fixation of joints and vertebræ.

**Treatment.**—No treatment has availed in any of these forms of acute inflammation.

PROGRESSIVE MUSCULAR DYSTROPHIES—PRIMARY  
MYOPATHIC FORMS OF MUSCULAR ATROPHY.

In addition to the spinal or myelopathic forms of muscular atrophy described under nervous diseases, there are several varieties of muscular wasting which apparently reside in the muscles themselves, and which are therefore strictly idiopathic. These forms occur in the young, and follow decidedly upon hereditary disposition. They are all probably the result of a congenital tendency to defective development.

There are several clinical types of primary muscular atrophy, of which the principal are:

1. Pseudo-hypertrophic muscular paralysis.
2. Erb's form of juvenile muscular paralysis or the scapulo-humeral form.
3. The facio-scapulo-humeral type of Landouzy and Dejerine.

These are all forms of one disease, called by Erb progressive muscular dystrophy.

## 1. PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

**SYNONYMS.**—*Pseudo-hypertrophy of Muscles*; *Lipomatosis luxurians muscularis* (Heller); *Atrophia musculorum lipomatosa* (Seidel).

**Definition.**—A state of muscular paresis associated with an atrophy of the muscles involved—an atrophy obscured by interstitial fatty overgrowth.

**Etiology.**—This is especially an affection of childhood, and heredity is an important causal factor, many members of the same family being sometimes affected through several generations. Boys are more frequent subjects than girls, though the disease is more likely to be transmitted through the mother, even though she may not herself be a subject. Heredity is not invariable. The disease usually begins before puberty, though sometimes as late as the 20th or 25th year or even later. Hysteria, epilepsy, feeble-mindedness, with an occasional anomaly of the skull, have been observed in the same families.

**Morbid Anatomy.**—The nervous system is not involved except in rare cases. Minutely examined, the muscles exhibit marked differences in the size of the muscular fasciculi, some being wider, many narrower than normal, while there is considerable increase in the adipose and connective tissue between the fasciculi. The fibrillæ themselves are not fatty.

**Symptoms.**—The disease begins gradually with paretic symptoms, without the hypertrophic appearances which are later so pronounced. A child previously healthy exhibits clumsiness in its movements and insecurity on its legs, being especially awkward in jumping and running upstairs. Then close examination discovers that certain muscles or groups of muscles are enlarged, the calves of the legs being especially conspicuous. The extensors of the leg, the glutei, the lumbar muscles, the deltoid, triceps, and infrapinales next become enlarged, while the hands, arms, and neck are

rarely involved, in strong contrast to the spinal atrophies. *Walking* becomes more and more *difficult*, until finally a diagnosis may be made from the gait alone, which becomes waddling, while the shoulders are thrown back, the belly is thrown forward, the vertebral column being also arched forward in the lumbar region. The buttocks stand out, and the legs are far apart. In walking the legs are raised slowly, the toes dropping from paresis of the dorsal flexors. Especially characteristic is the child's method of rising from the floor. He first gets on all-fours, and raises his trunk by moving the arms along the floor. The arms are then drawn toward the legs until the knees can be reached, when, with one hand on the knee, he pushes himself up, then grasps the other knee, and completes the act of raising himself to the erect position. Late in the disease the same paretic condition may extend to the upper extremities, making it impossible to rise.

The enlargement of the muscles is due to an interstitial deposit of fat, and as a consequence they are soft and flabby instead of hard and firm, as in true hypertrophy. Thus the hypertrophy is truly a pseudo-hypertrophy, the condition being really one of atrophy of muscular substance. Along with this may be associated a genuine atrophy of other muscles, with loss of substance unassociated with fatty infiltration, especially in the upper extremities. Very rarely there is a true hypertrophy, except of individual muscle-fibers.

*Fibrillar twitchings* are rarely present. *Electrical excitability* is diminished in proportion to the destruction of muscular tissue, but there is never a reaction of degeneration in a typical case. *Sensibility* remains normal, and the sphincters are intact. The patellar *reflex* is sometimes absent. The skin, especially of the legs, sometimes presents a peculiar bluish mottling. As a rule, the *intelligence* of the child is *preserved*, though sometimes there is mental and moral obliquity.

## 2. ERB'S JUVENILE FORM OF PROGRESSIVE MUSCULAR DYSTROPHY

SYNONYM.—*Scapulo-humeral Form of Muscular Dystrophy.*

This type is also commonly found before the age of 20, usually between 15 and 20, but its subjects are not so young, as a rule, as those of the pseudo-hypertrophic form. It is, like all the forms of muscular dystrophy, hereditary in families of which female members are affected, while the boys may have pseudo-hypertrophic paralysis. It starts rather more frequently in the upper extremities, the upper arms and shoulders, but may begin also in the back and legs. The following are the *muscles involved*, according to Erb: In the upper extremities the pectoralis major, latissimus dorsi, and later the triceps; while there remain normal, at least for some time, the sternomastoid, the levator anguli scapulæ, the coracobrachialis, the teres major and teres minor, the deltoid, the supraspinatus and infraspinatus, and the small muscles of the *hand*, which, it will be remembered, are remarkably wasted in myelopathic atrophy. The muscles of the forearm, except the supinator longus, remain exempt for a long time, if not altogether. In the lower extremities the glutei, the quadriceps, the

peronei, and the tibialis anticus are affected, while the sartorius and calf muscles are spared for a long time.

Very characteristic is the marked projection of the scapula, due to paralysis of the serratus. The gait in this form becomes waddling, and walking is ultimately impossible, although, like its congeners, the progress of the disease is slow, 23 to 28 years being the range of duration of cases described by Erb. Bulbar symptoms are rare, but the diaphragm may atrophy and death be due to respiratory deficiency.

The muscular changes are essentially atrophic, though in the beginning a few of the muscular fibers may be hypertrophied. The interstitial connective tissue is increased, its nuclei proliferated, and there is no interstitial fat. The number of muscle nuclei is also increased, and vacuoles may be seen in the individual fasciculi.

### 3. THE FACIO-SCAPULO-HUMERAL TYPE.

This is also a family form. Duchenne called attention to the fact that in certain children's palsies the muscles of the face are involved in the atrophy, but the fact was overlooked until Landouzy and Dejerine opened the subject anew, and showed that this event is not infrequent—indeed, may be the first symptom. This atrophy may begin later in life—say the twentieth to thirtieth year. In these cases the eyes can no longer be completely closed, and whistling, laughing, and talking become difficult. An appearance characteristic, even diagnostic, known as the *facies myopathique*, results, to which the half-closed eyes, the sunken cheeks, and the tapir mouth contribute. The muscles of mastication, the internal ocular, and those of the forearm and hand remain normal. Fibrillary contractions are absent, and there is no reaction of degeneration. In other respects it resembles the juvenile form of Erb's palsy, with which it is closely allied. From what has been said it is evident that the three forms just described are modifications of one variety, a view strengthened by the fact that two or more of the types may be present in the same family.

### THE PERONEAL TYPE OF PROGRESSIVE MUSCULAR ATROPHY.

SYNONYM.—*Progressive Neural Muscular Atrophy.*

This form of atrophy, described by Charcot and Marie, and independently by Tooth, is met in the second half of childhood, seldom after 20. It occurs also in families, more frequently in males. It begins in the peroneal muscles, involving also the intrinsic muscles of the foot, and may lead to club-foot, of the variety *pes equinus* or *pes equinovarus*. The upper extremities may be affected after many years, and rarely it begins in the hands. It differs from the other forms of juvenile atrophy in the presence of fibrillary contraction and the occasional presence of the reaction of degeneration, while vasomotor and sensory disturbances may also be present.

Degeneration of the peripheral nerves has been found with ascending degeneration of the posterior columns, and some change in the lateral columns. Both the symptomatology and morbid anatomy of this, so far as known from a limited number of autopsies, go to show that it is a combination of neuritis and alteration in the spinal cord.

**Prognosis and Treatment.**—These are also essentially identical with those of progressive muscular atrophy.

### MYOTONIA CONGENITA.

SYNONYM.—*Thomsen's Disease; Myohypotania.*

**Definition.**—A hereditary affection, characterized by overdevelopment of muscles and by tonic cramp on attempt at voluntary motion.

**Historical.**—The disease was described in 1876 by Thomsen, a Schleswig physician, in whose family it had been present for five generations. Since then numerous cases have been described in Scandinavia, Germany, France and Italy. It is rare in this country and in England. In 1880 Hale White made a thorough study of the subject and published his results in "Guy's Hospital Reports" for that year.

**Etiology.**—The disease is always congenital, the symptoms making their appearance in early childhood and in family groups, more frequently in men. Cases of acquired myotonia have been observed, but these are regarded as somewhat different from Thomsen's disease. A few isolated cases presenting the same symptoms have been described. It is to be regarded as a congenital anomaly of the muscular system.

**Morbid Anatomy.**—The muscles are characterized, especially in the extremities, by voluminous development in strong contrast to their power. In addition to an obvious macroscopic enlargement there is also found histologically an evident increase in the volume of the muscular fasciculi, recognized by Erb and confirmed by Hale White, together with intermuscular proliferation of the muscle nuclei and moderate increase of the connective tissue itself. The heart is exempt, but the diaphragm may be involved. There is no lesion of the spinal cord. The only necropsy in a case of Thomsen's disease ever observed was reported by Dejerine and Sottas. The muscles were altered, but the nervous system was normal.

**Symptoms.**—The disease manifests itself at first in childhood by a *stiffness* or "mild tetanus," in which the relaxation which necessarily precedes each muscular act is delayed. Voluntary contraction takes place slowly and with difficulty. The arm and leg muscles are involved, and thus the child's play is interfered with. There is, however, *no paralysis*, and after motion is started, it proceeds with facility. Prompt, rapid, and precise muscular movements are, however, difficult, and military service, for example, becomes impossible. Rarely facial, ocular and pharyngeal muscles are involved. *The condition is aggravated by cold and emotion.* Sensation and the reflexes are normal. Rarely there is mental weakness.

A peculiar reaction of muscle and nerve to *both* currents is developed, called the *myotonic reaction* of Erb. The motor nerves show quantitatively a normal faradic and galvanic excitability, and all briefly acting stimuli give

short contractions; but with continuous irritation by both currents the contractions attain their maximum slowly and relax slowly, while vermicular wave-like contractions pass from the kathode to the anode. The *muscles* are also faradically easily excited, responding to a fairly strong current always with the above described prolonged contraction. To galvanic irritation of muscle there is a slight increase of excitability, and to somewhat strong currents the contractions are sluggish, tonic, and continued. They occur only with current closure and not with current opening. The mechanical irritability of the muscles to strokes from the percussion hammer is also increased.

**Diagnosis.**—If more is needed than the peculiarity of the muscular phenomena, the electrical and mechanical muscular reactions described are characteristic.

**Prognosis.**—The disease is incurable, but patients become accustomed to the defect and conceal it as much as possible.

**Treatment.**—Nothing specific is known. Friction and massage, with muscular gymnastics, are rational measures to be recommended.

## AMAUROTIC FAMILY IDIOCY.

**Definition.**—A rare and generally fatal disease affecting several children of the same family, characterized by a feeble mental development, by progressive weakness of all the muscles of the body and by failing vision terminating in complete blindness depending on optic nerve atrophy and changes in the macula.

**History.**—The disease was first described by Warren Tay in 1881 in a child 12 months old. In the same family three similar cases occurred, also under Tay. The ophthalmoscopic finding was confirmed by Magnus, Goldzieher, Wadsworth of Boston, Hirschberg, of Berlin, and H. Knapp. In 1887 B. Sachs described a similar case without knowledge of previous cases. In 1896 Carter collected 19 cases of which eight came under his notice. After this numerous cases were published in America and Europe and finally in 1901 Falkenheim analyzed 64.

**Etiology.**—This is obscure. Singularly the disease is apparently almost confined to Hebrews, and Sachs tells us that he knows of no undoubted cases in other races. It cannot be ascribed to syphilis though the nerve atrophy resembles that due to hereditary syphilis, with which it may therefore be confounded. Its duration is usually less than two years. The disease is regarded by some as acquired, by others as congenital; the latter is more likely.

**Morbid Anatomy.**—The morbid changes are essentially those first described by Sachs who found them similar to those in brains of arrested development. There was confluence of the median and Sylvian fissures and complete exposure of the island of Reil. The cortex was hard and grating to the knife. Microscopic examination found destruction of the brain cells whose contour was rounded or elongated and the cell protoplasm was variously degenerated. The nucleus and nucleolus were sometimes wanting. Very few pyramidal cells were left. Hirsch found these same changes in the gray matter of the entire central nervous system, including the spinal cord and spinal ganglia.

Retinal changes are thus described by Tay:<sup>1</sup> "The optic disks were apparently healthy, but in the region of the yellow spot of each eye there was a conspicuous, tolerably diffuse, large white spot more or less circular in outline, and showing at its center a brownish-red fairly circular spot contrasting strongly with the white patch surrounding it. This central spot did not look at all like a hemorrhage, nor as if due to a pigment, but seemed a gap in the white patch through which one saw healthy structures."

**Symptoms.**—The child is well nourished at birth and the disease does not usually set in until the third to sixth month of life, when the mental and physical defects begin to be noticed. The child becomes quiet, listless and apathetic, and visual disturbance makes its appearance. As time passes muscular weakness occurs, the child is unable to hold up its head or sit up, the muscles are soft and flabby though they may be spastic. The reflexes may be normal, slightly subnormal or exaggerated. There is sometimes hyperacusis to sound and touch; on the other hand, a loss of hearing has been noted. Convulsions may occur but are not essential. Bodily functions and vitality are lowered resulting in susceptibility to bronchial and gastro-intestinal derangement. Retinal changes occur as described from Tay. (See morbid anatomy.) The symptoms gradually increase in severity and terminate in ultimate complete mental imbecility, marked palsy and total blindness. The child wastes and dies usually before the end of the second year.

**Treatment.**—None has ever proved of use. Proper and sufficient nourishment with wholesome hygienic surroundings naturally suggest themselves.

<sup>1</sup> For a fuller presentation of this subject the student is referred to the paper by B. Sachs in Posey and Spiller's book on "The Eye and the Nervous System," 1906.

## SECTION XI.

### THE INTOXICATIONS.

#### ALCOHOLISM.

**Definition.**—The effect on the human economy of the intemperate use of alcohol in some one of the forms in which it is used as a beverage. Such effect is either acute or chronic.

#### ACUTE ALCOHOLISM.

**Definition.**—This is the condition known as inebriety or drunkenness. Varying amounts of alcohol are required to produce it, very small quantities sufficing to intoxicate those unaccustomed to its use, while the habitual drinker may consume large quantities without effect.

**Symptoms.**—The order of symptoms is not always the same. More frequently the primary effect is one of excitement, associated with flushed face, bright eye, and loose tongue. To this succeeds the well-known staggering gait of drunkenness, which increases until its subject is unable to walk and finally falls to the ground. The ready speech, at first coherent, now wanders at random, and finally ceases altogether. The stage of narcosis is reached, and the drunken man breathes stertorously in his sleep, his face being congested and his breath alcoholic. He may, perhaps, be aroused, and may respond vaguely and incoherently to a question, but soon drops off to sleep again.

In another subject the first stage is much more violent, and he may cry out boisterously, and either spontaneously or upon the slightest provocation inflict injury or even commit murder. In other subjects, again, there is no stage of excitement, and they are morose, or pass gradually and directly into stupor. The stage of inco-ordination and ultimate stupor is, however, invariable if the quantity of alcohol drunk is enough to bring it about. The effect is upon the cortical nerve-cells of the brain.

Other less conspicuous features are a lowered temperature—96° to 90° F. (35.6° to 32.2° C.), or even lower—involuntary evacuations of the bowels and bladder, dilated pupils, and muscular twitchings.

**Diagnosis.**—The diagnosis of drunkenness is usually easy, yet mistakes are not infrequent; it has been mistaken for *apoplexy* or *apoplexy with fracture of the skull*. In the latter case stupor is usually deeper, and the patient cannot be aroused, while the breathing is more stertorous. The subject should always have the benefit of the doubt, and resident physicians in hospitals will often save themselves and the institution they serve much opprobrium if they will remember this. *Uremic coma* developing with convulsions also simulates drunkenness, and, when the existence of Bright's disease is unsuspected, may cause error. In such the odor of

alcohol in the breath is wanting, while that of urine is sometimes present, although, of course, a person with nephritis might have an attack of uremic coma after he had been drinking alcohol. In acute alcoholism the pupil is commonly dilated. In uremia it is variable, being sometimes dilated and sometimes contracted. In all doubtful cases the urine should be drawn by the catheter and tested for albumin. In *opium poisoning*, which may also be confounded with alcoholism, the pupil is contracted.

#### CHRONIC ALCOHOLISM.

**Definition.**—This is a condition which supervenes sooner or later in individuals who habitually use alcohol intemperately. *Dipsomania* is a term applied to a condition in which there is an inherited immoderate desire for alcohol at times, followed by periods in which there is no such inclination. Intemperance does not always imply the consumption of the same amount of alcohol, smaller quantities producing harmful effects in some persons while larger amounts are apparently harmless in others. The predisposition in some persons to be easily affected organically by alcohol is due to some constitutional weakness as yet not understood. It is alleged that the children of alcoholics are not only more susceptible to the degenerative effects of alcohol, but also to other diseases, such as gout, rheumatism, syphilis, and diseases of the nervous system. Among the latter may be mentioned, especially epilepsy, melancholia, dementia, and insanity.

**Morbid Anatomy.**—If we include under this the numerous morbid states which are directly or indirectly ascribed to the long-continued use of alcohol, such as cirrhosis of the liver, gastritis, low grades of meningitis, and the arterial changes so frequently ascribed to it, a large amount of space would be consumed. Fortunately, these conditions have already been described as separate entities, and their relation to alcohol as a cause has been discussed.

A few words may, however, be devoted to the consideration of the effect of alcohol on the cellular elements, since it is through such effect that its consequences are produced. Some time ago Lionel S. Beale called attention to the destructive effect of alcohol on protoplasm. More recently, in 1894, Obersohn, working in the laboratory of Gaule, in Zürich, demonstrated not only that alcohol, ether, and chloroform destroy cellular protoplasm, but also that the cells which are the most complicated, so far as function is concerned, such as nerve-cells, are the most vulnerable. These conclusions were confirmed by other experimenters, among them Wilkins, in this country, in 1895, and the whole tendency of experiment and observation at the present day is to show the degenerative effect of alcohol on elementary histological units.

Chronic alcoholism, like acute, predisposes to other diseases. Its direct effect is, as already stated, mainly on the protoplasm of cells, modifying or impairing their normal metabolism, at times destroying cells and substituting them by fibroid material, at others inciting to inflammatory action; at others still simply delaying oxidation, as in the case of the adipose

vesicle, whose fat remains unoxidized because its congener, alcohol, is more easily oxidized. In some instances, as in the case of the liver-cells, fat is deposited in new situations because it cannot be sufficiently burnt up. Different kinds of alcoholic beverages also seem to act differently, some, as gin, producing destruction of liver-cells and cirrhosis, while others, as malt liquors, produce fatty livers. It is also true that persons addicted to intermittent debauch are less liable to inflammatory lesions than constant consumers.

As a consequence of irritation of the intima by the alcohol, arise endarteritis, sclerosis, and thickening followed by atheroma and fragility. Irritation of nervous tissues results in different forms of meningitis and cerebritis with degeneration.

Thirty years ago Lancereaux announced that alcoholic excesses are one of the principal causes of tuberculosis, affecting by preference the back of the right lung, while disease of the left in front is the result of insufficient aeration or defective alimentation; also that such disease is characterized by improvement and general arrest if the patient leaves off his habit, and by recurrence if he relapses. As recently as 1895<sup>1</sup> this clinician retracted this view, while the observations of Lagneau developed the remarkable fact that tuberculosis only became prevalent in France after the phylloxera had ruined the vines and curtailed the supply of wine. Then tuberculosis, previously only one-half as common in men as women, reversed its election, twice as many men being affected as women.

The effect of alcoholism on the *kidney* is also two-fold in the direction of contraction and enlargement, the former due to gradual destruction of renal cells and tubules with substitution of interstitial tissue, the latter to fatty infiltration and hypertrophy. I have often expressed the belief that alcohol is a less frequent factor in the production of interstitial nephritis than was formerly supposed, because of the facilities for its elimination in its long journey from the stomach through the liver and lungs before it reaches the kidney. In this I am sustained by W. Howship Dickinson and the enormous experience of the late Henry F. Formad as Coroner's physician in Philadelphia.<sup>2</sup> The enlarged kidney of alcoholics was also studied by Formad, who called it the "pig-back" kidney, and found it a true hypertrophy rather than a degenerative change.

**Symptoms.**—These may be classified according to the systems they invade. Thus we have the effects of alcohol on the—

*Nervous System.*—The most constant of these is the well-known unsteadiness—especially of the hands in the performance of muscular actions. It is also apparent in an attempt to protrude the tongue. Gradual mental deterioration is an inevitable consequence, sooner or later, of chronic alcoholism. It is manifested in sluggishness of intellect, in weakness of resolution, a loss of moral character, in irritability, restlessness, and occasional dementia and insanity. Yet it is surprising how some enormous consumers of alcohol maintain their mental acumen and ability to manage large financial interests, while their vascular and digestive apparatus is evidently the

<sup>1</sup> "Effets comparés des boissons alcooliques chez les hommes et leur influence prédisposante sur la tuberculose." "France Med.," xliii, et al., 1895.

<sup>2</sup> "Heart and Kidney in Bright's Disease." "Trans. of the Assoc. of Amer. Physicians," vol. iv., 1889. Formad's experience covered as many as 1172 autopsies in a single year.

seat of advanced degeneration. When dementia and insanity are present, they are probably due to vascular degeneration and consequent secondary changes in the brain structure. The tendency of such insanity is toward delusions, including suspicion, distrust, fear of impending evil, and, more rarely, delusions of grandeur, as in general paralysis of the insane.

Multiple and simple neuritis is a well-recognized and almost characteristic symptom of chronic alcoholism, and has already been considered.

Pachymeningitis hæmorrhagica is sometimes met. More frequent are slight thickening and turbidity of the pia arachnoid membrane. But this is not peculiar to alcoholism, being the same as that found in the neuroses of insanity.

*Digestive Apparatus.*—This is a favorite point of attack in alcoholism. Chronic gastric catarrh is one of its most frequent consequences, producing loss of appetite, nausea, constipation, coated tongue, and foul breath, symptoms which are always worse in the morning, and are temporarily relieved by the dram which the habitual drinker is apt to seek at this time of day. Autopsy in such cases may be negative as to the stomach, or reveal the changes described under chronic gastric catarrh.

*Symptoms due to Liver Changes.*—From these arise the symptoms due to cirrhosis and contraction, fatty infiltration, and enlargement. The interstitial overgrowth so characteristic of cirrhosis is probably secondary to a primary poisonous and destructive effect of the alcohol on the cells, as confirmed by the experiments of Weigert, and later by those of Obersohn and Wilkins, previously referred to. The compression of the cirrhotic liver on the portal vessels produces secondary effects, viz., hyperemia of the stomach, causing gastric catarrh; hyperemia of the rectum, producing hemorrhoids; and of the esophagus, pharynx, and nasal mucous membrane, resulting in hemorrhage in any one of the localities; in dilatation of the venules of the face and nose, and eruptions on the latter, constituting the acne rosacea or "blossom," by which the toper is so often marked. In many cases, on the other hand, the livers of hard drinkers have been found normal.

*From vascular changes* result cardiac and renal diseases, and their symptoms, unequal distribution of the blood in the brain, and consequent symptoms, viz., dizziness, thrombosis, apoplexy, softening.

#### DELIRIUM TREMENS, OR MANIA A POTU.

**Definition and Symptoms.**—This is a special manifestation of chronic alcoholism, ascribed to the long-continued action of alcohol on the brain, though its occurrence coincides rather with the sudden withdrawal of the drug. On the other hand, a debauch, however prolonged, by a person previously temperate, is never followed by mania a potu, so that the relation of the illness to the withdrawal of alcohol may be more apparent than real. Purely accidental circumstances may determine the cessation from drinking. It is very frequently an attack of acute illness, especially pneumonia, to which drunkards are especially predisposed. The first symptom is usually sleeplessness associated with intense depression, or there

may be intense restlessness, during which the patient, unless restrained, will go out of the house on some imaginary business. To this succeed hallucinations of vision, as the result of which he imagines he is pursued by monsters, serpents, rats, mice, and other vermin. The intense shivering terror of the victim under these circumstances is pitiable, and the "horrors"—a term applied to the disease—is but a feeble expression of the terrors of the patient. Frequently, in his attempts to escape these objects, he is unmanageable, and must be confined. Suicide is not infrequent with such patients. At other times the eager though misguided intelligence displayed in watching the imaginary objects is amusing. Auditory hallucinations may be present, and unusual noises be complained of. At the same time, even though the patient is violent, the pulse will be found frequent, feeble, and often irregular. There is great muscular weakness, as evidenced by the tremor which accompanies all muscular acts. There is slight fever,  $102^{\circ}$  to  $103^{\circ}$  F. ( $38.9^{\circ}$  to  $39.4^{\circ}$  C.), which is increased if there is intercurrent inflammatory disease.

**Diagnosis.**—This is never difficult. The symptoms certainly resemble those of *meningitis*, and *meningitis* is also sometimes present, but with the history of the case and the general appearance of the patient a mistake is not likely to be made. It is most important, however, to examine each case thoroughly, as *pneumonia* is so frequently associated with *delirium tremens* and constitutes its most serious danger. Again *pneumonia of the apex* is sometimes accompanied by *delirium* similar to that of *delirium tremens*.

**Prognosis.**—If there is *pneumonia*, recovery is a rare event, but if *delirium* is uncomplicated, recovery generally takes place, certainly from the first attack, and generally even after one or more attacks and a duration of from three or four days to a week. If recovery does not take place, the *adynamia* increases, the pulse grows increasingly feeble, the tongue dry, the *delirium* becomes muttering, and the patient dies with the usual symptoms of the typhoid state. The event is, of course, more common in hospital practice.

### Treatment of Alcoholism.

*Acute alcoholism* rarely requires any treatment except restraint from the further use of alcohol and opportunity to sleep off the debauch. A full dose of chloral—from 15 to 30 grains (1 to 2 gm.)—may be necessary when there is extreme excitement. Morphine is indicated, but as alcoholics sometimes have contracted kidney, caution should be exercised in its use. In cases where the subject is not too drunk to swallow, from half a dram to a dram (1.85 to 3.7 c.c.) of aromatic spirit of ammonia often acts happily; and when there is reason to believe that alcohol or undigested food is in the stomach, an emetic of warm water and mustard—a heaped dessertspoonful of mustard to half a pint of water (250 c.c.)—may be given and the stomach washed out. Should it be deemed desirable that an emetic be given to one unconscious, apomorphine hypodermically administered is the best—from 1/15 to 1/10 grain (0.0044 to 0.0066 gm.).

The first step in the treatment of *chronic alcoholism* is the withdrawal of the poison. Except when *mania a potu* is present, this may be total.

Nothing is to be gained by gradual withdrawal, while it only prolongs the struggle. No drugs like morphin or chloral or cocain should be used in the treatment of chronic alcoholism, as to do so is simply to substitute one evil for another, and to weaken the resolution of the victim. The bromids may, however, be availed of, and trional, chloralamid, and sulphonal may be employed to procure sleep. Not less than 15 grains (1 gm.) of any of these drugs should be administered for an adult, while twice the dose may be necessary. Hydrobromate of hyoscin is often an admirable remedy to quiet excitement. It may be given in doses of  $\frac{1}{96}$  grain (0.0007 gm.). Attempts at reformation are rarely successful, but success is not impossible. Some means of restraint is usually indispensable, and as a rule can only be secured in an institution. Unfortunately, relaxation of this is apt to be followed by a relapse. The difficulties increase in the presence of hereditary tendency. An abundance of nutritious food should be insisted upon, as it is found to be the best substitute for alcohol, while tea and coffee may be allowed freely, having the advantage of being stimulating without intoxicating. Tonics, such as strychnin  $\frac{1}{30}$  grain (0.0022 gm.) three or four times a day, or quinin, should be administered.

As to the remainder of treatment, it must be mainly symptomatic, directed to the symptoms as they arise. Neuritis, one of the most important of these, has been elsewhere considered.

Still another drawback is the intense depression which succeeds the exciting effect of alcohol and often impels to a return to its use.

Various means have been at different times resorted to with the object of disgusting the victim with alcohol. C. Carter strongly commends atropin, because of its physiological antagonism to alcohol. He says that if small doses—less than  $\frac{1}{100}$  grain (0.00066 gm.)—of atrophin be administered hypodermically three or four times a day to a victim of the alcoholic habit, it will produce a great distaste for alcoholic liquor in from one to five days. Whisky will become repellent both to sight and smell, and will have a most intolerable taste, resembling that of turpentine or benzine. If, under these circumstances, drinking is still attempted, nausea and vomiting follow without the addition of apomorphin or other emetic to the liquor.

### Treatment of Mania a Potu.

The first indication after withdrawal of the alcohol is to secure sleep. For this purpose the soporifics previously named scarcely suffice, though they may be tried in the full doses specified. Especially may we hope to obtain some result from the hyoscin in doses of  $\frac{1}{96}$  grain (0.0007 gm.) given hypodermically. In many cases of delirium tremens it is scarcely possible to do without morphin, which may be given hypodermically in  $\frac{1}{4}$  grain (0.0165 gm.) doses, caution being observed not to repeat too often. Chloralose may be given in from 5 to 10 grain (0.33 to 0.66 gm.) doses, dissolved in warm water; it has the advantage of small doses, equal in effect to the largest of chloral, while it also diminishes tremor and has no harmful secondary effects. R. Bellamy gives 20 grains (1.32 gm.) of trional, mixed in water, with 10 minims (0.62 c.c.) of tincture of capsicum, after a calomel purge. A very hot bath is given, of which the temperature is

gradually lessened. If in 30 minutes the delirium shows no signs of abatement, 10 grains of trional (0.65 gm.) are again given. In all cases forced feeding in small quantities often repeated is practiced, the diet consisting of milk, eggs, and soups. Paraldehyd in fluidram (3.7 c.c.) doses is a remedy which may be expected to be of service. The fluid extract of ipecac has recently been recommended by W. F. Waugh, of Chicago, to produce sleep, in from 20 to 30 minim (1.23 to 1.85 c.c.) doses in water, followed by dorsal decubitus for at least five minutes to avert nausea. A cold bath sometimes has a tranquilizing effect, especially if there is fever, or sponging the body may suffice. Many things must be done to keep the patient occupied, because, after all, the treatment amounts for the most part to a conflict between the patient and faithful attendants and the irrepressible and, at times, almost maniacal desire of the patient to get away. In preventing this it may sometimes be necessary to confine him to bed, but all gentleness should be exercised in carrying out this measure. It is much better to use a folded sheet than the unsightly straps which are sometimes used in hospitals.

I have said that alcohol may be withdrawn at once. Some object to this because of fear of resulting adynamia, and it may happen that there is great weakness, as indicated by frequent and feeble pulse demanding alcohol. As a rule it is much better to stimulate with the aromatic spirit of ammonium, digitalis, and strychnin, one dram (4 gm.) doses of the first, 10 minims (0.62 c.c.) of the second, and 1/30 grain (0.00022 gm.) of strychnin being given every three hours to overcome such weakness. Even larger doses may be demanded by emergencies. Nourishing food in easily assimilable shape, repeated at short intervals, should be insisted upon as the best substitute for alcohol. With the first sound sleep comes, usually, relief and the patient awakes convalescent, unless, as already said, the mania is accompanied by acute disease, like pneumonia, when death is apt to be the termination, whatever our efforts.

## THE MORPHIN HABIT.

SYNONYM.—*Morphinism*.

**Definition.**—An irresistible craving for morphin, which is commonly used in gradually increasing daily doses to meet the demand. Periodic attacks, or "morphin sprees," comparable to alcohol sprees, during which large quantities are used for the time being, also occur.

**Etiology.**—The morphin habit is most frequently acquired as the result of long-continued administration of morphin, by a physician's order or otherwise, to relieve some suffering caused by a painful or incurable malady or for insomnia. The influence of heredity in favoring the formation of the habit is acknowledged. Neurotic persons are more apt to become its victims. The victim of alcohol often becomes a morphin fiend, being deluded by early experience with the drug to believe that he can thus overcome the previous more disgusting, if not more terrible, habit. The same is true of cocain.

The quantities consumed are often enormous, as much as 400 grains (25.92 gm.) as a daily dose being reported.

**Symptoms.**—The chief symptom is, of course, the *craving for morphin*, but it brings with it others which are more or less temporarily relieved by a dose of the drug. Among these are *irresolution* and *loss of self-control*, and a *moral obliquity* similar to that induced by alcohol, especially in women, who are the most frequent subjects. *Untruthfulness*, especially with regard to the drug and the quantities used, is habitual. Epigastric *pain* or *nausea*, or both, are frequently complained of toward the time when another dose is due, though whether this is actual or feigned is not always easily determined. *Mental depression* is a more constant and characteristic symptom, associated with *intense anxiety*, *restlessness*, and a *sense of impending evil*, both relieved for a time by the dose. All of these symptoms are increased by a more prolonged withdrawal of the drug, when the mental depression becomes intense, sometimes impelling to suicide. So far from the usual constipating effect of morphin being produced by the drug thus used, diarrhea is not infrequent.

As the habit is prolonged *tremor*, *paresis*, and more rarely *ataxia* are superadded, while diffuse and neuralgic *pain* is complained of. *Sleep* is irregular, digestion is bad, and appetite and nutrition fail, the pulse becomes feeble and rapid, vasomotor derangements appear, as shown by a tendency to sweating and by dilatation of the pupils. Except when under the direct influence of the drug the patient grows weak and becomes a ready victim to acute disease.

On the other hand the opium eater sometimes attains old age, presenting a wizened, sallow appearance quite characteristic. The pleasurable effect so often ascribed to opium is rarely realized, though it is not unlikely that a certain amplification and distortion of actual facts which may arise in the dreamy state may form the basis of such weird and beautiful fancies as are pictured by DeQuincey.

**Diagnosis and Prognosis.**—The diagnosis is easy, but the prognosis is exceedingly uncertain because of the difficulty in carrying out treatment.

**Treatment.**—Successful treatment is scarcely possible outside of an institution, and even within one serious difficulties beset the way, the chief of which is the deception practiced by the patient. Patients should be divested of their own clothing and put to bed in hospital garb, because in this way alone can we be sure that morphin is not concealed about the person. In the case of women, whenever possible, a special nurse should be assigned to each case. The latest testimony favors complete and sudden withdrawal of the drug as furnishing a short struggle, though a severe one. Such treatment is usually followed by diarrhea, vomiting, and insomnia. In most cases it is impossible to secure the consent of the patient to sudden and complete withdrawal, when the gradual plan must be adopted. The success of either plan depends on securing effectual control of the patient, and if this cannot be obtained, all efforts fail. Some counsel even that no adjuncts should be employed, but certainly there can be no harm in the employment of general tonic treatment and remedies directed to the irritability of the stomach and torpor of the liver.

A calomel purge is useful at the start. It is a well-established fact that, as in alcoholism, the patient should be well nourished, given such food as milk, cream, beef-juice, or beef peptonoids, rich broths, and beef-tea. When there is great asthenia, aromatic spirit of ammonium, strychnin, and digitalis may be given as directed under alcoholism. If possible an occupation of an absorbing kind should be furnished.

To promote sleep, one of the numerous hypnotics in which the present day is rich should be given. Chloralamid is probably the best of these. It is not easy of administration, because of its pungent taste and difficult solubility. Twenty grains (1.32 gm.) or 30 grains (1.98 gm.) are a moderate dose, and are easily soluble in a fluidram (3.7 c.c.) of a mixture of two parts alcohol and one part glycerin. Of such solution two teaspoonfuls should be given in a glass of sherry wine or four table-spoonfuls of milk at the ordinary temperature. Trional and sulphonal or somnal may be given in from 15 to 20 grain (0.99 to 1.32 gm.) doses dissolved in hot water. Hyoscin in doses of 1/96 grain (0.0007 gm.) may also be tried. Chloral itself may be used in doses of from 10 to 30 grains (0.66 to 1.98 gm.). If there is cardiac weakness, the dose should not exceed 10 grains (0.66 gm.). Chloralose may be given in 5 grain (0.33 gm.) doses in wafers or in hot milk.

Too much carelessness is practiced by physicians in placing morphin in the hands of patients to be used at their pleasure. The hypodermic syringe has wrought untold mischief, and should never be placed in the hands of patients. On the other hand, when morphin is judiciously ordered for patients suffering extreme pain only, it is very rarely the case that a habit is established.

## CHLORALISM.

**Definition.**—The chloral habit or the habitual use of chloral.

This habit is sometimes acquired when the drug is used to obtain sleep or prescribed by the physician for any purpose.

**Symptoms.**—For symptoms and treatment of *acute chloral poisoning* see page 1400.

The presence of the *chloral* habit is characterized by nervousness, mental weakness, and depression of spirits, even to a degree of melancholia. There may also be general weakness, characterized by muscular tremor and cardiac palpitation. Lowered temperature is characteristic. These symptoms are aggravated by sudden withdrawal of the drug. There is sometimes dyspnea, aggravated at meals or after exertion. Mania and dementia are reported.

Various skin eruptions or a tendency toward them are a symptom. Though there may be no eruption, the slightest exertion or a glass of wine will produce an intense erythematous redness on the face and elsewhere on the body. This erythema, which may also extend to the mucous membranes is ascribed to vasomotor weakness. There may be diarrhea from the same cause.

**Treatment.**—Treatment requires the gradual withdrawal of the drug

and cardiac stimulation by ammonia and digitalis, the use of nutritious food, tonics, massage, and electricity. For insomnia if needed, sulphonal or trional, administered as previously directed, are more suitable than chloralamid. In extreme cases morphin may be used. It is not usually difficult to master the habit.

### COCAINISM.

Cocainism has become a comparatively frequent modern habit. It is especially common among physicians, some of whom acquire the habit in tentative local applications to their own mucous membranes in the treatment of patients. I have known three successive chiefs of clinic in throat and nose dispensary service to acquire the habit. Cocain is also taken as a substitute for some other drug, and its subjects are very apt to be those with neuropathic tendencies.

**Symptoms.**—The effect is a total demoralization of the individual, who loses all moral responsibility, delaying and neglecting appointments in the most remarkable manner. There is volubility of tongue, suggesting alcoholism, and the presence of hallucinations, which also resemble those of the alcoholic effect. The eyes are bright, and the pupils are dilated. The subject becomes suspicious, charging his wife with infidelity, and his best friend with persecuting him. Hallucinations of hearing, sight, and smell are sometimes present, including tinnitus aurium. Mild epileptoid seizures, with partial loss of consciousness, may occur, limited to muscle groups, as about the eyes. Nystagmus is also a symptom. The pulse becomes weak and feeble. The symptoms are often associated with those of alcoholism and opium.

A symptom to which a certain amount of diagnostic value has been attached is a sensation of foreign bodies under the skin. In one case observed by Rybakoff of Moscow, was a sensation as of worms beneath the skin. The recognition of the symptom is ascribed to M. Magnan of Paris.

**Treatment.**—If uncomplicated, treatment is promising. It mainly requires withdrawal of the drug, which should be total. The assistance of a trusty nurse or friend may be needed, but it is not often necessary to remove the patient to a sanatorium—I am speaking of uncomplicated cases. Cases complicated with alcoholism or the opium habit are more difficult to handle, and incarceration in an institution becomes necessary.

Tonics of the usual kind—strychnin, in full doses, and quinin—should be ordered. Non-intoxicating stimulants, like ammonia and coffee, should be given to counteract the depressing effect, while good, nourishing, easily assimilable food is necessary.

### THE TOBACCO HABIT.

TO CURE: Apomorphin,  $1/30$  grain (0.0022 gm.), fresh and pure, every two hours, increasing the dose until slight nausea is felt.

## LEAD-POISONING.

SYNONYMS.—*Colica pictorum; Plumbism; Saturnism; Devonshire Colic.*

**Definition.**—A disease of manifold symptoms resulting from the toxic effect of lead on the system, having its subjects mainly among workers in lead-works, and among painters, glaziers, and plumbers.

**Etiology.**—The lead enters the system by inhalation, through the digestive tract, or by the skin. Almost without exception the cases I have had in hospital were from the lead-works in the neighborhood of Philadelphia. The Philadelphia Hospital is almost never without one or more such cases. Even animals in the neighborhood of lead-works are said to have had the disease; also birds which have been fed on berries grown in the vicinity of such works. Water which has been kept in lead tanks, or even painted tanks, or water passed through lead pipes, has produced the disease. It must, however, be very pure water, such as rain water, and it is the very impurities of our drinking-waters which protect us. Almost all drinking waters contain sulphate of lime, the sulphuric acid of which combines with the superficial layer of lead and forms an insoluble coating of sulphate of lead which prevents further solution.

Accidental contamination has been caused by the use of cosmetics and hair dyes. To the use of chrome yellow as a substitute for eggs for coloring were traced a number of cases occurring in Philadelphia in a very interesting study by D. D. Stewart.<sup>1</sup> Even the use of vegetables canned in tin vessels is held to have produced lead-poisoning.

All grades of what is known as tin, which is really iron coated with a layer of tin, contain a small quantity of lead; and the more inferior the tin, the larger the quantity of lead. Certain conditions favor the solution of this lead. Thus, if any of the vegetable acids, as acetic, tartaric, or citric, be present, they may dissolve the lead and form soluble salts, which are readily absorbed. Of course, such solution is favored by prolonged action of the acids; hence old canned vegetables are more dangerous than those recently canned, and it would be a wise measure to insist that canned foods should be stamped with the date of the canning. The solder used in closing the cans may also be a cause of poisoning. When it is considered how enormous is the consumption of canned foods, and how few the cases of lead-poisoning traceable to it, it is evident that even moderate precautions may suffice to remove the danger altogether.

Among the more rare cases of lead-poisoning may be named materials used in making rag carpets,<sup>2</sup> cooking in badly glazed crockery-ware, beer drawn through lead pipes, or beer, cider, and wine from bottles which have been washed with shot of which some have been left behind, the use of snuff packed in spurious tin-foil containing lead, and from sleeping on mattresses the hair in which was dyed black by some lead-containing substance; and one, a most incredible case, mentioned by Naunyn, is that of a proof-reader who was poisoned after many years' reading of printed proof. Notwithstanding the solubility of the acetate of lead so much used

<sup>1</sup> "Philadelphia Med. News," June 18 and December 21, 1887.

<sup>2</sup> A very interesting case thus caused is reported by J. Milton Miller and G. Oram Ring in the "Amer. Jour. of the Med. Sciences" for February, p. 193, 1896.

in medicine, it is very rare that poisoning has resulted from its administration, and there need be no fear of using it for the purposes in which it is indicated until at least 2 drams (7.4 gm.) have been given. Cases of poisoning by lead administered as a medicine are reported by Taylor and other toxicologists. To these J. Milton Miller has added two interesting instances and reviewed others.<sup>1</sup>

It has always been an interesting question how lead in the system operates to produce its peculiar effects. That the lead itself lodges in the tissues is easy of demonstration, and analysts have gone so far as to determine the exact quantity in the different tissues of animals poisoned by lead; which, by the way, is surprisingly small, the largest amount found being  $1/4$  of one per cent. in the bones, while that in the muscles was but  $2/1000$  to  $3/1000$  of one per cent. On the other hand, it would seem that lead is contained in the tissues of many persons who are healthy—according to J. J. Putnam, in 25 per cent. It was formerly customary to ascribe the symptoms of lead-poisoning in part to the direct action of lead in the tissues; the cramps and the palsy to the presence of lead in the muscular substance; the colic to the lead in the unstriated muscular fiber-cells, and the nervous symptoms to the lead in the nerve-centers. In part, too, these phenomena were ascribed to anemia of the tissues, due to the contraction of the arterioles, stimulated by the presence of lead in the muscular coat of the vessel. More recently, there has been a disposition to account for certain of the symptoms by lesions in the central nerve-centers in the brain and spinal cord. These views are sustained by the studies of Huebel and Lugaro who induced degeneration of central nerve-cells and fibers by the action of lead, and they may be in part thus produced. The phenomena of lead-poisoning have been compared to those of chronic alcoholism, which are ascribed to effects upon the nerve-centers, of circulating blood charged with alcohol.

Some recent studies by Strauss and Phillipson on metabolic changes in lead-poisoning found certain toxic products of decomposition in the intestines which it is reasonable to suppose might produce the symptoms in lead cases. Whether the lead or the atony of the bowel produced these toxins could not be proven.

Most cases occur among adults, usually between the ages of 30 and 40, but in children occasionally. Women are said to be more predisposed than men, as four to one, and to be more readily brought under its influence. Yet one seldom sees a case of lead poisoning in women, because they are less frequently exposed to the cause.

The period of exposure necessary to produce lead-poisoning varies greatly, from a month or less to many years.

**Morbid Anatomy.**—This is not striking. Tissue may contain a considerable amount of lead without exhibiting changes. Fatty degeneration and fibrosis are, however, characteristic. Thus, the muscles become fatty and fibroid. The kidneys gradually lose their parenchymal cells and become fibroid, while nerves exhibit fatty degeneration. In the spinal cord are found in chronic lead-poisoning the changes characteristic

<sup>1</sup> Lead-poisoning from the therapeutic use of lead-acetate in capsules with a report of two cases. "Therapeutic Gazette," Aug., 1904.

of anterior poliomyelitis—i. e., sclerosis of the anterior cornua, with atrophy of the cells and nerve-fibers, but the remainder of the cord and nerve-roots are not altered. Demonstrable changes in the central nervous system, even when there are symptoms of lead encephalopathy, are not numerous. In 32 out of 71 cases Tanquerel found none. Von Monkalow discovered a high degree of atrophy of the cortex, especially marked over the frontal region at the vertex, and in the crura cerebri. Small hemorrhages in various parts of the brain and atheroma of the arteries have been noticed; also overgrowth of connective tissue. Severe enterocolitis has been found in acute cases.

**Symptoms.**—While the symptoms which make known the presence of lead-poisoning are at times rapid in their development and at others slow to appear, there seems on this account scarcely sufficient reason for dividing them into two classes of acute and chronic.

The most striking of the symptoms, and often the first to which attention is called, is *colic*. Indeed, it, with constipation, next to be considered, is often the sole manifestation of the disease, and from these two alone a diagnosis may be made, after exposure to lead absorption. The term *lead colic* has long been a recognized term in medical terminology. It is most frequent in the region of the umbilicus, and is often relieved by pressure. It varies greatly in degree, being sometimes a simple grumbling pain, at others of extreme severity, the patient writhing in the paroxysm. This, as a rule, does not last long, but is soon followed by another. On the other hand, the pain may continue for hours or until relief is afforded by treatment. It is probably due to powerful contractions of the muscular wall of the intestine, by which the nerve filaments distributed through it are compressed. As contrasted with flatulent colic, the abdomen is not distended, but flat, and may even be contracted, sometimes so much so that it is said that the vertebrae may be discerned through the abdominal walls. Yet distention of the abdomen is occasionally present. The pulse during the attacks of colic is often strikingly slowed, having been noticed as infrequent as 30 beats in a minute.

Groups of muscles anywhere, and especially the flexor muscles, as of the arms and legs, become involved in cramp, the latter more frequently. There may also be cramps in the fingers and toes. In addition to these painful cramps, which, like the colic, are intermittent, there is pain in the neighborhood of the joints. The sum of these painful joints and muscles has received the name *arthralgia saturnina*. They are quite frequent, occurring, according to statistics of Tanquerel, in 755 out of 2151 cases.

*Constipation* is very common, even more commonly present than the colic, and yet it is not invariable, and may even be substituted by *diarrhea*.

A *blue line* on the patient's gums is a very characteristic symptom, and appears at the border of contact of the gums with the teeth, or just above it. As a rule, it is easily recognized when present. It is caused by the presence of sulphuret of lead, produced by the action of sulphureted hydrogen upon the lead in the tissue of the gums. Hence the line is more common and distinct on the gums of those who take no care of the mouth,

and in whom sulphureted hydrogen is generated in the decomposition of the food. This line often remains after all other symptoms have subsided, and although it is not invariably present, its disappearance may be considered as quite a certain sign that the lead has been practically eradicated.

*Anemia* of the simple variety is a very constant symptom in lead-poisoning, and its higher degrees are attended by a sallowness which early gave rise to the term *icterus saturninus*, but which is in no way due to a deposit of bile pigment. In more serious cases, too, the impaired nutrition results in an *emaciation* which is sometimes extreme. Along with the anemia there is often *loss of appetite*, and frequently a *sweetish taste* and *fetid breath*.

Comparatively recent studies have found associated with lead-poisoning in common with other toxic conditions a granular degeneration of the erythrocytes. The granular change which responds to the basophilic stains was first investigated by Geelmyden, Hanseemann, Von Noorden and others, but Grawitz was the first (1889) to lay particular stress on the condition as evidence of a special form of degeneration. It would appear from the recent studies of Alfred Stengel, C. Y. White and Wm. Pepper, 3d,<sup>1</sup> that no poison thus far studied is as regular in its production of degeneration or as prompt in its action as lead. Cadwallader has also shown the occasional occurrence of nucleated red corpuscles in the blood of lead poisoning.

Another symptom of great importance is *muscular paralysis*, which may be *localized or general*. The localized palsies, in contrast with muscular cramp, are more likely to involve extensor muscles than flexors, and especially those of the wrist, giving rise to the very characteristic symptoms known as "wrist-drop," which, in Tanquerel's experience, occurred in 107 out of 2151 cases. Usually it is not until the colic and arthralgia present themselves that the paralysis appears. On the other hand, it has been the first symptom observed. It may last but a few days, or it may resist all treatment. It may affect a single muscle or groups of muscles. It is further characterized by the fact that the muscles affected are subject to rapid and extreme *atrophy*, so that they seem almost to disappear. Dislocations of the more movable joints, as the shoulders and phalanges, may occur in consequence. While sensibility is but slightly impaired, *electromuscular contractility* rapidly *disappears*. The muscles cease to respond to the faradic current, while the reaction to galvanism is unchanged or slightly increased at first.

The palsies of lead-poisoning are commonly ascribed to *neuritis* which may also be acute.

The localized forms of lead palsy are divided by Madame Dejerine-Klumpe in her masterly monograph<sup>2</sup> into the following groups:

1. The *antibrachial type*, the most frequent of all forms, and in which the musculo-spiral nerve is involved, producing paralysis of the extensors of the fingers and the characteristic wrist-drop, the supinator longus

<sup>1</sup> "Further Studies of Granular Degeneration of Erythrocytes," "American Journal of the Medical Sciences," May, 1902.

<sup>2</sup> Des Polynévrites en general et de Paralysies et Atrophies Saturnines en particulier par Madame Dejerine-Klumpe, Paris, 1889.

usually escaping. As the result of the prolonged flexion of the wrist there may be slight displacement backward of the ends of the bones with distention of the synovial sheaths producing the so-called Gruebler's tumor over the wrist.

2. The *superior* or *brachial type* involving the deltoid, the biceps, the brachialis, the supinator longus and rarely the pectoralis. It is much rarer than the anti-brachial type. The atrophy is of the scapula-humeral type and is commonly bilateral. It may be primary or secondary to the first form.

3. The *Aran-Duchenne* type in which the small muscles of the hand and the thenar and hypothenar muscles are involved producing a paralysis like that of the early stage of polio-myelitis anterior. This group seems to be always primary and may be the first manifestation of lead intoxication.

4. The *peroneal* type in the lower extremities producing foot-drop and steppage gait, due to paralysis of the peroneal muscles, of the common extensor of the toes and of the extensor proprius of the great toe.

5. *Laryngeal* form invading the adductor muscles of the larynx as noted by Morell MacKenzie.

In the generalized palsies the invasion may be gradual, beginning in the wrist and ankles and extending gradually over the body, or it may extend rapidly becoming complete in a few days.

The *central nervous system* may also be invaded by lead-poisoning. Occurring usually in those who are peculiarly exposed, the symptoms come on in from eight days to 50 years, the majority showing themselves, according to Tanquerel, within the first nine months. The most frequent mode of manifestation is in *eclampsia* independent of Bright's disease. True epilepsy may follow these convulsions. But there may be headache or amaurosis, optic neuritis, apathy, stupor, or the opposite condition of maniacal excitement or melancholia and hallucinations. In a few cases of lead-poisoning the symptoms are limited to the central nervous system—in 72 out of 1390 cases observed by Tanquerel. *Tremor* of the paralyzed muscles is a frequent nervous symptom.

A frequent complication, more especially when it has been present for some time, is *interstitial nephritis*, and its resulting morbid product, the contracted kidney, as shown by the presence of a small degree of albuminuria and hyaline tube-casts; and as this is the form of kidney disease in which uremic convulsions are most frequent, it is evident that these must be distinguished from the convulsions just referred to as part of saturnine encephalopathy. Hence an examination of the urine in every case should be early made in the study of the case. *Arteriosclerosis* is often a direct result as well as *hypertrophy of the heart*.

*Gout* is a well-recognized symptom, but the relation between the two was sufficiently considered in treating of that disease. True uratic deposits may occur in the big toe joint and in the tissues, their precipitation being favored by the lead, which may act by diminishing the alkalinity of the blood, as suggested by Rolfe. I may repeat, also, that in this country the association is an uncommon one.

**Prognosis.**—As to prognosis, it depends largely upon the degree of saturation of the system with lead. Ordinary lead colic is commonly

followed by recovery. As a rule, therefore, persons who respond most quickly to the action of the poison are those who most promptly recover, provided, of course, they are removed from the influence of the lead, for such persons, too, being most susceptible, are in great danger from prolonged exposure. We are enabled to infer something of the prognosis from the symptoms which are present. If the attack be ushered in by a colic, and there be no other symptoms except constipation, we may confidently expect our patient to recover completely. If there be arthralgia and palsy, the prospect is less certain, still less so if there be atrophy, and least of all if there be encephalopathy, though even here recovery may take place. Contracted kidney due to lead-poisoning is also usually incurable. No favorable prognosis should be given when the patient is unable to remove himself from the cause. It must be remembered, too, that relapses occur, often at long intervals, even when the patient is removed from exposure, and that the primary disease has been known to make its appearance a long time after exposure.

**Treatment.**—Much may be done to guard against the occurrence of lead-poisoning by *proper precautions* on the part of those exposed to it, and those employed in lead-works may do much to protect themselves, or rather their employers may do it for them. Such persons should keep themselves scrupulously *clean* by frequent *hot baths* and frequent changes of clothing, which should never be allowed to become saturated with lead. Mehu recommends that *hypochlorite of sodium* be added to the hot baths. It is made by mixing in 2  $\frac{1}{2}$  gallons (10 liters) of water 13 ounces (400 gm.) of chlorinated lime with 11 drams (43 gm.) of sodium carbonate. *Sulphur baths* were recommended by Todd, it being thought that sulphur has the power of neutralizing lead by forming insoluble compounds with it. From 2 to 4 ounces (62.5 to 124.5 gm.) of sulphuret of potassium are mixed in from 20 to 30 gallons of water (75.5 to 113.4 liters). Above all, the employees in lead-works should *not* be allowed to *eat meals* in the lead factory, as the metal is often introduced with food. Finally, the *ventilation* of the factory should be of the best. Experience has shown that much may be done to arrest the dangers of lead-works by such precautions. The same remarks as to cleanliness, bathing, and change of clothing apply to painters, and indeed to all who have to do with lead in any shape or degree. It is evident that leather-lined and painted cisterns should never be used in houses, that cosmetics and hair-dyes are dangerous, and that care should be taken in the selection of canned foods not to use those which have been too long canned.

The curative measures may be divided into those for the immediate relief of urgent symptoms and the removal of the lead from the system. It is scarcely necessary to say that the patient should be promptly removed from the influence of the lead. The extreme pain of the lead colic requires to be relieved by the hot bath or poultice, and an opiate, of which the best mode of administration is by the hypodermic syringe,  $\frac{1}{4}$  or  $\frac{1}{3}$  grain (0.016 or 0.02 gm.) of sulphate of morphin being required for the purpose. Identical treatment is required for the arthralgia. The accompanying constipation is best relieved by sulphate of magnesium, the sulphuric acid of which, on theoretical grounds, at least, aids in render-

ing inoperative the lead which has entered the system by forming an insoluble sulphate.

These more urgent symptoms being relieved, measures directed to the *elimination of the lead* should be taken. The hot baths already referred to may be used for this purpose, as well as for prophylaxis, while *purgatives* and *diuretics* may aid elimination. The *iodid of potassium* is the remedy most relied upon to eliminate lead. It is believed that after its absorption the lead becomes intimately united with the albumin of the tissues, forming an insoluble compound; that the iodid of potassium, after its absorption, combines with the lead and forms a soluble iodid of lead, which is dissolved out, re-enters the circulation, and is passed out with the urine and feces. It is evident that elimination by these channels will be encouraged by purgatives and diuretics. It is even suggested that acute lead-poisoning may be produced by the liberation of the soluble lead salt into the blood in this way. Hence caution is suggested in the use of the iodid. Practically, I can scarcely conceive this to occur with such doses as are ordinarily given, 10 grains (0.66 gm.) three times daily, after a time reduced to 5 (0.33 gm.), but this dose should be kept up indefinitely. Iodid of potassium is more efficient when given fasting and freely diluted.

For the paralyzed muscles *faradic electricity* is indicated and should be daily applied, both to resist the tendency to atrophy and to overcome it.

That *restorative* and *blood-making* remedies, in the shape of nutritious, easily assimilable food, together with iron, should also be given to antagonize the cachexia which is always a part of plumbism is evident. In view of the nervous and muscular symptoms which enter so largely into the disease *strychnin* may be expected to be a useful adjunct to our treatment, and it is generally so considered. It should be given in full doses, 1/30 grain (0.0022 gm.) three times a day, and increased to 1/20 grain (0.0033 gm.), which should be kept up. *Ergot* is said to have been useful in restoring the power of muscles involved in the palsy.

## ARSENICAL POISONING.

**ACUTE ARSENICAL POISONING.**—Acute arsenical poisoning is usually the result of accidental or intentional ingestion of Paris green or "Rough on Rats," prepared and sold for the destruction of rats, mice, vermin, and insects. Occasionally it is taken also with suicidal intent.

**Symptoms.**—These are intense *abdominal pain*, at first gastric, with *vomiting*; later intestinal, with *diarrhea* and *tenesmus*, which may be followed by collapse and death. The symptoms are not unlike those of cholera, including rice-water stools, cardiac weakness, and cyanosis. Sometimes a *skin eruption* makes its appearance, and sometimes *blood* and *albumin* appear in the *urine*. Fatal cases terminate in one or two days.

Recovery from these acute effects may be followed by paralysis.

**Treatment.**—The ingestion of a poisonous dose of arsenic is apt to be followed by free vomiting. But even in the event of emesis, mustard, or sulphate of zinc from 10 to 30 grains (0.66 to 0.1944 gm.), should

be administered, and the stomach well washed out with draughts of warm water. With the emetic or before it the antidote should be administered. The best antidote is freshly precipitated sesquioxid of iron, which forms, with arsenic, an insoluble compound. It must be freshly prepared, taking any of the sesqui solutions of iron, preferably the chlorid, and neutralizing it with sodium carbonate or magnesia. The precipitate, being hastily washed by emptying on muslin or a filter, pouring water on it and allowing it to drain, should be freely administered. Dialyzed iron may be used, but it is best also precipitated with ammonia or other alkali before using. In extreme cases the tincture of the chlorid of iron, Monsel's solution, or any of the sesqui preparations may be substituted for the precipitated sesquioxid.

After the emetic has acted, and while the antidote is being given, castor oil should be administered to carry off the poison from the bowels.

**CHRONIC ARSENICAL POISONING.**—This is ascribed to wall-papers covering occupied apartments, to artificial flowers, and clothing fabrics colored or dyed with arsenic. The glazed green and red papers are those especially dangerous. Occasionally, arsenic medicinally administered may produce the symptoms of slow arsenical poisoning.

**Symptoms.**—Chronic arsenical poisoning may be suspected in the presence of unexplained *anemia* and *debility*, *irritation* of the conjunctiva, mouth, pharynx, and lower digestive tract, *numbness*, *tingling*, and *gastralgia*; also nervous symptoms and altered nutrition in special parts. All these symptoms may, however, be produced by other causes. *Paralysis* may also ensue, resembling that of lead palsy, but affecting rather the lower extremities, especially the extensors and peroneal group, whence may arise the characteristic *steppage gait* of peripheral neuritis. These symptoms have been ascribed by some authorities, as in the case of lead-poisoning, to central lesions rather than to alterations of the nerves. *Deranged electrical reaction* may be present before any loss of power, but on differential examination a weakened power of wrist extension and feeble power to spread the fingers may be detected.

**Treatment.**—The patient should be removed from the exposure and the symptoms be treated as they arise. The iodid of potassium may be used.

### BISULPHID OF CARBON POISONING.

**History.**—A. Delpach first described carbon bisulphid poisoning in France in 1850, and F. Delpach added to the knowledge in 1863. In 1883 Frost, Gunn and Nettleship considered especially the eye symptoms. James Ross described the paralytic symptoms in 1886, and Pierre Marie emphasized hysterical symptoms in 1888. Maass made it the subject of an inaugural thesis in Berlin in 1889. In 1892 MacGregor in Australia and Peterson in America published papers. Lastly Henry D. Jump and John M. Cruice published two cases of chronic bisulphid poisoning in 1904<sup>1</sup> arising in artificial silk-works near Philadelphia, U. S. A. It occurs to those working in the fumes of bisulphid as in the process of vulcanizing rubber. In the artificial silk mills cellulose is treated with caustic soda and then with bisulphid of carbon.

**Symptoms.**—The acute symptoms are those of exhilaration followed by depression, excitement or taciturnity, loss of appetite and headache.

<sup>1</sup> "University of Pennsylvania Med. Bulletin," July, Aug., 1904.

Overwhelming doses cause great weakness. Mania and hysteria have been reported. The chronic symptoms are those of peripheral neuritis resembling those caused by alcohol, great muscular weakness, followed by wasting; sluggish reflexes, tremor. Absence of sexual desire is a characteristic symptom. There may be foot-drop, wrist-drop and finger extension, or the fingers may become stiff and numb. There may be scotoma and limitation of the field of vision with hyperemia of retinal vessels. These symptoms may occur after short exposure or only after long periods. The urine has been affected in some cases, shown by the presence of hematuria, albumin, indican, and hydrobilirubin. Blood changes are not marked or numerous but the hemoglobin may be reduced.

**Prognosis.**—Death never occurs from the poisoning alone though it may be caused by resulting cachexia. Recovery is more or less complete, some claiming that it is never complete. Muscular weakness is often permanent in mild degree.

**Treatment.**—Prophylaxis should be observed to protect the workmen. The work-room should be on the ground floor with vents next to the floor to carry off the gas which is heavier than air. Such removal can be facilitated by the air-pump. The muscular weakness is best treated by electricity and massage; general weakness by strychnin and nourishing food.

## PTOMAIN AND LEUKOMAIN POISONING.

Ptomain, from Greek *πτῶμα*, a cadaver, is a word suggested by the Italian toxicologist, F. Selini, for substances generated in the decomposition of organic matter, which more recent studies have shown to be the result of bacterial action. Ptomains are basic, uniting with acids to form salts. Leukomains are similar basic substances formed in the living body. Ptomains differ greatly in their character and properties, certain ones being intensely poisonous, others harmless. For the former L. Brieger suggested the name toxins, retaining that of ptomains for the non-poisonous basic products; but, as Victor C. Vaughan suggests, there are difficulties in the way of such classification, because a ptomain may be poisonous under certain conditions and harmless under others.

Leukomains are more usually harmless, although they may also produce disease under certain conditions.

Among ptomain poisons are the agencies which are responsible for various forms of meat poisoning, of poisoning by milk products, by shellfish and fish.

**MEAT POISONING.**—This succeeds the eating of various forms of meat which has been the seat of a decomposition in the whole or some one of the constituents of the mass.

*Sausage poisoning*, also called botulismus and allantiasis, follows the eating of infected sausage. Numerous outbreaks have occurred in Germany, more particularly in Wurtemberg and adjacent Baden. In 1820 Kerner had collected reports of 76 cases, of which 37 were fatal, and in 1822 he had increased the number to 155, with 84 fatal. The poison-

ous qualities are referred to defective methods of preparation which permit decomposition.

*Ham poisoning* not due to trichina has occurred in England, Germany, and Switzerland, while poisoning has also been traced to beef, mutton, veal, turkey, and goose-grease, and in America to canned meats. Some of these must be ascribed to muriate of zinc and tin, but others are doubtless due to the meats. Poultry, especially if kept too long, and game birds also prove poisonous at times.

**Symptoms.**—The symptoms of various epidemics vary somewhat, but the following are more constant, after a period of incubation of from one to 48 hours: *nausea, vomiting, cramps, and diarrhea*—in a word, acute gastro-intestinal irritation. To these may be added *dryness of the mouth, constriction of the throat, difficulty in swallowing, vertigo, indistinctness of vision, dilatation of pupils*, while sometimes *constipation* substitutes diarrhea. *Thirst, headache, and muscular weakness* may also be present.

The symptoms may begin at once without incubation in a feeling of languor and general malaise, loss of appetite, nausea, and griping pain in the belly.

In fatal cases the symptoms of cholera are simulated, such as cramps in the legs or arms, or both, muscular twitchings, stiffness of the joints, drowsiness, coldness of surface, pinched features, blueness of fingers and toes and around the sunken eyes—in a word, the symptoms of collapse. On the other hand, the temperature sometimes rises to 101° to 103° F. (38.3° to 39.4° C.), with a pulse of from 100 to 128.

**POISONING BY MILK AND ITS PRODUCTS.**—The causes of poisoning by cheese claimed attention as far back as 1827, when analyses of poisonous cheese were made by Hunnefeld. The older view that the poisons are fatty acids has been refuted, and Vaughan isolated a ptomain in 1884 which he has called tyrotoxinon' (*τυρότοξινον*, cheese, and *τοξινόν*, poison). Tyrotoxinon was not, however, always found by Vaughan in cheeses of acknowledged poisonous properties. In 1885 he found tyrotoxinon in milk which had stood in well-stoppered bottles for about six months, and in 1886 Newton and Wallace obtained it from milk which had poisoned a number of persons in a hotel at Long Branch, N. J. Since then tyrotoxinon has been isolated many times from poisonous milk. Finally, in 1886, Vaughan obtained tyrotoxinon from ice-cream which had proved poisonous, and since then it has been frequently found in such cream. A number of cases of poisoning after eating "cream puffs" have been reported in Philadelphia and elsewhere, in which doubtless the same ptomain is responsible. A family under my observation was poisoned by *blanc mange*, of which all had eaten freely, and which had been made for several days.

**Symptoms.**—The symptoms of milk and cheese poisoning are those of gastro-intestinal irritation, comparable in various degrees to those described as due to meat poisoning, etc

**POISONING BY SHELL-FISH AND FISH (*Ichthysmus*).**—The mussel furnishes the most frequent source of poisoning from this cause, instances of which were reported as early as 1827 by Combe. A ptomain was isolated by L. Brieger in 1885, from poisonous mussels, at Wilhelmshaven, where

numerous instances occur. Brieger has called it mytilotoxin, from *mytilis*, a mussel. It is found chiefly in the liver of the mussel, but whether in a special poisonous mussel or a mussel which becomes poisonous under certain circumstances is not settled, though the latter would seem to be true, since Schmidtman found that non-poisonous mussels placed in the waters of Wilhemshaven Bay became poisonous, and poisonous mussels from the latter became harmless after being placed in the open sea.

**Symptoms.**—Both cooked and raw mussels may produce the poisonous symptoms. Three sets are described:

*First*, those of gastro-intestinal irritation, similar to those described as due to meat poisoning, and which may terminate fatally within two days, the autopsy revealing inflamed stomach and intestines.

In a *second* set of symptoms the nervous system seems to bear the brunt of the poison, and these cases are said to be the most frequent. The symptoms include a sense of heat and itching, usually beginning in the eyelids, but soon extending over the whole face and sometimes over a large portion of the body. An eruption, vesicular and papular, makes its appearance and intensifies the itching. The eruption is often followed by asthmatic breathing. Sometimes the dyspnea precedes the eruption, the face becomes livid, the patient unconscious, and there are convulsive movements of the extremities. In other cases there are delirium, convulsions, coma, and death within three days. In other nervous cases there are numbness and coldness, frequent pulse but no fever, the pupils are dilated, and death takes place in a couple of hours with symptoms of collapse.

In a *third* set of cases a symptom like intoxication by alcohol is present, followed by paralysis, coma, and death.

### Treatment of Ptomain and Allied Poisoning.

This is mainly symptomatic—the *purgative* and *emetic* effect of the poison generally promptly gets rid of any residue which may be in the stomach or intestinal canal. But if there is any reason to believe that these are not emptied, purgatives should be administered, and of these calomel is probably the best because it is less apt to be rejected.

In addition counterirritation by mustard, hypodermic injection of  $\frac{1}{4}$  grain (0.0165 gm.) *morphin*, repeated if necessary, to relieve pain, digitalis from 10 to 30 minims (0.66 to 2 gm.), and strychnin  $\frac{1}{30}$  grain (0.0022 gm.) administered in the same manner to counteract collapse may be given. *Stimulants* by the mouth should be given if retained, and to this end champagne becomes very suitable, or milk mixed with carbonated water may be given in small quantities.

### GRAIN POISONING.

For a century or more districts have been subject to ailments which have been traced to the use of certain grains as food, some of which have been found to be spoiled or the seat of disease. People in some parts of France, Germany, Switzerland, Italy, Spain and India have been thus affected.

1. **ERGOTISM.**—Ergotism is one of these ailments. It is a disease found to succeed upon the use of meal contaminated with the *sclerotium*, an intermediate stage of development of the *claviceps purpurea*, a fungus which infests the rye grain. An ergot is this sclerotium, which appears at the base of the grain as a hard, dark-hued "spur," which, as it grows, lifts up the diseased and withered mass of the original grain. Wheat, barley, and rice may also become spurred. The growth of the fungus is favored by wet seasons. The disease prevailed in France, Switzerland, and Germany much more commonly from the 10th to the 18th century than at present. The cause of ergotism was discovered in 1830 by Thuillier.

Two forms of chronic ergotism are recognized, one convulsive or spasmodic, the other gangrenous.

*Spasmodic Ergotism.*—In this form there is a prodromal period of from 10 to 15 days, during which there are a peculiar sense of weariness and anxiety, a tingling and sense of formication in the skin, especially of the fingers and toes, gastro-intestinal irritation manifested by vomiting, purging, and colicky pains, accompanied sometimes with slight fever. Then *spasmodic symptoms set in*. These consist at first in involuntary twitchings, which soon pass into painful continuous contractions, the arms being flexed and the legs and toes extended. The cramp lasts for an hour or more, followed by a period of exhaustion, which may be succeeded by another painful convulsion. There may be delirium, melancholia, or dementia. The urine may be suppressed or violent dysuria may be present from spasm of the bladder. Pustules, boils, whitlows, and other evidence of deranged nutrition may appear. Cardiac contractions are slow and feeble, the arteries are constricted and contain little blood. Death may occur from cardiac paralysis, and is often preceded by convulsions or paralytic symptoms. The duration of the illness is from four to eight weeks or longer.

Sclerosis of the posterior columns of the cord was found in some of the cases which came to necropsy. Thus, Tuczek and Siemens found it four times in nine autopsies, which represented, also, the deaths in a group of 29 cases.

*Gangrenous Ergotism.*—This form is ushered in by the same prodrome as that described for the spasmodic. On this succeeds, from the third day to the fourth week, an erysipelatous redness in some peripheral locality, as in the toes and fingers, ears, and nose. This is followed usually by dry gangrene, but the moist form, which may be confined to a finger or toe or may involve the whole hand or foot, may also appear. The disease may not go beyond the erysipelatous redness.

For acute ergot poisoning see concluding section.

2. **PELLAGRA.**—This is a disease thought to be due to a fungus which infests moldy maize or Indian corn. Lomborso and others have isolated a ptomain from the meal made of such corn. The disease occurs in Lombardy, the South of France, and in Spain, especially among the poorer classes in the country districts, where the meal of maize is largely used. It begins almost invariably in an erythema in the spring of the year, which is followed by a scaly and wrinkled condition of the skin, especially in the parts exposed to the air. Occasionally crusts form, and beneath

these pus is found. Along with these skin diseases there are digestive derangements, salivation, dyspepsia, and even dysentery. The disease lasts a few months, when improvement sets in. In the more severe and chronic forms there may be headache and backache, the strength and mental faculties are affected, sensation is obtunded, and cramps with convulsions supervene, such as in ergotism.

Recently pellagra has been found prevalent in the Southern United States, and among other situations in insane hospitals to which the patients were admitted on account of the mental symptoms peculiar to the disease. Only ten per cent. of the cases occurring in Southern Europe are found with the mental symptoms referred to.

Edw. J. Wood,<sup>1</sup> of Wilmington, North Carolina, has done much to enlarge our knowledge of the disease as it occurs in this country.

The *morbid anatomy* is vague. There may be fatty degeneration and a pigmentation of the viscera.

3. LATHYRISM, or LUPINOSIS.—This is a condition resulting from the use of meal made from the chick-pea, or grain of a variety of vetches, more particularly the *lathyrus salivus* and *lathyrus cicera*. It is used in admixture with barley and wheat in India, Italy, and Algiers. According to James Irvine, the symptoms supervene in India when the proportion exceeds 1/12.

The symptoms are, first, gastro-intestinal irritation, then a condition of spastic paralysis, which may pass on to complete paraplegia. The arms are rarely, if ever, affected.

No associated *morbid change* has been discovered.

### Treatment of Grain Poisoning.

This consists, primarily, in the removal of the cause and the substitution of wholesome food; in removal, also from the district, if possible, and suitable treatment of symptoms.

<sup>1</sup>"Jour. Amer. Med. Assoc.," p. 37, July 6, 1907.

## SECTION XII.

### EFFECTS OF EXPOSURE TO HIGH THOUGH BEARABLE TEMPERATURE.

Such effects are easily separable into two groups, covered by the terms heat exhaustion and thermic fever.

#### HEAT EXHAUSTION.

**Definition.**—A condition of syncopal exhaustion with vasomotor paralysis and lowering of body-temperature, caused by exertion under high temperature. Such condition may arise quite independently of the direct rays of the sun. The heat may be that of confined rooms and may be artificial heat.

**Symptoms.**—The sense of *great weakness*, often experienced in hot weather after some unusual exertion, exhibits the mildest degree of this condition. In the more severe forms a sense of faintness, associated with *pallor*, *dizziness*, at times *blindness*, and the starting of cold *perspiration* are the first symptoms. Sometimes the victim can get to a place where he may sit or lie down; at other time he faints away before assistance can reach him. Then follows a condition of *unconsciousness* or semi-consciousness, whence, under favorable circumstances, he may respond to simple stimulus by ammonia or wine and then fall into a sleep, from which he will awake in an hour revived.

In more severe cases the *collapse* is more permanent, the *pulse* is extremely feeble and frequent, the *skin* continues leaky, while there may be great *restlessness* and *muttering delirium*. It is characteristic of this form of heat affection that there is extreme *adynamia* with *lowered body-temperature*. H. C. Wood, whose name is inseparably associated with the subjects of heat exhaustion and thermic fever, reports a case with a temperature as low as 95° F. (35° C.), with complete collapse.

**Diagnosis.**—Heat exhaustion is characterized by *lowered temperature* and feeble pulse, as contrasted with the opposite in *thermic fever*. It is important that the two conditions should not be confounded, because of the widely different treatment required. The syncopal attack from *cardiac failure* or from *concealed hemorrhage* much more closely resembles heat exhaustion, being associated also with feeble pulse and lowered temperature, but as the treatment is identical, the distinction is less important. The fall in temperature is, however, less decided in *syncope*.

**Treatment.**—The patient should be put to bed at once with his head horizontal or slightly raised. When possible, stimulants should be administered moderately by the mouth—brandy, whisky, or ammonia with digitalis. If this is not possible, digitalis and strychnin should be given hypodermically from 10 to 30 minims (0.66 to 2 gm.) of tincture of the former and 1/30 grain (0.0022 gm.) of the latter. Friction should be applied, and dry heat by hot-water bags or cans.

## THERMIC FEVER.

SYNONYMS.—*Heat Fever; Sunstroke; Coup de soleil.*

**Definition.**—A state of high fever induced by exposure to heat, natural or artificial.

**Etiology and Pathology.**—In this country the majority of cases occur in the summer season in those exposed to the direct rays of the sun, though they occur also among those exposed to high temperature within doors, as in sugar refineries, fire-rooms of ocean steamers, laundries, and the like. A heated atmosphere charged with moisture, impeding, therefore, evaporation, produces fever much more rapidly than a dry heat, which is in fact slow to produce it. The habitual use of alcohol is found to be a potent predisposing cause—at least alcoholics succumb very much sooner to the influence of overheat than temperate persons.

The pathology of the two conditions of heat exhaustion and thermic fever is thus explained by H. C. Wood: "There is in the pons or higher portion of the nervous system a center whose function it is to inhibit the production of animal heat, and in the medulla oblongata a center (probably the vasomotor center) which regulates the dissipation of bodily heat. Fever is due to a disturbance of these centers, so that more heat is produced than normal and proportionately less thrown off. Let it be supposed that a man is placed in such an atmosphere, that he is unable to get rid of the heat which he is forming. The temperature of the body will slowly rise, and he may suffer from a general thermic fever. If early or late in this condition the inhibitory heat center becomes exhausted by the effort which it is making to control the formation of heat, or becomes paralyzed by the direct action of the excessive temperature already reached, then suddenly all tissues will begin to form heat with the utmost rapidity, the bodily temperature rises with a bound, and the man drops over with one of the forms of coup de soleil.

"Heat exhaustion," on the other hand, "with lowered temperature, represents a vasomotor palsy—i. e., a condition in which the existence of the heart paralyzes the center in the medulla oblongata, and the heat is dissipated more rapidly than it is produced." It must be admitted that the explanation of heat exhaustion is less satisfactory than that of thermic fever.

**Morbid Anatomy.**—The high temperature characteristic of heat fever remains a long time after death. Hence putrefaction sets in early. Rigor mortis also occurs promptly. The blood remains liquid. There is general venous engorgement, especially of the lungs and cerebrum. In early autopsies the left ventricle is found contracted, the right dilated.

**Symptoms.**—A sense of uncomfortable *burning heat* and feeling of *oppression* may precede the "stroke" which fells its victim, who quickly becomes *unconscious* and comatose, perishing sometimes instantly, at other times in a few hours. In other cases there are intense *headache*, *dizziness*, *oppression*, *nausea*, and *vomiting*, occasionally *diarrhea*. *Chromatopsia*, or colored vision, may be present. Sooner or later unconscious-

ness sets in, and may be associated with *muttering delirium* and intense *restlessness*. In this condition the patient is commonly admitted to hospital with face flushed, eye suffused, skin hot and dry, temperature from  $107^{\circ}$  to  $112^{\circ}$  F. ( $41.6^{\circ}$  to  $44.4^{\circ}$  C.), the *breathing* labored, and sometimes *stertorous*, the *pulse* frequent and full. The *pupils* at this stage are usually contracted, though at first dilated. The urine is scanty, sometimes albuminous. Usually there is relaxation of the muscles, but at times there is a *convulsive tendency*, shown by twitching and jactitation, and occasionally by epileptiform convulsions. The *skin*, usually dry, may become moist and bathed with perspiration, which does not, however, reduce the temperature. Wood speaks of a peculiar *odor* exhaled by the entire body as characteristic.

Attention has been called by C. F. Close<sup>1</sup> to cardiac dilatation as a symptom of thermic fever.

In fatal cases the stupor deepens, the pulse becomes more frequent and loses even its seeming strength, then becomes irregular; the breathing is labored and irregular, and toward the last, shallow, or assumes the Cheyne-Stokes type previous to death. Death does not usually take place for several hours. In favorable cases improvement is indicated by a falling temperature and a return to consciousness.

Iron and steel workers, ship's stokers, and a variety of other persons, whose occupation exposes them to very intense heat, frequently develop attacks of muscular spasm, which may be of very mild character, but are often violent and intensely painful, and in rare cases even fatal. The spasms especially affect the flexors of the forearms, legs, hands and feet, and at times have a superficial resemblance to tetany; but any or all the muscles of the trunk and extremities may be affected and Chvostek's and Trousseau's phenomena are absent. Signs of involvement of the cerebrum, spinal cord and nerve-trunks are usually absent also, and the disorder seems to be resident chiefly in the muscles themselves. The temperature may be somewhat elevated, normal or, especially in the severe cases, subnormal. There is likely to be marked and at times dangerous general collapse in the very bad cases. In the cases studied by my colleague D. L. Edsall there were very remarkable disturbances of metabolism, showing severe tissue destruction, probably chiefly in the muscles. Elliott has reported practically negative postmortem findings.

Recovery may be complete, but more rarely a permanent condition results in which there may be more or less constant *mental weakness*, as evidenced by incapacity for sustained mental effort, while exposure to moderate degrees of temperature produces great excitement or headache or pain in the upper cervical region. *Epileptic* convulsions sometimes occur. In these cases there is probably a certain degree of meningitis.

Mention has already been made, when treating of fevers, of the form of continued fever occurring in the south of the United States, where it is known as "Florida fever" and "country fever," and in India and the West Indies as *fièvre inflammatoire*, for which John Guitéras proposes the name *continued thermic fever*, but which more recently he is inclined to ascribe to a septic origin.

<sup>1</sup> "Journal of the Am. Med. Assoc.," March 1, 1901.

**Diagnosis.**—The diagnosis of heat fever presents no difficulties. The distinction between it and *heat exhaustion* has been alluded to.

**Prognosis.**—The prognosis depends partly upon the severity of the

**Treatment.**—The success of treatment of thermic fever depends altogether upon our ability to lower the temperature. To this end the patient should be placed in a *bath of water* to which ice is freely added to keep the temperature down as low as it can be, which in summer is not likely to be below 60° F. (15.54° C.). The surface of the body is further vigorously *rubbed with ice*. In the absence of bathing facilities the patient should be placed on a mattress covered with a mackintosh and be rubbed with pieces of ice. The refrigerating effect may be further increased by *ice-water enemas*. This treatment should be regulated by the thermometer in the rectum, and abated as the temperature approaches the normal, and renewed as it again rises.

After this, or in addition to this, *treatment* should be *symptomatic*. For convulsions, chloral or chloroform; for heart failure, digitalis and strychnin hypodermically; for asphyxia, bleeding. Mild cases or recurrent fever may be treated with the antipyretics represented by antifebrin, phenacetin, and antipyrin.

In the cases associated with muscular spasm, treatment consists of the use of laxatives and sedatives, though in the bad cases the effects of even morphin are unsatisfactory. Normal salt solution by enema or subcutaneously, and freely used, may prove valuable, since chlorids are absent from the urine; and some cases seem to have been benefited by this.

## SECTION XIII.

### ANIMAL PARASITES AND THE CONDITIONS CAUSED BY THEM.

Parasitism is essentially a condition of infestation of some form of life by another living organism, usually of lower type. The parasite is the invading form, whether animal or vegetable, and is spoken of as either an *ectoparasite*, if living upon the surface, or as an *endoparasite*, if inhabiting some part of the internal structures of the invaded organism. The latter is spoken of as the *autosite*, or *host*; and when in the life of the parasite there are special stages in its cycle, the host of the fully developed organism is spoken of as the *primary* or *definitive host*, the one or more hosts accommodating the intermediate stages of the parasite being denominated the *secondary* or *intermediate hosts*. While the vegetable parasites present a number of features in common with those of animal parasites in their effects upon the organisms invaded by them and while many of these are in their organization distinctly separated from the bacteria, for convenience it has become customary to consider the various vegetable parasites of whatever degree of organization in the special field of bacteriology; and for the same reasons animal parasites are usually grouped for study in separate treatises.

The effects of animal parasitism may be practically nil according as the numbers of parasites present are small or the influences of the parasites are slight, or according to the part of the host affording accommodation to the parasites in question. On the other hand, pathogenic influences are exerted and anatomical changes and symptoms of variable intensity are produced by animal parasites just as in case of infection by pathogenic bacteria. The irritation caused by the presence and by the movements of the parasites, with consequent inflammatory effects, as well as the possibility of tissue destruction, pressure atrophy, and secondary degenerations, must be taken into consideration. The possibility of obstruction of more or less important channels, as the occlusion of blood or lymph vessels by the ova of blood flukes or the embryo filarial worms, as well as a large number of similar possible disturbances in other parts of the body by one or other form of parasites, must from time to time be reckoned with. The abstraction of food-stuff from the economy of the host by the parasite cannot be looked upon as of serious import in itself, but the possibility of loss of valuable matter, as in blood destruction by the malarial hematozoon or the loss of blood by hemorrhage from the wounds in the intestinal mucosa through lesions caused by hook-worms and other sucking parasites, may constitute serious factors of disease for the host. Moreover, there unquestionably are toxic influences generated in one or other manner in animal parasitism which may exert marked and deleterious influences upon the infested organism, as doubtless in malaria, in uncinariasis, bothriocephalus disease and a number of other similar affections.

Out of the vast number of animals which in one or other period of the life cycle are parasitic upon some higher form of life, the group which infests man either as the definitive host or as host of some intermediate stage is comparatively small; and that which includes only the more important forms capable of actually working harm to the human host is much smaller. Representatives of the animal parasites of sufficient importance to be here considered are distributed among the *protozoa*, the *worms* and *arthropods*.

## I—PROTOZOA.

Protozoa are animals composed of but a single cell. Although exceptionally such single-celled animals may associate themselves in colonies or groups for convenience or advantage of life and function, for the most part each pursues its life isolated as a single individual. A few are of sufficiently large size to be appreciable to the unaided eye, but the vast majority are minute and difficult of observation. In their structure they follow in general the organization of the ordinary cell and consist essentially of a mass of protoplasm (*cytoplasm*, *sarcode*), with differentiations for functional purposes (*organelles*) of variable character, constancy and prominence in the different examples. Thus the sarcode is at times separable (as in *ameba*) into an internal distinctly granular portion known as the *endosarc*, and a peripheral clearer portion known as the *ectosarc*; a cell-membrane in some instances is a well-marked feature, while in others (naked forms) it is absent; and in some of the free-living protozoa special external covering (*case*, *exoskeleton*) of chitinous, siliceous or chalky composition, incloses the protozoon. Of the various parts the nucleus is, after the cytoplasm, the most constant (absent in *monera*?), varying much in appearance, shape, size, and number in the individual forms (*single nucleus* of variable size and shape; *double* or *dimorphic nucleus*, a macronucleus of vegetable character, a micronucleus with creative function; *polymorphous nucleus*, multiple nuclear granules more or less widely distributed in the cytoplasm). Not uncommon examples of specialization are met in the *contractile vacuoles* (respiratory, excretory), in pigment spots (sensory?), in mouth-like ingestion foci (*cytostome*) and their pits (*cytopharynx*) on the surface of many forms with relatively firm cell-membranes, in the anus-like excretory point (*cytopygon*) of the same forms, or the peripheral motor organelles (*cilia* and *flagella* of infusoria and the flagellates), in the sucking tubes of the suctor, the hook-like fixation apparatus of gregarines, etc.

Motile protozoa move by a variety of ways. The naked rhizopods move by a peculiar rolling due to currents in the internal substance of the cell or by the protrusion of the cell substance as extensions or *pseudopoda*, these movements being always accompanied by change in the cellular shape of the animals. Ciliates and flagellates move through the activities of the special cuticular appendages known as cilia and flagella; and in the stationary examples the movement of these appendages is utilized for the creation of currents in the surrounding liquids to aid in the acquirement of nutritive materials. Gregarines move by the excretion of material upon a particular side of the animal, the expelled matter forcing the cell body passively in the opposite direction. Finally many forms are fixed, or movable only by passive convection in the medium in which they happen to exist.

The acquisition of nutritive material presents even more variation in the different forms. Those having rigid body-walls and no naked portion of such covering (*cytostome*) acquire all their matter by osmotic process, excretion being accomplished essentially by the opposite means. Those with cytostome; whether fixed or motile, may take in nutritive material also by osmosis, but particularly are able to ingest particles coming in contact with the naked protoplasm at the site of the cytostome; and these usually have about such stoma a collar of cilia or flagella (*peristome*) through the active movement of which currents are generated carrying the particles in contact with the uncovered protoplasm and into the pit of the cytostome. In the naked rhizopods particles brought into contact with any part of the surface may sink into the sarcode, the acquirement of such particles being often aided by the animal thrusting its substance out and around the former in the form of pseudopods. Excretion in the forms fixed in shape and provided with definite wall is sometimes accomplished through the cytostome, or through other special unclad portion of the surface (*cytopygon*), or in more or less measure by exosmosis. Excretion in the naked forms is by the reverse of the engulfment of particles; that is, by the flowing of the cell mass away from excretory particles extruded to the surface of the animal.

The reproduction of protozoa, at one time regarded as extremely simple (by ordinary cell division either amitotic or mitotic, or by budding), is really in its variability and possible complexity one of the most interesting phenomena con-

nected with life. Cell-division, direct or mitotic, gives origin to two or more individuals of the same character as the parent. The entire parent cell may thus be utilized in the offspring or some *residual portion* incapable of further life may be left. On the other hand, the offspring may present characters differing from those of the parent cell, and whether produced intracellularly or, as in budding, at the periphery of the parent, these are spoken of as *spores*; these subsequently, directly or after special changes, developing into the original type. Multiplication is often without the least approach to the fertilizing processes seen in higher forms of life; but not infrequently an approach to sexual fertilization is seen. Thus two similar individuals (*isogamous*) may merge before cell division occurs; or two individuals of the same kind but different in appearance (*anisogamous*) may similarly unite before multiplication. Such union of two parent forms if permanent, both thus being sacrificed in the succeeding division, is spoken of as *copulation*; if only temporary as *conjugation*. Further, alternation of generations is not uncommon, in which in one generation multiplication may proceed by ordinary division or by budding, with or without previous copulation or conjugation; while in an intermediate generation male and female elements may form; and maturation of the female cell by extrusion of nuclear matter, with fusion of the male cell with the matured female cell, may take place as in the higher forms of life.

Protozoa have a wide distribution in nature, commonly live in fresh or salt water, in moist soil and similar locations, and are not infrequently parasitic.

The following outlined classification has been adopted with a few minor modifications from Braun (*Die tierischen Parasiten des Menschen*: 1903):

- I. Class: *RHIZOPODA* (Sarcodina): protozoa whose cytoplasm forms pseudopods; often forming cases of chitinous, siliceous or chalky composition (exoskeleton), which permit the extrusion of the pseudopods either generally over the surface or at special points; with single or multiple nuclei.
  - Order 1. *AMEBINA* (Lobosa): naked or with a simple case made up of foreign particles glued together; pseudopods irregular and shred-like or digitate; contractile vacuole present; usually a single nucleus; living in fresh or marine water, in earth or as parasites.
  - Order 2. *FORAMINIFERA* (Reticularia): generally with chalky and commonly many-chambered exoskeleton, permitting the extrusion of the pseudopods generally over the surface or only at one part; pseudopods filiform and often anastomosing; contractile vacuole absent; nucleus generally multiple; marine.
  - Order 3. *HELIOZOA*: naked, or with a chitinous or radially constructed siliceous exoskeleton; pseudopods filiform and often supported by cross filaments, but not tending to anastomosis; contractile vacuole present; nucleus single or multiple; fresh water.
  - Order 4. *RADIOLARIA*: cell mass with radial filiform pseudopods and with a "central capsule" surrounding nucleus; exoskeleton common, chalky, composed of radially or tangentially arranged pieces, or as lattice-work; contractile vacuole absent, but in the peripheral cytoplasm always vesicles; marine.
- II. Class: *FLAGELLATA* (Mastogophora): protozoa with one or more long, lash-like extensions (flagella) which are employed for progression or for food acquirement; cytostome frequently present; contractile vacuole always; naked, or with definite cell-wall (cuticle), or with case; single nucleus; living in fresh and salt water or as parasites.

This class is subdivided into a number of orders of which only the following are here of interest: *Monadida*; *Polymastigida*; *Heteromastigida*.

- III. Class: *SPOROZOA*: living only as parasites in the cells, tissues and hollow viscera of other animals, receiving their nutriment only by osmosis; cell-surface covered by an ectoplasmic layer or cuticle; in stage of full development without cilia; very rarely with pseudopods; flagella only in the male germ (sporozoite); single or multiple nucleus; reproducing characteristically by encysted spores (sporocyst) and germs or sporozoites formed either directly from the parent or indirectly through the spores.
  - A. Subclass: *TELOSPORIDIA* (Cytosporidia): usually of fixed cell-outline, rarely ameboid; in developing stage always with a single nucleus; as adults are endocellular parasites; sporulation as end of life-cycle.
    - Order 1. *GREGARINIDA*: bodies of fixed, usually elongate shape, with definite cell-wall; endocellular in stage of development; in intestine or stomach of invertebrates, especially in arthropods, and as intestinal parasites have special fixation apparatus; isogamous (or without conjugation); spores encysted, usually containing sporozoites, without polar bodies.
    - Order 2. *COCCIDIIDA* (Coccidiomorphia): bodies of fixed spherical or ovoid shape; endocellular, not living free in cavities; anisogamous; spores encysted, without polar bodies, usually with numerous sporozoites.
    - Order 3. *HEMOSPORIDIA*: parasitic upon blood-corpuscles of vertebrates, ameboid; with alternation of generations and of host; sporulation asexual in one generation, in intermediate host sexual; spores not encysted.

- B. Subclass: NEOSPORIDIA: in developing stage with multiple nuclei; shape of cell variable; sporulation throughout life-cycle and before completion of development, the entire cell not being used in spore formation.
- Order 1. MYXOSPORIDIA: spores encysted, with or without terminal appendage, usually with two or four polar capsules (containing threads like a nematocyst); ameboid; multinuclear; free in hollow viscera (urinary-, gall-bladder) or in the tissues as in fish.
- Order 2. MICROSPORIDIA: spores encysted, without filament, with one polar capsule; living especially in body tissues of arthropods.
- Order 3. SARCOSPORIDIA: generally elongate parasites of muscle fibers of vertebrates, rarely also in the connective tissues; spores naked, without polar body (?), usually kidney-shaped or falciform (all within the cyst wall of parent).
- IV. Class: INFUSORIA (Ciliata); cell-body usually of fixed shape, with ciliæ; contractile vacuole; usually with cytostome; almost always with macronucleus and micronucleus (dimorphic); living free in water or as parasites. The orders: *Holotricha*, *Heterotricha*, *Hypotricha*, and *Peritricha*, are based on the arrangement of the ciliæ.
- V. Class: SUCTORIA: cell-body provided with suctorial tubes; contractile vacuole, macronucleus and micronucleus; without cytostome; usually ectoparasites in water-animals and plants; early stages ciliate and not infrequent parasites of infusoria.

# I. CLASS: RHIZOPODA;

Order: AMÆBINA;

Genus: *Amæba*.

*Amæba Coli*, Lösch.

(*Amæba dysenteriae*; *entamæba coli*, Schaud.; *entamæba histolytica*, Schaud.; *entamæba hominis*, Casagrandi.)

The *amæba coli* is a naked, colorless rhizopod, of long oval or pyriform shape, extending one or two coarse lobose pseudopods when active, spheroidal when quiescent; varying between 10 and 50 micromillimeters in diameter; cytoplasm showing but little of the clear ectosarc in rounded form but with ectosarc evident toward anterior end and in pseudopods when active; endosarc finely granular and usually containing numerous foreign particles (as fecal waste, bacteria, and blood cells or their débris); usually several non-contractile vacuoles; single rounded, vesicular nucleus, showing a nucleolus in stained preparations; moving by formation and retraction of pseudopods and more actively progressive by the peculiar rolling movement caused by currents within the cell mass, known as *ameboid*; reproducing ordinarily by cellular division, but apparently also by endogenous formation of young amæbæ in quiescent, encysted parent amæba (cf. Casagrandi and Barbagalli, Schaudinn); parasitic in human colon and regarded as the cause of "amebic dysentery."

The *amæba coli* is commonly observed in the stools and in the wall of the colon of human beings subjects of so-called *amebic* dysentery.

FIG. 140.—*Amœba coli* in fecal matter; several of the parasites show included red blood cells. In the fecal matter in addition to the granular (largely bacterial) matter, one may note red blood corpuscles, muscle and elastic tissue, a vegetable spiral duct and numerous crystalline bodies.

Its demonstration in the dejecta is to be made by placing a bit of fresh warm material upon a slide, and covering with slip without further precaution than to obtain a thin and even layer. The blood-stained mucus in the dysenteric stool is especially suitable for the purpose. The parasite may be recognized by the characters above outlined, but for easy recognition and identification it is desirable to obtain the cells in active motion. They are very susceptible to the influence of cold and then quickly become quiescent; it is therefore best to insist that the stool should be quite

fresh and warm from the body or with its warmth artificially maintained, and that the observation be made in a warm room or with the aid of a warm stage. In such case the movements are usually quite active and

readily draw attention to the parasites; but even if slow and uncertain they may be surely determined by making outline drawings of a cell at frequent intervals for a few minutes and comparing these. It is difficult to reinduce movement when the animals have become chilled. In such preparations of dejecta, especially after they have become cold, encysted forms (spherical and with an apparent cell-wall) are often to be observed; this condition being apparently assumed as more resistant to the influences of heat, cold, drying, etc., and believed to be that most favorable for prolongation of life and the usual condition of amœbæ in transmission from one to a second host. In the walls of the colon the amœbæ are found in the necrotic matter of dysenteric ulcerations and in the surrounding tissues of the mucosa and submucosa, often being seen in great numbers in the lymph spaces of the latter layer, even at some distance from the base of the ulcer. (For the general description of the pathological changes, symptoms, and treatment of amebic dysentery reference should be made to the special section dealing with this disease (p. 104).

Errant examples of the parasite are most frequently met in the pus of secondary hepatic abscesses in dysenteric subjects and in the bordering hepatic tissue, and in the lung and expectoration where such abscesses have perforated the diaphragm and penetrated the lung. Smith and Magnenat have described a case of acute cystitis with amœbæ coli in the urine in a dysenteric subject, the cystic symptoms and the amœbæ from the urine disappearing with the disappearance of the intestinal amœbæ and recovery from the dysentery. It seems quite probable that the so-called *amœba urogenitalis* of Baelz and others may be similarly regarded, being morphologically identical with amœba coli. So, too, it seems quite possible that the amœbæ met by Flexner and by Kartulis in abscesses of the jaw may be looked upon as errant amœbæ coli. The transmission of amœba coli is by no means clear. It is thought that the parasites when passed from the intestine of the original host assume an encysted condition and are carried to the alimentary canal of the second individual in impure water, or perhaps by foods tainted by such water or by contact with insects carrying the amœbæ from the dejecta in which they originally existed. Arrived in the large intestine the parasite multiplies by division; Grassi believes, too, that he has seen endogenous formation of small amœbæ within the encysted form.

There is considerable difference of opinion as to the pathogenic importance of the amœba coli. On the one hand, there are those who insist that this organism is directly and solely responsible for the changes met in amebic dysentery, basing their views mainly upon the large number of

FIG. 141.—Section of wall of colon at border of dysenteric ulcer; showing loss of substance of mucosa, thickening of submucosa from inflammatory changes and in the latter large numbers of amœbæ coli.

the parasites to be found in the stools and in the diseased tissues, upon the coincident disappearance of the amœbæ with the recovery of the patient from the dysenteric attack, and upon similar data. On the other hand, it is well known that amœbæ morphologically identical are not infrequently met in individuals presenting no symptoms of dysentery and without history of dysentery; it has been impossible to carry out conclusive inoculation experiments because it has been impossible to isolate the organisms from bacteria, with which of course they are associated in the infected fecal matter; and further it has been shown that certain bacteria of the group of Shiga's bacillus are capable without the presence of amœbæ of inducing dysenteric results. There are those persons who would in consequence of such objection recognize the existence of innocuous and pathogenic types of amœbæ coli, the true dysenteric form according to these individuals being mainly distinguishable by the blood cells and blood débris which the parasites have by their phagocytic action included in the sarcode. Others would not insist upon such a division; but regard the amœbæ as exercising perhaps some minor influence in producing the irritative and inflammatory changes in the intestine and elsewhere, but as being of more influence as the conveyers of the more important bacteria into the intestinal walls, and into the liver and other sites of secondary changes in dysenteric individuals. It has been objected to this view that a large proportion of such secondary lesions, as amebic abscesses of the liver, are bacteriologically sterile; yet it must be acknowledged that sterile cultures from such lesions may have been due to fault of method or fault of time. At least the experience of the writer, who in about a dozen such abscesses has not failed to demonstrate the existence with the amœbæ of some form of bacterium (usually one of the colon group or ordinary pyogenic group), would suggest this; and he is disposed to give credence to the last idea, accepting, however, the probability that the amœbæ, although of minor irritative influence, do possess some agency in this direction in combination with the more important bacterial infection.

Schaudinn and other authors distinguish especially between the amœbæ met in individuals free from evidence of dysentery and those met in dysenteric conditions. Schaudinn, for example, speaks of the first as *entamoeba coli* and the second as *entamoeba histolytica*. Recently, too, there has arisen a feeling that among the definitely dysenteric amœbæ several species are included, workers in our Philippine dependency recognizing as a separate species certain smaller parasites than the ordinary amœba coli. The experience of J. Allen Smith in Texas tends to confirm the view that certain cases of dysentery are characterized by such small parasites in contrast to others in which the organisms conform to the ordinary mensurations.

A remedial measure of considerable value which should be mentioned in addition to the procedures recommended in the section upon amebic dysentery (p. 104) is the use of infusions or the fluid extract of the *chaparra amargosa*, a simarubacea growing in Mexico and Texas, given preferably by the mouth but also employed in enemata. The infusions of the entire plant seem to be more valuable than the fluid extracts of the pharmaceutical houses; and, given in wineglassful measure three or four times daily,

often show extremely satisfactory results, causing the disappearance of the symptoms of amebic dysentery and at the same time the rapid disappearance of the parasites from the stools. As prophylactic measures, the thorough filtration or boiling of all water used for drinking in infected districts and the protection of articles of food from access by flies and other skatophagous insects which may bring the amebæ to such substances, should be enforced.

*Other types of amæba in man:* Smith (personal communication) has once encountered an amœba of medium size, with long delicate pseudopods, in considerable numbers in the pus of a subphrenic abscess which was regarded as *amaba gracilis*. The bodies known as *Leydenia gemmipara* obtained in serous fluids from the pleura and peritoneum in cancerous affections of these parts and looked upon by several observers as amebic in character are doubtful; it being held by a number of authorities that they are no more than altered cells, probably of endothelial nature. The amebiform bodies encountered in the oral secretions and about the teeth by several observers, having been classified as amœbæ under the names *amaba dentalis*, *a. buccalis*, *a. gingivalis*, are likewise of uncertain nature. Ijima has described under the name *a. miurai*, certain amebiform bodies found in the fluid from a case of adenocarcinoma (originally thought to have been an endothelioma) of the peritoneum and pleura, and in the last day or two of life also in the feces of the same case, each showing a peculiar protuberance at one side with fine, thread-like pseudopods projecting from it. Such an appearance is met in certain marine amœbæ; but the case must as yet be held in doubt, awaiting confirmatory instances, and as open to the same objections offered to *leydenia gemmipara*, Schaudinn.

## II. CLASS: FLAGELLATA; SUBCLASS: *FLAGELLIDIA*;

Order: POLYMASTIGIDA; MONOSTOMEA;

Genus: *Trichomonas*.

*Trichomonas vaginalis* (Donné),

*Trichomonas intestinalis* (Leuckart, etc.).

Colorless protozoon, usually of a pyriform or spindle shape with the posterior end pointed, but not bearing a flagellum, and with the anterior end more obtuse or rounded and bearing three flagella which are apt to be merged at the base and which are easily lost; about 20 or 25 micromillimeters in length and 8 or 10 in width at thickest part; along the body starting from the base of the flagella runs an undulating membrane in a somewhat spiral manner to the posterior end; this in motion gives the effect of a series of cilia with which it is apt to be confused; thin cuticle; finely granular cytoplasm; nucleus vesicular, at anterior end; cytosome sometimes evident; multiplication by cell division; encysted forms not known surely.

Originally it was believed that *trichomonas vaginalis* was to be met solely as a parasite of the vaginal canal, in women with an acid, spumous type of vaginal secretion, occurring mainly in young females, but possible at any time of life and irrespective of conditions of pregnancy or of actual menstruation at the time of examination. A number of instances of its occurrence in the urinary bladder and urethra of the male have, however, been recorded; and at present it is generally accepted that the organism described under the name *trichomonas intestinalis* is identical. It is believed, too, that similar organisms met in the mouth, stomach, and in pulmonary cavities and described as separate species are really of the same nature. It may be accepted, however, that it most frequently occurs in the vaginal secretions. It is apparently unproductive of any important results. There need be no definite vaginal discharge or any recognizable degree of vaginal catarrh; doubtless in the existence of such condition the parasite may have some minor influence in maintaining the irritative state, but is apparently unable or unlikely to initiate it. So, too, while symptoms of cystitis coexisted with the presence of the parasite in the bladder and urine in certain cases, it is not to be held as

the essentially influential agency in their production. In the intestine it is present along with other protozoa, either with diarrheal symptoms or entirely without any symptoms.

As to its origin in the human host practically nothing is known. For the intestinal occurrence it is natural that unfiltered water should have been suspected and several instances suggestive of this mode of acquirement have been published; perhaps females may by the use of similarly unclean water in bathing the genitals transmit it to the vaginal mucous membrane; and it has been suggested that it may be air-borne to explain its occasional occurrence in the lung. Experiments seeking to transmit the organism by the mouth to lower mammals have failed. Its persistence is variable. Often in young females it would appear that the menstrual discharge mechanically rids the canal of the parasites, yet it may in instances not infrequently be found persisting over months and years. It is not difficult of destruction by the use of alkaline vaginal douches or douches of very hot water. In the intestinal occurrence it often disappears without treatment of any kind; and generally the use of calomel and intestinal antiseptics is followed by the early disappearance of the organism.

FIG. 142.—*Trichomonas vaginalis*.

Genus: *Lamblia*.

*Lamblia intestinalis* (Lambl),

(*Cercomonas intestinalis*, Lambl, 1850—nec 1875; *Hexamitus duodenalis*; *Dimorphus muris*; *Megastoma entericum*; *m. intestinale*).

Colorless, pyriform protozoon with anterior end rounded; posterior end continued into a pointed extremity bearing a pair of flagella; the anterior end has one side concave, with a raised border or lip, one pair of flagella arising at the anterior border of this disk-like concavity, and two pairs together from its posterior margin; thin cuticle covering the finely granular cytoplasm, but not preventing limited change of body shape from time to time; a dumb-bell-shaped nucleus at anterior about middle level of the mouth-like concavity; reproduction not completely known, but encystment occurs; encysted form appearing as oval cells, 10. : 7. microm., with thick wall and containing organism with recognizable features.

This parasite has been frequently found in the intestine of man and of a number of lower mammals, notably rats. Its common habitat is in the upper part of the small intestine, where it adheres to the epithelial cells by means of its mouth-like disk. For the most part its presence is not attended by symptoms, but it has been found not infrequently in individuals who are afflicted with some type of diarrheal condition, and has been suspected of bearing some causal relations. Especially in such cases the parasite is met lower down in the intestinal canal and is found with greater frequency in the dejecta. In the stool it is apt to be found in the encysted form and is supposed to be transmitted in this condition. Man is thought to acquire the parasite from the rat, such an animal perhaps having soiled

FIG. 143.—*Lamblia intestinalis*, showing disk-surface and lateral views in larger figures, and three epithelial cells with attached examples to the right.

some article of food, as bread or one of the cereals, with its dejecta in which the parasites have existed in encysted form. It has been reported from a wide distribution, but most of the cases recorded have been European.

Order: MONADIDA; Family: CERCOMONADIDÆ;

Genus: *Cercomonas*.

*Cercomonas hominis* (Davaine),

(*C. intestinalis*, Lambl, 1875; *trichomonas intestinalis*, Leuckart, 1879; *monocercomonas hominis*; *cincomonas hominis*; *trichomonas hominis*).

A small flagellate, colorless, pyriform, 8.-10.-12. microm. long, with round anterior and pointed posterior ends; anterior end with one long flagellum; no undulatory membrane; at base of flagellum a cytostome (?); one or two non-contractile vacuoles toward posterior end.

Cercomonads probably identical with this form are not infrequently met in wide geographical distribution coming from the intestine of human beings, mainly in diarrheal affections; but there is no clear evidence of their bearing causal influence. A number of instances in which cercomonads have been obtained from other than intestinal situations, as in the sputum of persons with pulmonary cavities, and from pleural exudates, should probably be referred to this species.

Grimm in 1804 recorded the discovery of a large type of monad in the pus of a lung and liver abscess in a Japanese, to which Blanchard has given the name *monas pyophila*. Including the long, flagellum-like anterior end, it varied from 30. to 60. microm. in length, and had the appearance of a large spermatozoon, the body of the cell being of a cordate shape. It was quite active, was able to retract the flagellum, and was provided with a very definite cell-membrane. The recorded case is isolated and further observations are needed for fuller knowledge.

Family: RHIZOMASTIGIDA;

Genus: *Trypanosoma*.

*Trypanosoma gambiense* (Dutton); (*Sleeping Sickness*).

Elongate flagellates, two to four times the length of a human red blood-corpuscle: with an undulatory membrane extending the length of the more or less curved and slightly spirally twisted, delicately fusiform body, and prolonged into a long, single flagellum at one end; at base of undulatory membrane at non-flagellate end is a small refractile body regarded as a centrosome or by others as a micronucleus; an oval nucleus near middle of body; reproduction by cell division (believed to take place after sexual fertilization and ookinet formation in the intestine and body of the human tse-tse fly, the definitive host); parasitic in human blood and cerebrospinal fluid (human beings regarded as the intermediate hosts).

Trypanosomes of different species have been discovered in the blood of frogs, birds, rats, rabbits, guinea-pigs, of horses suffering from diseases

known as surra, douraine, mal de caderas, of cattle with tse-tse fly disease; and within recent years the form above outlined has been encountered in the human blood by Nepveu, Dutton, and Manson. Quite recently Castellani has demonstrated with much uniformity the presence of the same species in the cerebrospinal fluid of individuals, almost invariably negroes, presenting the symptoms of the African *sleeping disease*;

and has apparently led to the solution of this mysterious and fatal affection, the etiology of which has hitherto been entirely a field for

FIG. 144.—*Cercomonas hominis*; A, larger and B, smaller varieties.

FIG. 145.—Trypanosomes; showing ordinary structural appearance on left; in middle a trypanosome undergoing division; on the right an agglutinated group.

surmise. This malady is practically unknown save in Africa; and is but infrequently met in Europeans in the locations where it is endemic. It runs a rather long course, the period of incubation being of months or even a year or two in duration, the period of the active manifestations extending over three, four or five months in addition before the fatal termination. When fully developed the disease is essentially a meningo-encephalo-myelitis and is characterized by progressive lassitude and mental dullness, deepening into somnolence and coma, by tremors and uncertainty of gait and eventually inability to progress, edema of moderate degree, especially about the face, irregular temperature, rapid pulse, emaciation, glandular enlargements, a papulovesicular eruption becoming superficial ulcers, and eventually death. L. Lorand ascribes the malady to a degeneration of the thyroid consequent on the action of the toxins generated by the trypanosime.

The parasites are readily found in the cerebrospinal fluid and at times also in the blood. They may also be obtained in the juices removed by a hypodermic syringe from the enlarged lymph nodes. They are to be sought for in ordinary fresh moist films or in dried preparations just as one examines the blood for malarial hematozoa; and in dried and fixed films are stained in the same manner as are the malarial organisms. In the moist film the trypanosomes may be seen winding their way among the corpuscles, imparting a slight motion to the cells. There can be little doubt from the symptomatic picture of the disease and from the experimentally discovered fact that the pathogenic power of an allied species (*T. evansi*, of the rat, cultivated by Novy on agar with defibrinated rabbit blood added—the first successful artificial cultivation of a protozoon) may be lost by prolonged artificial culture, that the effects of the parasite are largely the result of some toxin in some way elaborated by it. It has been shown both by clinical studies and by experiments upon monkeys that this species is transmitted by the human tse-tse fly (*glossina palpalis*), thus closely following the transmission of *t. brucei* in cattle which is conveyed by *glossina morsitans*, the tse-tse fly of cattle. It is of interest to know that Schaudinn has recently suggested that spirochetæ, regarded as of bacterial nature, and known best in connection with relapsing fever, are in reality trypanosomes. Trypanosomes of the rat and of horses are known in this country, but as yet no instances of human trypanosomiasis have been published from the United States or elsewhere in America.

In the treatment of sleeping sickness a number of trypanocides are available, as members of the benzidin group such as trypan red, various arsenical compounds, among which atoxyl (an aniline compound of arsenic acid) has attained especial prominence, and various basic anilines, as well as mercurial. Atoxyl, administered by subcutaneous injections in doses of 0.4 or 0.5 gm., has been widely used with marked benefit, but cannot be employed with impunity because of serious complications to which it gives rise. The method best suited to escape such consequences is to administer the chemical in the dose mentioned for two days, then to permit an interval of ten or 15 days for the elimination of the drug, repeating this plan for months. In the intervals mercurials may be given or some of the anilines. The combination of trypanocides in this fashion is further

sustained by the fact that Ehrlich has shown in experimentations that trypanosomes may attain immunity against the various chemicals used for their destruction and that such resistance may be carried forward for many generations; but that where a strain of trypanosomes is encountered which is resistant to a given chemical it may be readily destroyed by some other type of trypanocide. After administration of atoxyl the parasites are soon diminished or even lost from the fluids used for examination, but improvement of the general condition of the patients is not likely to be recognized until after some weeks of persistence of treatment.

Prophylaxis must of course be of great importance. It contemplates the destruction of herbage about the damp places where the human tse-tse flies around, the careful screening of all dwellings, the proper protection of those exposed to their bites by suitable clothing, the removal of all infected individuals from districts where the disease does not ordinarily prevail to situations where the disease is endemic, and the destruction of such animals (crocodiles) from which the flies seem ordinarily to obtain the blood which seems necessary for their life and reproductive ability.

Order: HETEROMASTIGIDA; Family: BODONIDÆ;  
Genus: *Bodo*.

*Bodo urinarius* (Hassall),

(*Cystomonas urinaria*; *plagiomonas urinarius*; *p. irregularis*).

Small, colorless flagellates, pyriform, about 10 microm. in length, with two flagella at the anterior rounded end, and with the posterior extremity prolonged into a flagellum-like point; no undulatory membrane; nucleus at anterior end.

These minute objects, with rapid, darting motion, are to be met in the urine, especially in that of persons showing albuminuria or having some admixture of pus and similar inflammatory products from disease along the urinary tract. By some it was held that they do not properly belong in the urine, but when found have fallen from the air into the urine and there rapidly multiplied; this objection being especially directed to the *bodo* described by Hassell; but in case of the organisms in an instance described by Künstler, regarded generally as identical, there could be no doubt, as they were found in the freshly passed urine. Nothing is known of the mode of acquirement; and there is no evidence pointing to any pathogenic influence possessed by these organisms, which are probably only accidental parasites finding favorable nutritive matter in the altered urine.

### III. CLASS: SPOROZOA (PSOROSPERMIASIS); SUBCLASS: TELOSPORIDIA.

The sporozoa embrace large numbers of parasites, comparatively few of which, however, are known to occur as parasites of the human body. The class is subdivided into two great groups: the *telosporidia* (cytosporida), which are usually of fixed cell-shape, rarely ameboid, always mononucleated in the early stages and living at least in their developing period as cellular parasites, sporulation occurring at the close of the life-cycle; and the *neosporidia*, with variable shape, polynucleated in the earlier stages, and with sporulation proceeding during the growth of the individual cell. Numerous studies of recent years have led to stubbornly debated claims of different authors that parasites of this class and mainly of the first subclass are responsible for the production of cancers, perhaps also of sarcomas and as well perhaps of a group of infectious fevers, including smallpox, scarlet fever, measles, and possibly yellow fever. Discussion of these claims and description of the supposed parasitic organisms cannot properly here be entered upon for the reason that too much uncertainty, and in some instances improbability, are as yet attached to these views.

While a few types of neosporidia have unquestionably been established as parasites in man, the bulk of interest attaches to the telosporidia. This subclass includes three important orders, the *gregarines*, *coccidia*, and *haemosporidia*, which in many particulars of their life-history, especially in their modes of reproduction, present analogies. Of these three orders the gregarines are but little likely to be met in human pathology, being well known as parasites of the cells lining the intestinal tract of arthropods, but unknown as parasites of the mammals and vertebrates generally. Briefly, these organisms are elongated cells of fixed shape and with a rather thick cell-membrane, often with division of the cell into an anterior portion known as the *protomerite* and a posterior (nucleated) known as the *deutomerite*, some forms showing a special part of the anterior division adapted for fixation purposes known as the *epimerite*. They are incapable of much motion, being slightly contractile and slowly progressing by secreting material at one part, which matter serves to push the cell in the opposite direction. The parasite gains entrance to a cell in the host's intestines as a naked and motile young form known as a *sporozoite* (or as a *merozoite*, which is not quite synonymous) and in its growth comes to occupy more and more of the cell space until it breaks through the cell-wall into the intestinal lumen.

The coccidia, on the other hand, are of an oval or spherical shape, without divisions of the cell, fixed in their shape, thick-walled and non-motile; and are endocellular parasites throughout the life-cycle. These are encountered not infrequently in the higher animals and man; most of the debated instances of parasitism above referred to being suspected of belonging to this order.

The third order, that of the haemosporidia, includes a number of sporozoa of small size, living in the blood cells and blood plasma of various vertebrates including man, as well as in a few invertebrates; are more or less mobile, often amebiform.

Two modes of reproduction are possible for each order, *schizogony* (a sexual division) and *sporogony* (sexual and complicated process of multiplication). The gregarines are true cellular parasites only in their early state, the adults either with or without conjugation reproducing after having broken from their cellular position to the lumen of the host's intestine, whence they may be carried with the intestinal material to the exterior to enter under favorable conditions a second host. The coccidia are completely intracellular parasites both in the adult period and after schizogony or after the sporocyst stage, their mode of transmission to a second host being practically unknown (but probably as spores). The haemosporidia in schizogony are the parasites of the blood cells and plasma of one host; but undergo sexual reproduction after withdrawal by some blood-sucking organism, as a mosquito or tick, in whose economy the sporocyst stage and formation of sporozoites take place.

In schizogony, these telosporidia after full development undergo nuclear division by a process reminding one of fragmentation, the nuclear fragments being distributed in the cytoplasm (often especially toward the periphery of the cell); where small portions of the protoplasm of the parent surround each (*merozoites*, in distinction to the sexually produced *sporozoites*, but otherwise not necessarily different, both being able to grow into the adult sporozoon); these with rupture of the parent cell-wall escape, enter a second cell, and grow directly into the adult form. This asexual form of reproduction is of special importance in the explanation of the continued infestation of the original host in such case where the sporocysts are carried from the host or form only in a second host. In sporogony, the difference rests in the fact that of the merozoites formed in schizogony some grow into large ovoid cells (*female, macrogametocytes*); while others develop into cells (*microgametocytes*) which give origin to a number of small, flagellate male elements (*microgametes*). The latter penetrate the macrogametes as a copulatory act; nuclear fusion of the male and female cells and division by repeated mitosis take place; and within the body of the fertilized female cell spores are formed (*sporocyst*), which may be of constant and specific appearance in different cytosporidia. Within each of these spores there then develop germs or *sporozoites*, which later, upon rupture of the spore-membranes and wall of the macrogamete, escape, and under suitable circumstances penetrate a proper cell, where they again grow into adult sporozoa.

Order: COCCIDIE; Family: TETRASPOREA;  
Genus: *Coccidium*.

### 1. *Coccidium cuniculi* (Leuckart),

(*Psorospermium cuniculi*; c. *oviforme*).

A coccidium ordinarily parasitic in the epithelium of the gall-ducts of rabbits; reproduction by schizogony and by sporogony; in latter after growth of macrogamete (*oocyte*) this appears as a long, oval cell, surrounded by a well-marked, double-contoured cell-wall with distinct micropyle at the narrower end, measuring 33.-46. microm. in length and in breadth, 15.-28. microm.; this is filled with a uniformly granular cytoplasm and has a faint greenish tint; after fertilization by microgamete entering through the micropyle the cytoplasm shrinks toward the

middle of the oocyte (*oocyst*) and gradually develops from its substance four oval bodies (spores), no residual substance remaining; by this time the parasite has increased to such extent as to have broken through the wall of the infested epithelial

FIG. 146.—Development of *coccidium cuniculi*; a, b, c, young coccidia in epithelial cells of gall duct; d, e, f, fully grown encysted coccidia; g, h, i, k, l, showing development of spores; m, isolated spore, greatly magnified, showing the two falciform bodies (*pseudonavicella*; *sporozoites*) in natural position; n, a spore compressed so as to separate the two sporozoites; o, a sporozoite or falciform body with  $\gamma$ , its nucleus. (From Railliet after Balbiani.)

cell and falls into the bile duct of the host; if favored it is hence carried to the exterior by way of the gall-passages and intestines, where in water or in moist earth the process continues, to the formation within each spore of two falciform bodies (sporozoites) with a small amount of residual material; the spores with contained sporozoites being swallowed by a second host with water or food, the sporozoites are freed by the digestive juices and in unknown way enter the bile ducts to invade the lining epithelial cells and grow into adult coccidia.

As above indicated, the common habitat of this organism is in the biliary epithelium of rabbits; it has also been observed in the cells lining the upper part of the intestine. A few cases have been reported as occurring in man, in whom too the most frequent situation has been the liver. It causes considerable epithelial destruction and regeneration with inflammatory changes in the deeper portions of the wall of the infested ducts; often eventually leading to the formation of tumor-like nodules from the size of miliary tubercles to that of a small cherry, which are apt to present a cheesy center made up of shed epithelial cells, pus, coccidia in varying stages of development, and granular and fragmentary detritus. The general appearances of these nodules and the evidences of epithelial prolifera-

FIG. 147.—*Coccidium cuniculi*: photomicrograph of portion of wall of gall duct and of its distended lumen, from rabbit. In lumen are seen great numbers of coccidia together with cellular debris; the fibrous thickening of the wall duct, the villous growths into the interior, the proliferated epithelial lining, at places showing the contained coccidia, are distinct.

tion in them have long caused the idea of some relation with cancerous formations, and have been suggestive of much of the effort to establish the latter as the result of some allied form of cellular parasitism. Coccidiosis is often fatal to the infested rabbits, is readily transmitted, and when introduced into a rabbit hutch may quickly devastate it of its inhabitants. In several of the human instances the hepatic coccidial nodules have been large enough to have been recognized in life, were accompanied by more or less hepatic enlargement and by both local hepatic and peritoneal symptoms and by general phenomena. In one of these (Silcock's case) foci of the same nature were found in the spleen. The parasite is widely distributed over the world.

FIG. 148.—*Coccidium hominis*, from intestine of rabbit: 1, a degenerate epithelial cell containing two coccidia; 2, free coccidium from intestinal contents; 3, coccidium with four spores and residual substance; 4, an isolated spore; 5, spore showing the two falciform bodies— $\times 1140$ . (From Railliet.)

## 2. *Coccidium hominis* (Rivolta),

(*Cystospermium hominis*; *coccidium perforans*).

A coccidium differing from the *coccidium cuniculi* by the more rounded shape and smaller size (24.-35. : 12.-20. microm.) of the oocyst, by the persistence of a small amount of residual substance in the latter after spore formation, as well as by its shorter period of sporulation and its more common habitat in the epithelium of the intestinal wall.

This species, like the preceding, is most common in rabbits, in the small intestine, causing a rapid, severe, and often fatal inflammation and diarrhea. The parasites may be found as intracellular parasites or oocysts or sporocysts within the intestinal lumen or in the crypts of the mucous membrane where they have fallen after breaking through the wall of the cells formerly infested. Examples of this species with the same pathological results have been found in horses, goats, cows, sheep, in the hog, mole, marmot, guinea-pig, and weasel; and in man a few instances of intestinal disease have been reported with findings of this parasite.

A number of cases originally regarded as coccidial infections of man, as that of Wernicke, of Rixford and Gilchrist, and of others, are now known to be due not to coccidia, but to blastomycetes and blastomycetoid organisms of a number of different types. So, too, the older views as to the coccidial nature of certain bodies found in the tissues of such lesions as Paget's disease of nipple are no longer held. Rarely the *coccidium bigeminum*, ordinarily found in the intestinal villi of dogs and cats, has been met in the same site in man; it is known by the usual occurrence of the coccidia in twos as the result of cellular division. The effects of internal coccidiosis in general are those of intense irritation of the part invaded and are not infrequently fatal.

Order: HEMOSPORIDIA.

In this order are included a number of sporozoa, parasitic in the blood of various animals, of much importance in comparative and in human pathology. To man the species met in the different clinical forms of malaria, *plasmodium malariae* (of quartan), *plasmodium vivax* (of tertian), and *plasmodium præcox* of estivo-autumnal malarial fever), are of extreme importance and interest; for the consideration and description of which the reader is referred to the section of this work dealing with malarial fever.

It has been suggested, following the discovery of organisms very similar to those of malarial fever in the blood of individuals suffering from beri-beri, that perhaps this disease is also one induced by some form of the hæmosporidia; but the general feeling in this connection is that the findings referred to were merely the result of a coincidence of malaria in persons afflicted with beri-beri. In cases of leukemia certain bodies met in the white blood cells (and in the cells of some of the organs, as spleen), have been tentatively regarded as forms of hæmosporidia; but questions of artificial production by cellular degeneration have not been eliminated and it is impossible to accept as yet claims for their parasitic nature and identity.

FIG. 150.—Longitudinal section through muscle of hog containing Miescher's tubules. 30/1. (From Braun.)

of the parasite (*pansporocyst*); spores covered with a membrane and dividing into sporozoites (sometimes with a polar, thread-bearing capsule) complete organization, modes of development and transmission as parasites not known.

These intramuscular or intermuscular parasites are known (Miescher's or Rainey's tubules) in hogs, sheep, beef, deer, mice, and other animals, and

FIG. 149.—*Coccidium bigeminum*, from intestinal villi of dog: A, B, C, D, E, double coccidia showing development of spores; F, G, H, I, isolated coccidia; G, showing granular protoplasm; H, showing four spores and residual mass; I, same as H, seen from pole; J, two coccidia in a single envelope— $\times 650$ . (From Railliet.)

SUBCLASS: NEOSPORIDIA;  
Order: SARCOSPORIDIA.

Sporozoa whose early stage is passed in the muscle of vertebrates; usually elongate, tubular, oval, or rounded bodies of variable but small size (when fully formed sometimes large enough to be detected by the unaided eye and mistaken for trichina cysts); forming spores throughout the life of the ameboid parent, these contained in the body of the parasite.

in some of the birds (duck). It is impossible at present to distinctively arrange and classify them. They may be of minute size or may appear as small yellowish-white foci in the flesh of the infested animal, sometimes in large numbers. They are probably of long duration in the host, and are sometimes distinctly calcified and gritty. Microscopically they are doubtless often passed over as areas of disintegration and calcified granular detritus. When comparatively young, however, the pansporocyst should be recognized by its delicate but clear membrane surrounding the elongated or rounded mass of finely granular protoplasm, in which occur numerous rounded bodies, each with a definite membrane (spores), many of which, particularly toward the middle of the mass, contain a number of falciform or reniform sporozoites.

A very few instances of human infestation involving the skeletal muscles, the heart (or in one case recorded by Kartulis, the liver) have been published.

FIG. 151.—*Balantidium coli*, free and encysted: *a*, cytostome; *b*, nucleus; *c*, cytopig; *d*, masses ingested. (From Braun, after Cassagrandi and Barbagallo.)

FIG. 152.—*Balantidium coli*: *a*, nucleus; *b*, vacuoles; *c*, cytostome, with pit and peristome; *d*, ingested material. (From Leuckart.)

#### IV. CLASS: INFUSORIA;

Order: HETEROTRICHIDA; Family: BURSARIDÆ;

Genus: *Balantidium*.

##### 1. *Balantidium coli* (Malmsten).

Infusorium of ovoid shape; colorless; 70.-100.: 50.-70. microm.: with finely granular cytoplasm containing fragments taken up from surrounding intestinal material; a clear ectoplasm showing numerous longitudinal striations; cuticle firm and provided generally with cilia which run in rows longitudinally between the striations; with the anterior end somewhat more rounded than the posterior; at anterior end a funnel-shaped cytostome ending in a short pharynx and surrounded with cilia, which anteriorly and along the left border are especially large (*peristome*); cytopig at posterior, obtusely angular extremity; usually to slightly contractile vacuoles; macronucleus and micronucleus toward the anterior end, the former large and bean-shaped, the latter small and spherical; reproducing by longitudinal division and also by conjugation and encystment (but the subsequent life of the encysted form is not known).

This parasite has been found in the intestines and dejecta of hogs and man. It is not an uncommon parasite of man; has been found in connection with various types of diarrheal affections and also in persons who were entirely free from intestinal symptoms. It is of wide distribution, and while not published extensively from this country, is by no means uncommon.

It is of doubtful pathogenic importance. It is not known how it is obtained, but presumably with unfiltered water. It is not difficult to destroy it by administration of dilute hydrochloric, acetic, or salicylic acid or similar remedies.

2. A considerably smaller species (*balantidium minutum*) with a more pointed anterior and rounded posterior extremity, measuring 32. : 20. microm., has been encountered twice from the human intestine in connection with diarrheal symptoms. In one of these cases a bean-shaped infusorium with cytostome and peristome along the concave border (*nictotherus faba*) was also discovered, thus far being recorded from but this single instance.

## II—VERMES OR WORMS.

Worms are bilaterally symmetrical, more or less elongate animals, without articulated members, with the body usually showing a number of apparent rings or segments (metameres), and are either flat or cylindrical in transverse section. Excluding a number of classes as of no interest in the present connection, there remains the classes of Flat worms and Round worms as including various genera and species in which occur human parasites.

### A—PLATHELMINTHES (FLAT WORMS).

Several orders of flat worms live free, non-parasitic lives, the Turbellarians and Nemertines, both being recognizable by the presence of hair-like projections upon the surface of the body, as well as by their habitat (in water) from the parasitic flat worms, which at least in their adult stages have the cuticle free from hairs (small spines sometimes found, however). With the exception of a few comparatively rare intermediate forms (grouped under the name *Cystodaria*) the parasitic flat worms are divided into two orders: the *Trematodes* or Fluke-worms (with but an incomplete digestive canal, without anus), and the *Cestodes* or Tapeworms (devoid of any digestive tube).

#### I—TREMATODES OR FLUKE-WORMS.

Flukes are naked and unsegmented flat worms, usually of the shape of a leaf or of the tongue (occasionally pyramidal or elongated and more or less cylindrical), provided with incompletely digestive canal (without anus), possessing one or more suckers and occasionally hooklets; with but few exceptions hermaphroditic, and as a rule presenting a complicated series of metamorphoses in their development. Most examples are comparatively small worms.

In structure it is customary to speak of the surface upon which the genital pore opens as the ventral; this surface commonly also showing the orifices of the mouth and one or more suckers. On the dorsal surface in many occurs the opening of a small canal, spoken of as *Laurer's canal*, of unknown function. The surface of the body is covered by a fairly thick and firm cuticle, often provided over variable areas with small spines or tubercles. Beneath the cuticle over its internal surface is spread the *superficial muscular layer* (not showing the structure of muscle of higher animals, however), with longitudinal, circular, and diagonal fibers, while within this along the borders (and in thin strands or as isolated dorso-ventral fibers running through the general body tissue) is met the *parenchymatous muscle*. The general internal tissue of the body, spoken of as the *parenchyma*, is a fine reticular connective tissue which closely surrounds the various organs.

The suckers of trematodes vary in number and arrangement on the anterior and posterior extremities, the ventral surface and its borders, and in a few cases also on the dorsal surface. Usually the oral opening is surrounded by such a sucker (*oral sucker*) and in addition, in the forms likely to be met in man, on the ventral surface some distance posterior to the oral sucker is a second, known as the *ventral sucker* or *acetabulum*, in the median line. Not infrequently in the lining of these suckers, on their lips or on the cuticle close to the lips, chitinous hooklets are to be found.

The alimentary system consists of a mouth, opening in the oral sucker and situated terminally or on the ventral surface of the anterior end of the worm. This cavity continues into a dilated tube with thick walls, the *pharynx*, this extending posteriorly by a short, straight, and usually narrow *esophagus*, which divides in the anterior portion of the body into the two *intestinal tubes* or *ceca*; these running,

one in each longitudinal half of the worm, either as simple tubes or more or less branched, to the posterior portion of the body, where they end blindly (in a few cases joining in posterior portion to form a single cecum). About the esophagus more or less developed single-cell digestive glands are attached to the outer surface. It may readily be seen that in such arrangement the mouth must serve both for ingestion and as an anus. At the posterior extremity of the body as a small orifice the *excretory pore*, which serves as outlet for a series of more or less complex canals for the convection of the fluid waste, which begin in various parts of the body in special "excretory cells"—the arrangement representing a low nephridial apparatus.

Flukes present a fairly definite but low type of nervous system. A ganglionic mass on each side in the cephalic end sends three trunks to the posterior end of the body (*dorsal, lateral, and ventral*), there existing commissures in the head, about the pharynx, and anastomosing branches between the longitudinal trunks, as well as a complex system of fine branches to the various parts of the body tissues. Moreover in the larval stage (as in the cercarial period) there may be seen in this or that species certain superficial pigmented spots regarded as *eye-spots* or *ocelli*, examples of low sensory apparatus; these disappear from the adult animal.

The reproductive system is highly developed, showing numerous minor variations in the different genera and species. In general, taking the more common hermaphroditic forms as examples, the following features may be recognized. The sexual organs for the most part lie in the so-called "middle area" of the body, that is between the two lateral ceca. Usually there are two testicles, variable in size and shape, most frequently situated in the posterior portion of the worm; a seminal duct arising from each passes forward and toward the middle line to unite in a *vas deferens*, which extends anteriorly to continue into a thick-walled pouch (*cirrus pouch*), the latter opening on the ventral surface at the *genital pore*, either in close proximity or in common with the vulvar opening of the female canal. This genital pore is generally in the anterior portion of the body, in or near the median line, and near (anteriorly, laterally, or posteriorly) the acetabulum. A thread-like organ, the *cirrus* or *penis*, of variable size and appearance, lies in this pouch or is sometimes seen protruded externally from it. Internal to the vulvar orifice the *vaginal tube*, here spoken of as the *metratrum*, is continuous with the uterine tube, which extends in numerous folds or coils in the area between the intestinal ceca, generally anterior to the testes and ovary. At its inner end the uterus communicates in the midst of a mass of cells, spoken of as the "shell gland" (the function of which is not known and very probably not that of furnishing shell material in the formation of the ova), with three other tubes. One of these is the *oviduct*, a simple tube arising from the ovary (which as a rule lies anterior to the testes, is smaller than the latter, single, and generally rounded or lobate). Another is the *vitelline duct*, formed by the union of two tubes passing transversely to the median line from the *yolk glands* (or *vitelline follicles*), which are distributed in greater or less number along the lateral margins of the body; the third is a small canal, Laurer's canal, opening on the dorsum of the worm, and often distended in its inner end into a *receptaculum seminis* (which in adult specimens is found filled with sperm). Where these four tubes unite in the shell-gland (uterus, oviduct, vitelline duct, and Laurer's canal) is commonly a small vesicle known as the *oötype*.

Both cross-fertilization and self-fertilization probably take place (but in the former case it is not likely that the sperm enters by way of Laurer's canal as once believed, but rather by the vagina and through the uterine canal to the oötype and receptaculum seminis). After formation the ovum is passed from the uterine canal by route of the vagina and vulvar orifice, either without evident development or in some instances with a well-formed embryo showing within its wall. Commonly the ovum has at one end a small opening (*operculum*) covered until the escape of the embryo by a lid (demonstrable where not evident by the addition of a little sulphuric acid to the medium containing the ovum under observation). For the development and emergence of the embryo the egg (directly in case of the ectoparasitic forms; after discharge from the definitive host in case of endoparasitic trematodes) should be deposited in water. Here the embryo leaves the ovum as a ciliated and minute form (*miracidium*), swimming free for a time, and eventually under favorable circumstances gaining entrance into the tissues of a first intermediate host (molluscs, leeches, worms, arthropods, fish, amphibia). In this host after simple intermediate development the larval forms may remain encysted until the host is devoured by the definitive host, in whom they develop into the adult and sexual trematodes; or, as is quite common, one or two larval generations may be formed in this first intermediate host, a variable (multiple) number of larval flukes (*cercaria* being in such case produced from the one original ovum. These then entering a second intermediate host and becoming encysted, remain until it is eaten by the definitive host, when the larvæ grow into the adult form. In this latter and more complicated form of development the miracidium penetrates from the water in which it has been swimming into the tissues of the first intermediate host (as a snail) and becomes encysted (*sporocyst*), dividing into a number of individuals known as *rediae*. These, escaping from the distended cyst, penetrate further into the tissues of the host, each again to become encysted and multiplying into a number of the final larvæ which have

somewhat the shape of a tadpole and are known as *cercariæ*. These by disruption of the tissues of the host escape to the water and for a time live a free life; eventually, if fortunate, gaining entrance in unknown manner to the tissues of the second definitive host (snail, mollusc, or other water animal); lose their tails and again become encysted (in absence of such second host may become attached to a blade of grass or other foreign body and become encysted upon it, the cuticular glands furnishing a substance hardening into a resistant cyst wall), remaining in this situation until the second host (animal or grass blade) is devoured by a definitive host. Arrived in the alimentary canal of the latter the cyst-wall is dissolved off by the digestive juices and in unknown manner the larva finds its way to its preferred habitat and grows into the adult. (In case of ectoparasitic flukes the development is usually direct and simple, often in close proximity to the adult from which the ovum was derived—as upon the surface or gills of some fish.)

Adult flukes are parasitic upon a wide range of animal life, including the higher animals, fish, amphibia, reptiles, and birds, living both as ectoparasites and endoparasites. The endoparasitic forms prefer commonly the passages and cavities in communication with the exterior, alimentary system (any part from mouth to anus and branches), the urinary passages, bladder or kidneys, the respiratory tubes or air-sacs of the lungs. The genitalia, the blood-vessels, the eye, brain, cysts in the subcutaneous tissue and general tissues, may be the seat in this or that case of one or other species.

The varieties affecting man are comparatively few, of the very great number in existence; the most common parts of the human body to be infested being the intestine, gall-ducts, respiratory tubes, and blood-vessels.

The following classification of trematodes is here adopted from Braun with minor modifications:

I—*HETEROCOTYLEA*: ectoparasitic, with well-developed fixation organs (suckers, hooklets); distinguished by the excretory pores opening on the dorsal surface in anterior end, and by their direct development; living upon the gills of fishes (fresh-water and marine), but also in the urinary bladder of amphibia and esophagus of turtles.

II—*ASPIDOCOTYLEA*: endoparasitic; low trematodes with large ventral fixation apparatus; excretory pore posterior; and direct development; parasitic in the intestines or gall-bladder of turtles, marine fishes, as well as in certain mussels (in excretory organs of latter especially).

III—*MALACOCOTYLEA*: flukes with fixation apparatus usually consisting of one or two suckers (oral and ventral); accessory suckers rare (only in *Holostomidae*); without chitinous hooklets; intestine usually divided; oral opening at anterior end (except *Gasterostomum*); male and female organs usually in one individual; genital pore usually on ventral surface; excretory pore opening at posterior extremity; always endoparasitic and almost without exception in vertebrates, especially in intestine.

According to their mode of development this order is divided:

A—*METASTATICA*: development direct, without intermediate generations, but with two larval forms (miracidium, cercaria) and one change of host.

Family: *HOLOSTOMIDÆ*. (Genera: *Hemistomum*, *Holostomum*, *Diplostomum*, *Polycotyle*.)

B—*DIGENEA*: development complicated by the introduction of sexless, self-multiplying generations (sporocyst, redia) and with one or two changes of host.

Family 1—*PARAMPHISTOMIDÆ*: with posterior terminal sucker above which on dorsal surface the excretory pore opens; genital pore in median line of ventral surface in anterior third of body; intestine without appended glands; pharynx carried far anteriorly, generally into oral sucker; hermaphrodites. (Genera, *Paramphistomum*, *Gastrothylax*, *Gastrodiscus*, *Cladorchis*, etc.)

Family 2—*FASCOLIDÆ*: with oral sucker and acetabulum; excretory pore opening at posterior extremity; genital pore on ventral surface or on lateral or

FIG. 153.—A group of free cercariæ.

posterior border; intestine usually without glandular appendages; hermaphrodites. (Genera, *Fasciola*, *Fasciolopsis*, *Paragonimus*, *Opisthorchis*, *Clonorchis*, *Cotylagonimus*, *Dicrocoelium*, etc.)

Family 3—SCHISTOSOMIDÆ: approaching *fasciolida* in structure, but with sexes separate. (Genera, *Schistosomum*, *Bilharziella*.)

Family 4—DIDYMOZOONIDÆ: a poorly defined group whose representative (*Didymozoon*, *Nematobothrium*) live in couples in cysts in the superficial tissues or mouth or gill cavities of marine fishes; sexes separate.

Family 5—RHOPALIDÆ: hermaphrodites; approaching *fasciolida* in structure; with oral and ventral suckers and with two retractile snouts; genital pore in anterior third of body on ventral surface; genital glands in posterior portion. (Genus, *Rhopalias*.)

Family 6—GASTEROSTOMIDÆ: with ventrally situated oral opening and single intestinal sac. (Genera: *Gasterostomum*, in intestine of fish; here too the form *Bucephalus*, known only in cercarial stage.)

Family 7—MONOSOMIDÆ: approaching *fasciolida* in structure, but with only anterior sucker; genital pore ventral, in anterior third of body; genital glands usually in posterior third of body; intestine with or without glandular appendages; posterior portions of intestine often uniting into a single cecum.

Order: MALACOCOTYLEA; DIGENEA;

Family: PARAMPHISTOMIDÆ;

Genus: *Gastrodiscus*.

***Gastrodiscus hominis* (Lewis & McConnell),**

(*Amphistomum hominis*).

Measures 5.-8. mm. long and 3.-4. mm. wide; body consists of anterior rather slender conical part and a posterior broader, circular disk-like part with its ventral surface concave, each portion of about equal length; ventral sucker posterior; anterior sucker at anterior extremity, elliptical, transverse; genital pore about middle of anterior portion at level of bifurcation of esophagus; pharynx with two lateral pockets; fresh specimen reddish; ova ovoid, operculated, averaging 150.: 72. microm.

FIG. 154.—*Gastrodiscus hominis*: enlarged twice; A, ventral and B, dorsal view. (Railliet, after Lewis and McConnell.)

This fluke has been met twice in man (in an Assamese and in a Hindoo) in large numbers in the cecum and colon, fixed by its posterior sucker to the intestinal mucous membrane. It is probably only an accidental human parasite, its proper definitive host being in all likelihood some other mammal. The two individuals in whom it was encountered were dead from cholera and nothing is known of the symptomatology induced by the worm itself. The intestinal mucous surface of these subjects were dotted over with numerous small red foci looking like the lesions caused by some of the blood-sucking parasites.

Genus: *Cladorchis*.

***Cladorchis Watson* (Conyngham),**

(*Amphistomum watsoni*).

Worm pear-shaped, measuring 8 mm. in length, 4 mm. thick at thickest part, 5 mm. wide at posterior third, tapering anteriorly to 2.5 mm. It is rounded dorsally and is flattened or slightly concave ventrally; is of a dark slate color, the cuticle marked by transverse ridges which are best defined on ventral surface. Anterior sucker small, terminal, set in a small sulcus which extends ventrally. Posterior sucker larger, circular, subterminal. Genital pore rather prominent, in median line, about one-fifth the length of worm from head end. Pharynx small; short, muscular esophagus; cecal branches extend in lateral fields nearly to posterior end. Ovaries small, median, just in front of posterior sucker; shell-gland at same level, to the side of ovary; vitelline glands marginal from level of cecal division to posterior fifth of worm. Testes in median line, ventral to uterus, compactly arranged, occupying the middle third of length. Uterus plicated through the greater part of median field. Ova ovoid; 30.: 80. microm.

This parasite was discovered in the dejecta and in the upper part of the small intestine of a negro from German West Africa, the patient dying

from an intense diarrhea. Thus far this is the only instance of the recognition of the parasite.

Family: FASCIOLIDÆ;

Genus: *Fasciola*.

***Fasciola hepatica*** (Lambé),

(*Distomum hepaticum*; *d. cavia*; *fasciola humana*; *cladocælium hepaticum*; the common liver fluke).

A comparatively large fluke, measuring 20.-50. mm. long and 8.-13. mm. wide, of leaf shape, with anterior extremity prolonged into a small cone; greatest width of body about anterior third of length; light brown color; cuticle provided with alternating transverse rows of spines, extending on ventral surface to the posterior level of testes, but not as far posteriorly on dorsal surface; oral sucker at anterior end of cephalic cone, inclining to ventral surface (1. mm. in diameter); ventral sucker near anterior end behind cephalic cone (1.6 mm. in diameter); well-developed pharynx and short esophagus; intestinal branches extending nearly to posterior extremity of worm, approaching the median line posteriorly, with few median and numerous lateral branches; excretory pore at posterior extremity, with well-developed system of excretory tubes; genital pore in median line anterior to ventral sucker; two large, highly branched testes, mostly posterior to the transverse vitelline duct; ovary single, branched, lying in front of testes and to one side of median line; uterus coiled into a rosette, showing as a brown spot (from ova contained) just back of ventral sucker on ventral surface; vitelline glands numerous, ranging along each lateral border from the level of the ventral sucker to the posterior extremity of the worm; vitelline ducts running transversely at about the end of the anterior third of body; ova yellowish-brown, oval, operculated, measuring 130.-145. microm. long and 70.-90. microm. wide.

FIG. 155.—*Fasciola hepatica*: natural size; cleared in oil. (Gould after Leuckart.)

This parasite is a common one in sheep; and is also found in cattle, deer, goats, hogs, horses, asses, camels, rabbits, guinea-pigs, and other mammals. It is occasionally (23 cases recorded according to Braun) met in man. It has a wide geographical distribution over the world, and is not infrequently found in this country. Its usual habitat is the gall ducts; but it has been encountered ("errant flukes") in the gall-bladder, intestines, in the portal and other venous channels, and rarely in subcutaneous cysts. The life-history has been unusually well followed out and may be outlined as follows. The ova after oviposition are carried by route of the gall-passages and intestines to the exterior where, if fortune favors, they are deposited in water. Here the embryo develops and escapes through the operculum, swimming about as the free miracidium until it can gain entrance to the tissues of a snail (some form of *Limnæa*), in which the sporocyst is formed and the rediæ (half a dozen or more) develop; these presently emerge from the parent cyst and wander further into the tissues of the snail, each then again encysting and dividing into a number of cercariæ. By this time probably the snail has died from the effects of the parasites; and its tissues disintegrating, the tadpole-like cercariæ escape in the water and for a time swim free. These later become attached to a blade of grass or other similar object, lose their tails, and become covered with a hard covering, a product of their cuticular glands, and thus remain protected for a variable time. Later the definitive host, probably a sheep, devours the grass and with it the cercaria, which on arrival in the alimentary tract has its covering removed through the action of the digestive juices and in some manner (whether by the common duct into the hepatic duct and its radicals, or by boring through the intestinal wall into the portal vein and

thus carried to the liver, is unknown) finds its way into the bile ducts, where it grows into the adult worm. Doubtless in the occasional cases of human acquirement it is similarly conveyed upon some water vegetables, as cress, to the stomach. In the lower animals there are often found large numbers (from dozens to hundreds) of the flukes in the bile ducts of a single host; but in man, while this is possible, ordinarily one finds but very few.

FIG. 156.—Showing the sexual organs of *fasciola hepatica*; 5 x 1. O, oral sucker; D, intestinal caeca; Do, vitelline glands; Dr, ovary; Ov, uterine canal; T, testis; Sg., "shell gland," V, transverse vitelline duct; Gp, genital pore; S, ventral sucker. (Braun.)

FIG. 157.—Showing the alimentary system of *fasciola hepatica*, other parts suppressed; 5 x 1. (From a fluke as yet undeveloped in its sexual organs.) (Braun.)

The effects as seen in the lower animals—quite similar in general character in case of man—are of little severity and may well be overlooked in case the parasites are but few; but when the parasitism is of serious grade a condition often proving fatal, and known in sheep as "liver-rot," is induced. The worms are well anchored in the small tubes by their suckers and posteriorly inclined cuticular spines, and the ducts are often at site of the parasites distended into small cysts. The flukes suck blood from the walls of the ducts, and cause considerable biliary and peribiliary irritation with fibrous thickening of the walls and a cirrhotic extension into the surrounding hepatic tissue, which undergoes atrophic and degenerative changes in some degree. Hemorrhages into the ducts often occur, constituting one of the influences producing the more or less severe anemia characterizing the affection. Gallstone formation is quite common,

mixed concretions of biliary matter, mucus, and blood remnants sometimes forming complete casts of greater or less length of the infested ducts. Thus biliary obstruction with the development of icterus, and portal interference with the production of ascites, are common. At first, the liver is enlarged, but eventually becomes atrophic from the cirrhosis and tissue degeneration. Digestive disturbances with anemia, loss of flesh and enfeeblement appear, and eventually death is apt to take place from exhaustion. These symptoms, usually first appearing in a month or two after the parasites gain access to the liver, are evidence of an active but definite inflammatory and degenerative hepatic affection; and for the absolute diagnosis of the nature of the case recourse must be had to the microscopic examination of the dejecta for the ova of the parasites. The majority of instances encountered in man have been met at autopsy, without previous suspicion of their existence.

It is probable that the cases of flukes in the eye and described under the names *Distomum oculi humani* (Ammon, 1833), *Monostomum lentis* (v. Nordmann, 1832) and *d. ophthalmobium* (Diesing, 1850), were but errant and immature examples of the worm under discussion.

**Treatment.**—But little of value can be said in connection with treatment of the condition, the most important measures being prophylactic and looking to the restriction of the flocks and herds from pastures on badly drained land where the common grass snails are known to be present. In active treatment it must be clear, because of the position of the flukes, that difficulty exists to reach the parasites with medicaments capable of destroying them. Numerous remedies have been suggested for the affection in sheep and the same substances may be tried in human cases. Salol is said to have lethal effects upon the trematodes in the liver, but must be given in comparatively large doses and persistently; the ethereal extract of male fern is sometimes employed, as well as naphthalin, various salts of iron, sodium chlorid, and a number of other substances. In addition measures may be indicated to combat the digestive and nutritive symptoms, but these are in no wise peculiar.

FIG. 159.—Ovum of *Fasciola hepatica*.

FIG. 158.—Miracidium of *Fasciola hepatica*. (Gould after Leuckart.)

Genus: *Fasciolopsis*.

*Fasciolopsis buski* (Laukester),

(*Distomum buski*; *d. crassum*).

Length variable, 24–70. mm.; breadth, 5.5–14 mm.; lance-shaped; narrowing more rapidly anteriorly than posteriorly, maximal width about middle of length; no cephalic cone; brownish; cuticle without spines; oral sucker small, on ventral surface of anterior extremity; ventral sucker two or three times as large as oral, placed near anterior end and showing a saccular distention extending posteriorly; very short esophagus back of the fairly developed pharynx; the two ceca without branches; genital pore at anterior border of acetabulum; cirrus pouch large; testicles branched in posterior part of body, one back of the other; uterus in anterior half

of body, tortuously coiled; ovary at middle of length of body, to right of median line; Laurer's canal present; vitelline follicles numerous along lateral margins from level of ventral sucker to posterior extremity; the transverse vitelline ducts at equator of body; ova brownish, ovoid, operculated, measuring 12.5 : 7.5 microm.

Busk's intestinal fluke has been encountered but a few times (six or eight) in the small intestine of man in India and China. An unpublished case, in a Lascar sailor, has been reported personally to the writer from Galveston, Texas, by J. J. Terrill. Practically nothing is known of the intermediate stages and their hosts; but the common diet of India and China (fresh vegetables, fish, oysters, etc.) doubtless furnishes the means of convection to man and accommodates the cercariæ.

FIG. 160.—*Fasciolopsis buski*: *a*, oral sucker; *b*, acetabulum; *c*, cirrus pouch; *d*, vitelline glands; *e*, "shell-gland"; *f* and *g*, posterior and anterior testes; *h*, ovary; *i*, cecum; *k*, uterus. (Braun, after Odhner.)

coiled tube; vitelline follicles numerous along the lateral borders of body from anterior to posterior end, reaching well into the middle area of the worm, their transverse ducts at about the equator of body; ova yellowish, oval, thin-walled, operculated, averaging 94. : 57. microm., but varying on either side of these figures, in length and breadth.

The Asiatic lung fluke inhabits the bronchial tubes of man, cat, dog, hog, and mouse; it has also been recorded from the bronchial tubes of a tiger in the zoological gardens of Amsterdam; the worm has also been found in the brain and a few other situations in the body. Usually there are small bronchiectatic cysts in the lungs, in which in the midst of a reddish-brown mass of blood and mucus the worms are found, generally two in each such cyst; the pulmonary tissue about these cysts, fibroid or

A shorter and broader fluke, known as *distomum rathousi*, has been regarded by many as identical with Busk's fluke; but aside from its different shape there are a number of features (testes in same level in posterior part of body; ovary back, instead of in front of the transverse vitelline ducts; and the very small size of the oral sucker) which seem sufficient to separate the species. This form has been met three times in the human intestine in China and North Borneo.

Genus: *Paragonimus*.

*Paragonimus westermanni* (Karbut),

(*Distomum westermanni*; *d. ringeri*; *d. pulmonale*; *d. pulmonis*; *mesogonimus westermanni*; the lung fluke).

Length 8.-10. mm.; breadth (at anterior third) 4.-6. mm.; nearly as thick as broad; reddish-brown cuticle with scale-like spicules; oral sucker ventral at anterior end; ventral sucker just anterior to middle of length; pharynx small, esophagus short, ceca run a zigzag course rather close to the lateral margins to near the posterior extremity; the excretory system showing a large canal or vesicle in median line of body and numerous branched; excretory pore on ventral side of posterior extremity; genital pore just back of border of ventral sucker on one or other side; cirrus and pouch lacking; testes tubular, branched, back of transverse vitelline ducts, not quite on equal level, one on each side of excretory vesicle; just back of ventral sucker, in front of vitelline ducts, near equator of body, on one side of the median line lies the branched ovary; on the other side lies the uterus as a fairly closely

otherwise changed, and the bronchial mucous membrane in the vicinity of the cyst more or less inflamed. From tissue destruction in the cyst-wall bronchial hemorrhages from time to time are apt to take place, constituting

FIG. 161.—*Paragonimus westermani* (ventral view).  $10 \times 1$ . A, oral sucker; B, ceca; D, acetabulum; E, genital pore; F, uterus; G, ovary; H, testes; I, vitelline glands; K, excretory canal; L, excretory pore. (Braun, after Leuckart.)

the most pronounced evidence of the affection and leading to some degree of anemia. As a rule, the patient suffers but little inconvenience beyond a slight cough, and the hemoptysis rarely requires special attention. In

FIG. 163.—*Paragonimus westermani*: natural size; to left showing ventral surface; to right showing dorsal surface. (Braun, after Katsurada.)

FIG. 164.—Ovum of *paragonimus westermani*, from sputum;  $1000 \times$ . (Braun, after Katsurada.)

FIG. 165.—Ovum of *paragonimus westermani*, from sputum.

the sputum the ova are readily found, their recognition establishing the diagnosis. These are known to develop in from six to eight weeks in water into a ciliated miracidium; but all further knowledge as to the intermediate

stages and their hosts is lacking. The parasite has been encountered most frequently in Japan, Formosa, Korea, and China; in the hog, dog, and cat, it is known to exist in this country, and one imported case in man has been reported from Portland, Oregon.

The condition is not incurable; inhalations of balsamic material, of chloroform short of anesthesia, and similar measures holding out some promise of success in destroying the parasites and allowing them to be dislodged by coughing efforts, providing they are not too deeply encysted in the bronchial pockets. Nothing is known of the modes of acquirement of the worm and hence no known prophylactic measures exist at present.

Genus: *Opisthorchis*.

1. *Opisthorchis felineus*.

(*Distomum conus*; *d. lanceolatum*, v. Siebold, 1836; *d. sibiricum*; *d. tenuicollis*; the European cat fluke.)

Variable in size according to the state of contraction (8.-11. mm. long; 1.5-2 mm. broad); yellowish-red and nearly transparent; flat, lanceolate; anterior end constricted and attenuated into a cone; posterior end more obtuse; cuticle without spines; oral sucker toward ventral surface at anterior extremity; ventral sucker at base of cone (about one-fourth of body length); pharynx and esophagus of equal length, both rather small; ceca comparatively straight and unbranched, reaching

nearly to posterior extremity and often seen filled with blood; excretory pore terminal, and its vesicle (tubular) winds in median line between the testes and branches in front of the anterior testes; testes in posterior parts of body, one anterior (four-lobed) to other (five-lobed); cirrus and pouch absent; genital pore in median line, in front of ventral sucker; ovary in median line, anterior to testes, slightly lobate; receptaculum seminis prominent; uterus anterior to ovary and testes, coiled in middle third of body; vitelline follicles occupy about middle third of body, beginning anteriorly at level of ventral sucker; oval in shape, operculated, containing ciliated embryo when deposited, 30. : 11. microm.

FIG. 167.—*Opisthorchis felineus*: from liver of cat. 10×1. (Braun.)

FIG. 166.—Ovum of *opisthorchis felineus*: 830×1. (After Braun.)

This worm has been met as a parasite inhabiting the gall ducts in the cat, dog, fox, glutton, and in man. It has been reported from Russia, Siberia, France, Holland, Germany, Hungary, Italy, and Japan. In man it has been encountered in 6.45 per cent. of autopsies at Toms, constituting the most frequent example of all verminous parasites. It causes dilatation and thickening of the walls of the gall ducts with surrounding diffuse and focal atrophic and degenerative changes in the hepatic substance, leading after a period of hepatic enlargement to a condition of cirrhotic reduction in size, with icterus, ascites, and marked digestive and nutritive faults, anemia and exhaustion.

As many as several hundred parasites have been obtained from a single liver. Azkanazy, in two cases, has met carcinoma of the liver associated with conditions distinctly due to the parasites. In several cases reported by the latter writer and Winogradoff a few flukes were encountered also in the intestines in addition to those found in the usual position in the liver. Nothing is known of the intermediate stages and of their hosts.

In 1895 Ward stated that he had found this species in a cat in Nebraska. Further study has shown, however, that Ward's parasite is not identical, although closely allied; this species is known as *opisthorchis pseudo-felineus*.

## 2. *Opisthorchis noverca*.

(*Distomum conjunctum*; the Indian liver fluke.)

A small fluke, 10.-12. mm. long, 2.5 mm. broad; lanceolate, more attenuate anteriorly than posteriorly, but rather narrow toward each end; cuticle covered with small spines; oral and ventral suckers close to each other, former subterminal; pharynx globular, esophagus short, ceca slender, unbranched, reaching close to posterior extremity; genital pore in median line directly in front of ventral sucker; the two testes in posterior third of body, one on each side of median line, overlapping (anterior to left, posterior to right of median line) slightly lobate; cirrus absent; ovary in median line in front of testes; uterus in front of ovary, coiled in middle field and reaching anteriorly to ventral sucker and testes; excretory pore terminal, its tube (vesicle) branching in Y-shaped manner between the ovary and testes; ova oval, 34. : 21. microm.

The parasite has been encountered only a few times, at autopsy, in the slightly distended gall ducts of man in India. Similar parasites, but of doubtful identity, have been retained with this species from the dog in India and in one instance from an American red fox in the zoological gardens in London.

FIG. 168.—Ovum and miracidium of *Clonorchis sinensis*. (Braun, after Leuckart.)

FIG. 169.—*Clonorchis sinensis*: to left a young example from cat (ventral view); to right a more mature specimen from man (dorsal view).

Genus: *Clonorchis*.

### 1. *Clonorchis Sincusis*.

Gums: *Clonorchis*.

#### 1. CLONORCHIS SINCUSIS.

(*Distoma sincuse*; *d. spatulatum*, Leuckart; *d. hepatis innocuum*; *d. hepatis endemicum*; *s. perniciosum*; *d. japonicum*; *clonorchis endemicus*.)

Length, 10.-20. mm.; breadth (near middle of length), 2.-5. mm.; long, lanceolate; reddish, nearly transparent when fresh; cuticle without spines; oval larger than ventral sucker, on ventral face of anterior extremity; ventral sucker about one-fourth body length posterior to former; pharynx and esophagus small, and bifurcation of latter close to oval sucker; ceca unbranched, reaching close to posterior extremity; excretory pore terminal, its vesicle simple, curved like an italic S, dorsal to testes. In posterior fourth of body the two testes, one in front of the other, each with long coarsely divided branches reaching beyond the ceca laterally; no cirrus or pouch; genital pore in median line just in front of acetabulum; ovary trilobed, placed just anterior to a large gourd-shaped receptaculum seminis, both in median line and anterior to testes; uterus well developed and coiled in middle area of body between ovary and ventral sucker; vitelline glands in marginal fields along middle third of body. Ova brown, oval, operculated, 27.-30. microm. in length, 15.-17. microm. in width.

This fluke usually described under the generic name *opisthorchis* has recently been erected by Loos into a new genus, mainly because of the length of the testicular branches and the simple excretory vesicle. Loos, following in this respect Baelz, recognizes two species, although there has been some opposition. He describes as one species examples of comparatively large size, with a proportionately small ventral sucker and with yellowish to

FIG. 170.—*Clonorchis sinensis*: ventral surface, stretched; a, oral sucker; b, ceca; c, genital pore; d, acetabulum; e, uterus; f, vitelline glands; g, ovary; h, receptaculum seminis; l, Laurer canal; i, testicles; k, excretory canal; m, excretory pore. (Braun, after Leuckart.)

brownish granules in the parenchyma, applying to them the name *clonorchis sinensis* (*d. innocuum* of Baelz). Smaller examples, ranging from 6. to 13. mm. in length and from 1.8 to 2.6 mm. in width, without pigment granules in the parenchyma, and with a relatively larger ventral sucker, constitute, according to Loos, a second species, *clonorchis endemicus* (*d. endemicum*, *s. perniciosum*, of Baelz). For the present J. Allen Smith prefers to consider these possible species as one.

This fluke, comparatively common in Japan and Eastern Asia, has been reported also from this country in a few imported cases. It infests the gall-ducts, gall-bladder (has also been found in the pancreatic duct and in the intestine) of man, cat, and dog. The number of parasites in one host has in some cases reached several thousand; and serious, often fatal, changes result from the higher grades of infection. The liver for a time becomes more or less enlarged, but eventually is decreased in size, cirrhotic, and degenerated, with distended, obstructed, and thick, fibrosed-walled ducts. The symptoms are much as above outlined for other hepatic flukes,

as digestive disturbances, anemia, exhaustion, jaundice, and ascites. It is estimated that as high as 14 per cent. of infected individuals die from the affection. Nothing beyond the ciliated miracidium is known of the intermediate stages or their hosts, although it has been suspected in this as in case of *opisthorchis felineus* that fish may accommodate an intermediate stage. No successful mode of treatment or prophylaxis is as yet known; although suggestions along such lines as made in connection with *fasciola hepatica* should tentatively be adopted.

Genus: *Cotylagonimus*.

*Cotylagonimus heterophyes*.

(*Distomum heterophyes*; *mesogonimus heterophyes*; *canogonimus heterophyes*; *heterophyes heterophyes*; Egyptian intestinal fluke.)

Small fluke measuring two millimeters long and one broad; anterior end thin and contractile upon the thicker posterior end; former pointed and narrow, latter

more rounded; surface, except toward posterior end, thickly beset with quadrate scales; reddish-brown in color; oral sucker on ventral side of anterior extremity, smaller than ventral sucker, which is situated in front of the middle of the worm, near the junction of the thin anterior with the thick posterior portion; esophagus moderately long; ceca unbranched, reaching to terminal extremity; genital pore back of ventral sucker in median line or to one side, its border raised and beset with branched spines; male and female tubes unite to form a cloaca before opening in the genital pore; testes oval, in posterior extremity, lying close to ceca and parallel with the margins of the body; deferent canal widened to form a large seminal vesicle before opening in genital cloaca; ovary single, oval, anterior to testes in median line; large, gourd-shaped receptaculum seminis; uterus widely coiled in posterior portion of the worm, between ventral sucker and testes; vitelline follicles few, along the margins of the posterior fourth of the body length; ova oval, reddish-brown, thick-walled, 30. : 17. microm., containing, when deposited, the ciliated miracidia.

This worm has been found recently in increasing frequency at autopsy in the small intestine of man in Egypt; and is also reported from the same host and habitat from Japan. Identical forms have also been encountered in the dog, cat, and fox. It apparently gives rise to no important pathological changes. Its intermediate stages and their hosts are unknown.

Genus: *Dicrocoelium*.

***Dicrocoelium lanceatum***  
(Styles & Hassall).

(*Distomum lanceolatum*; *fasciola lanceolata*; lance-shaped fluke.)

Body lanceolate, a little more attenuate anteriorly than posteriorly; semi-transparent, yellowish, often blotched with brownish spots from the ova in the uterus; 8.-10. mm. long, 1.5-2.5 mm. wide (broadest about equator); smooth; oral sucker at anterior extremity, subterminal, smaller than ventral sucker; ventral sucker about one-fifth the body length posterior to the former; pharynx small and globular, esophagus rather long and slender; ceca unbranched, reaching to posterior fifth of worm; excretory pore at posterior end of worm with a simple tubular vesicle; genital pore in median line midway between suckers, close to the bifurcation of esophagus; testes in anterior half of body, one behind the other, lying just back of the ventral sucker in the middle area of the worm; ovary small ovoid, back of testes; uterus posterior to ovary, coiled loosely in posterior half of body, extending close to the margins of the body in the posterior extremity; ova brown, oval, thick-walled, 38.-45. microm. long by 22.-30. microm. in width, with miracidium ciliated at anterior portion in interior at time of oviposition.

FIG. 171.—*Cotylogonimus heterophyes*: 53×1; *a*, cerebral ganglion; *b*, cuticular glands; *c*, cecum; *d*, genital pore; *e*, uterus; *f*, Laurer's canal; *g*, receptaculum seminis, in front of which is the ovary; *h*, testes, between which is seen the excretory system; *i*, vitelline glands; *k*, seminal vesicle. To the left, above is shown the ovum, 700×1; below are three chitinous spines from the border of genital pore. (Braun, after Loos.)

The lanceolate fluke has been met in the gall ducts of a large number of herbivora and omnivora, sheep, cow, goat, ass, horse, deer, rabbit, hog; and is occasionally associated with the common large liver fluke (*fasciola hepatica*). Geographically it is widely distributed in Europe and in Siberia,

Turkey, Egypt, and Algeria. In man, according to Braun, but seven instances have been met, in all cases without definite symptoms of its presence, although in the lower animals, probably because of higher degrees of infection, its symptomatology is much as in case of *fasciola hepatica*. Nothing is known of the intermediate stages and their hosts.

Family: SCHISTOSOMIDÆ;

Genus: *Schistosomum*.

1. *Schistosomum hæmatobium* (Bilharz).

(*Distomum hæmatobium*; *d. capense*; *Bilharzia hæmatobia*; *gynecophorus hæmatobius*; *thecosoma hæmatobium*; African blood fluke.)

Sexes separate. *Male*: whitish, 12.-14. mm. long (often less), with margins back of ventral sucker folded on ventral surface so as to form a long groove (gynecophorous groove) and when thus folded the thickness is about half a millimeter; oral and ventral suckers close together in the attenuated anterior end of the worm on ventral surface, prominent; esophagus short, dividing into two simple intestinal tubes which back of the testes reunite to form a single cecum; numerous gland cells about esophagus; excretory pore opening at posterior extremity slightly dorsally; genital opening in median line back of ventral sucker; no cirrus pouch; testes five or six in number, vesicular; cuticle of

FIG. 172. — *Dicrocoelium lanceatum*: on left natural size; on right enlarged 10 times (ventral view); ph, pharynx; œ, œsophagus; i, intestine; t and t', testes; cd and cd', vasa deferentia; pc, cirrus pouch; o, ovary; ga, vitelline glands; u, uterus; v, vagina; w, acetabulum. (Railliet.)

FIG. 173. — Miracidium of *dicrocoelium lanceatum*: A, lateral and B, flat view. (Braun, after Leuckart.)

FIG. 174. — Ovum of *dicrocoelium lanceatum*.  $\times 600$ .

dorsal surface covered with small spinulated tubercles, of ventral surface bearing spines except along the median line. *Female*: whitish to reddish-brown; filiform; length 15.-20. mm.; suckers as in male, prominent; cuticle with spines; digestive tube as in male (single cecum from reunion of intestinal tubes posterior to ovary); ovary oblong, lobate, lying in posterior fork of intestine; vitelline follicles extend posteriorly to extremity of body from just back of ovary; oviduct and longitudinal vitelline duct run forward to unite at "shell-gland" with the uterus in a dilated oötype; uterus straight, tubular, extending forward to the genital pore, which opens at posterior border of ventral sucker. The two sexes lie constantly together, ventral surfaces in contact, the female in the gynecophorous groove of the male. Ova oval in shape, thin-walled, without operculum, with a spine at one end or along the side of one end, 135.-180. microm. long, 55.-60. microm. broad.

The blood fluke is found in the veins, commonly the portal veins and its branches, and the plexuses about the bladder and rectum, in man and a few species of monkeys. It is met mainly in Africa (Egypt, Abyssinia, Sudan, Mozambique, Natal, Tunis, Algeria, etc.); but has been reported in imported cases from this country and elsewhere. It is said also to occur in Cuba and Porto Rico. It is more common in the young than in adults.

The presence of the adult worm is not the serious feature of the infection, the fault depending rather upon the fact that the ova are liable to

obstruct the vessels and give rise to important pathological results. Lodged for example in the small veins of the vesical plexus, an inflammation of the bladder and rupture of the occluded vessel with appearance of blood in the urine are apt to result; or if in the wall of the lower bowel, a proctitis or colitis with dysenteric hemorrhages. The vesical symptoms are not infrequently marked, pain and tenderness in the hypogastrium, a burning pain in the urethra, especially on micturition, difficulty of micturition, sometimes evidence of prostatic swelling, with the urine containing blood, pus, and

FIG. 175.—Ova and miracidium of *schistosomum hamatobium*,  $\times 300$ ; A, ovum as seen in urine; B, the same after addition of water; C, miracidium. (Railliet.)

mucus as well as the ova of the parasite. Sometimes the inflammatory disturbances may extend along the ureter to the pelvis of the kidney and the latter organ itself, inducing the symptoms of a more or less grave nephritis. Occasionally from convection of the ova into the liver or lungs symptoms referable to these organs may also be met. Fatal results are to be apprehended after a variable period of such symptoms, with secondary anemia, debility, and exhaustion.

No knowledge is had of the intermediate stages beyond the miracidium, which is not infrequently seen in the ova in the urine or feces. It is suspected that the infection is carried through unfiltered drinking-water, and as a measure of prophylaxis this should be strictly cared for in infested districts. No plan of successful medication is known; but all means of ordinary character for conservation of nutrition and repair of blood loss should of course be undertaken as well as the usual methods of overcoming the actual hemorrhage, as the use of ergot, etc.

## 2. *Schistosomum Japonicum* (Katsurada.)

(*Schistosoma cattoi*; Asiatic blood fluke.)

Sexes separate. *Male*: brownish-yellow; 7.-12. mm. long, forming gynecophorous groove as in preceding species; cuticle provided in canal with minute spines, but on dorsum the spinulated tubercles met in *s. hamatobium* are wanting; oval sucker terminal, provided with minute spines; ventral sucker larger than oval and more prominent than in *s. hamatobium*, provided with small spines, situated

0.5 mm. posterior to oval sucker. Alimentary tubes much as in *s. hematobium*, but anastomoses several times. Genital pore closely posterior to acetabulum; vas deferens longer than *s. hematobium*; testes five or six in number, lobular, close set, in anterior part of posterior portion of body, between ceca. *Female*: darker in color, especially posteriorly, where the color becomes almost black; almost cylindric, somewhat longer than male, and 0.4 mm. thick at thickest part; suckers as in male; cuticle smooth; alimentary tubes as in *s. hematobium*; ovary and uterus much as in *s. hematobium*; vitellogenic glands more compactly arranged than in *s. hematobium*. Ova smaller and with blunter ends than those of *s. hematobium*, without spine, non-operculated, oval, brownish-yellow, 58.-90. : 30.-72. microm.

This fluke has been met in cats and in man in Japan and China. It is believed to be responsible for an endemic affection known in Japan as

FIG. 176.—*Schistosomum hematobium*: male with female in gynecophorous groove. (Braun, after Loos.)

Katayama, characterized by enlarged liver and spleen, disturbances of appetite, diarrhea (the dejecta often containing blood and mucus), and in severe cases anemia, fever, ascites and edemas, and occasionally death from exhaustion. The worms inhabit the vena porta and its mesenteric branches, and the ova are found in the liver and in the walls of the intestine, especially the large intestine. Unlike *s. hematobium*, these ova are not apt to be met in the urine but are found in the intestinal dejecta. In the liver and wall of the bowel, as well as in mesenteric lymph-glands, in the pancreas and other situations into which the ova are carried, there ensue either from the mechanical irritation of these objects or possibly partly from toxic factors produced by the worms and similarly disseminated (or from both of these influences) chronic hyperplastic and indurative changes which may be of serious importance. Anemic symptoms are best seen in heavy infestments, and are

thought to be partly due to the blood destruction and partly to toxic influences. Yamagiwa, according to Katsurada, believes that a case of epilepsy which he originally attributed to lodgment of ova of *paragonimus westermanni* in the brain of the patient was due in reality to ova of the parasite here mentioned.

## II—CESTODES OR TAPEWORMS.

**Historical.**—The larger forms, at least, of tapeworms, were known to the ancients as animal parasites infesting the alimentary canal. The correct notion of the origin and development of a tapeworm is, however, comparatively recent, and for a long time the young worm was supposed to start from the proglottids of the adult worm. The larval forms, or bladder-worms, have also been known, but were

regarded as simple cystic tumors, until almost simultaneously Redi in Italy and Hartmann and Wepfer in Germany inferred their animal nature, after which they were regarded as worms and made by Zeder, in 1800, a separate class, bladder-worms. In 1683 Edward Tyson discovered the head with its double row of hooklets in a large tapeworm in a dog; in 1684 Redi recognized the head and suckers of several forms; in 1700 Andry recognized the head of *taenia saginata*; and in 1777 Bonnet, and in 1776 Gleichen-Russworm, that of *dibothriocephalus latus*. From that time it was believed that a tapeworm was an animal which nourished itself by fastening its head into the intestinal wall. About the middle of the last century Kuchenmeister, by his celebrated feeding experiments, proved that the cysticeri or bladder-worms represented a larval stage in the development of the tapeworm, the latter having for its habitat the intestine of man (in case of those species infesting the human intestine), and the former the muscles and solid organs of certain lower animals and rarely of man.

**General Description.**—The cestodes or tapeworms are naked flat worms of elongated ribbon shape, endoparasitic at least in their adult stage, and in many instances in all stages, without a digestive canal, and always more or less distinctly divided into segments. The entire parasite, or *strobile*, may be looked upon as a colony of individuals united in ribbon fashion from their mode of origin, for convenience in their development and functional performance; the various segments being derived by a process of constriction from the originally acquired parasite, which is spoken of as the *head*, *nurse*, or *scolex* of the strobile. This scolex has obtained entrance as a larva into the intestinal tract (the natural habitat of adult tapeworms) of the host, has become attached by special fixation apparatus to the mucous membrane, and has there developed the adult characteristics of the parasite, forming the anterior extremity of the strobile in the developed worm. It is usually a very small and inconspicuous object, of globular, pyriform, or clubbed shape, with a short posterior extension spoken of as the *neck*. In the middle of the frontal face of the head there is often a small prominence, known as a *rostellum*, about which may be arranged in one or more rows, as one of the means of fixation of the parasite, small hooklets as a crown. As more constant means of fixation the head is provided with two or four suckers, rounded or linear depressions with more or less definite lips. Back of the head by a process of constriction from the neck, the segments, also known as *links* or *proglottids*, arise, the newest formed always being intercalated between the neck and the next older link. Thus the older segments are always by each newly formed proglottid, more and more separated from the head, each as it grows older and recedes farther and farther developing in size; the length of the strobile being thus dependent upon the two factors, growth of the individual links and the new formation from the neck of more and more links. These new segments as they are first formed are usually very short and proportionately broader, but as they increase in size with age they generally increase especially in their long diameter, and come to be more or less square or even elongate in their full development. The structure of each link, and hence of the whole strobile, includes an interior or matrix of an indeterminate connective reticular material, from which the various organs appear to develop and in which they are embedded; over which are to be recognized exteriorly a delicate cuticle and beneath the latter two layers of so-called muscle (contractile but not having the well-known appearance of ordinary muscle of higher forms of life), the outer layer disposed longitudinally and the inner transversely and circumferentially. These tissues, while more or less isolated into the different segments of the strobile, have some connecting filaments from segment to segment and maintain the continuity of the strobile. There is a low form of nervous system common to the entire strobile, beginning in the head as a set of commissural anastomosing fibers and extending in several longitudinal cords, with doubtful anastomoses, throughout all the links of the strobile. A so-called "water-vascular system" (*excretory canals*) also begins in the head and extends along the margins of the segments throughout the strobile, ending in a single excretory duct at the posterior end of the last link, which is re-formed each time a link is separated from the strobile. Transverse anastomosing canals exist in each link.

Aside from the common parts the various links may be looked upon as individuals. There is no digestive canal, all nutrition being obtained by the parasite from absorption of dissolved material from the fluids in the infested intestine. The only really highly organized parts are the generative organs, each link containing both male and female organs. The male organs reach their development the earlier, and after maturing the seminal elements and depositing them in the female canal undergo regressive changes and practically disappear, the female part meanwhile becoming more and more evident. Thus the links best showing the male part are usually but partially developed and comparatively near the head end of the strobile; those best showing the female parts are lower down; while the terminal links are usually so crowded with the ova in the gravid uterus that little else can be readily made out. The male parts consist primarily of a set (few or many) of small rather pyriform bodies variously situated in the different genera, the *testes*, each emptying by a fine duct into a larger canal, the *vas deferens* or *seminal duct*, which opens on the margin of the link or on its ventral surface in a prominence known as the *genital*

*prominence* (pore of genital prominence) in common with or in close proximity to the female orifice. At the outer end of the seminal duct its walls are somewhat dilated and thickened (*cirrus pouch*) containing a protrusile thread-like organ (*penis* or *cirrus*) which when inserted into the vagina serves to bring into contact the openings of the male and female canals for the penetration of the spermatozooids. The female canal (*vagina*) extends into the substance of the segment from its vulvar opening at the genital pore and is continuous with the *oviduct* (a canal which represents both *uterus* and at its inner end the oviduct proper); and close to its entrance into the proper uterine canal is usually somewhat pocketed for the accommodation of the spermatozooids (*receptaculum seminis*) which have been deposited from the already disappearing male canals. The inner end of the oviducts opens by a *pavilion* for the reception of the ova from the single or multiple *ovary*, and receives also the ducts of special glands (as of the *vitelline glands*). The ova in their development in the oviduct are formed of the ovum proper received from the ovaries, this being spoken of as the *embryophore*, and on the outside the vitellus deposited from the vitelline glands. Not infrequently the ova, as they are seen in fecal matter or in the uterus, retain more or less of the vitellus and its membrane; other instances show the embryophore alone. In their development the ova fill the canal of the oviduct more and more, often causing the appearance of side pockets of more or less branching character and giving the canal a distinctly branching appearance; either the entire length of the oviduct may thus accommodate the ova in the ripe segment or only a portion (to which the name of uterus is more clearly applied in such case).

In some instances the ova are discharged from the canal by route of the vagina and genital pore (as in *dibothriocephalus latus*); or they may rupture the uterine wall and be found scattered through the substance of the link and eventually break through the muscular and cuticular wall of the segment; or be retained within the segment until its discharge and disintegration. The terminal ripe links either actually containing the ova or after discharge of more or less of the original number (often some thousands) are apt to become separated from the strobile and be carried with the fecal matter from the intestine of the host; and by the older observers were looked on as special and individual types of intestinal parasites ("cucumber worms," etc.); thus discharged, in some instances they retain their vitality and may be more or less actively motile for a variable period (as in case of the proglottid of *tania mediocanellata*). Either free in the fecal matter or within the discharged ripe proglottids (which eventually disintegrate and free the contained ova), the ova thus escape from the host in which they were formed. They are themselves subject to disintegration, but are usually sufficiently protected by their walls from moderate drying, heat, and cold; and may under favorable conditions maintain their vitality until arrived in proper circumstances for their further development. As a rule, their deposit in moisture best favors their maintenance of life, and the water may serve as the medium for intermediate development (as in case of *dibothriocephalus*) or of convection to a fresh host within whom they may develop. Either with or without intermediate development the embryo is in some way, by water or on solids (perhaps herbage), carried into the alimentary canal of a second host. Arrived in this situation, both by its own activity and by passive convection by blood and lymph streams, the embryo penetrates the intestinal wall and becomes deposited in one or other situation as a *larva*, *bladder-worm* or *cysticercus*. There are variations in the type of this larval form, but in general it presents the following features: It is surrounded by a delicate connective-tissue outer wall, derived from the host by a process of reactive inflammation, within which lies the true bladder-worm. This is essentially the scolex or head of the future strobile, with beginning constriction of its neck into incomplete segments, the last one of which is itself cystic and distended into a bladder-like body. Into this the head of the larva is invaginated and can be detected as a small opaque body on one side of the cyst beneath the cyst membrane; while close inspection will usually reveal at the top of the slight eminence of this opaque spot a tiny opening, which is the outer end of the canal of invagination. Careful pressure on the freshly obtained cyst will generally cause the expulsion of the head through this opening and show the cyst to actually bear the relation to the head just described, that is, that it is a cystic condition of the posterior end of the neck. These bladder-worms in exceptional cases may multiply to the production of multiple cysts (as in the hydatid cysts of *tania echinococcus*), but are usually simple. Many of the smaller tapeworms have extremely poorly developed cysts in which the head is invaginated, these inconspicuous forms being spoken of as *cysticercoids*. It is believed that for a few forms of tape-worms in man there is a possibility of development of the ova directly in the original host (*hymenolepis nana*) with encystment as cysticercoids in the wall of the intestine and subsequent development of the strobile in the same intestine. The general rule prevails, however, that the cysticercus after remaining a variable period, perhaps a prolonged one, in the tissues, is devoured with the flesh of its host by a third (definitive) host; when the larva, having its cyst wall removed by digestion or otherwise freed, becomes attached by its fixation apparatus to the intestinal wall and gives origin to link after link and thus forms a new strobile.

The following system, arranged from Braun, may be offered as an outline of the classification of the cestodes:

I—*BOTHRIOCEPHALOIDEA*: scolex armed or unarmed, with two, generally poorly developed, shallow groove-like suckers; external segmentation absent or clear; three genital openings (cirrus, vagina, and uterus); genital parts rarely duplicated; yolk-gland follicles numerous and best seen about borders of segments; ova similar to those of *fasciolida*, but not always operculated.

1. Family, *DIBOTHRIOCEPHALIDÆ*: suckorial grooves variably developed (may be converted into tubes by union of the free margins or be replaced by an apical suckorial organ); uterus rosette-shaped; ova operculated.

Subfamily, *Ligulinæ*.

Subfamily, *Dibothriocephalina* (*Dibothriocephalus*, etc.).

Subfamily, *Cyathocephalina*.

Subfamily, *Triacnophorina*.

2. Family, *PTYCHOBOTHRIDÆ*: scolex unarmed; uterus does not form rosette; spacious uterine cavity; ova thin-shelled without operculum.

Subfamily, *Amphicotylina*.

Subfamily, *Ptychobothriina*.

3. Family, *AMPHITRETIDÆ*: vitelline glands in outer fields of segments; uterus with cavity apparent; ova thin-shelled, without operculum.

II—*TETRAPHYLLIDEA*: scolex armed or unarmed, with four very variable, raised or sessile bothridia or with four suckorial cups; segmentation always definite; cirrus and vagina open on margin of links; vitelline gland follicles lateral or about borders; ova thin-walled, without operculum.

1. Family, *ONCHOBOTHRIDÆ*: in the sessile or raised bothridia accessory suckorial cups, always hooks.
2. Family, *PHYLLOBOTHRIDÆ*: bothridia generally raised, simple, or with accessory cups or areole, always without hooks.
3. Family, *ICHTHYOTÆNIIDÆ*: with four suckorial cups, usually unarmed.

III—*CYCLOPHYLLIDEA*: scolex with four suckers, between which an apical rostellum may exist; hooklets on rostellum, rarely on suckers; segmentation almost invariably definite; no uterine opening; vagina and cirrus generally open on margin of link; genital organs rarely duplicated; yolk-gland unpaired usually posterior to ovary; ova thin-walled, non-operculated; oncosphere (embryonal enclosure) with one or more membranes.

1. Family, *TÆNIIDÆ*: showing the characteristics of the class.

Subfamily, *Mesocestoidina*: with genital pore on surface of link.

Subfamily, *Acoliina*: without vagina (*Acoleus*); separate sexually (*Diacoccestus*).

Subfamily, *Amabulina*: vagina opening on surface of link, cirrus on margin.

Subfamily, *Terabothriina*: yolk-gland anterior to ovary; anterior border of suckers grown outward into a muscular extension; genital pore unilateral.

Subfamily, *Anoplocephalina*: scolex unarmed, large, without neck; uterus transverse, tubular or reticular; ova with "pyriform apparatus."

Subfamily, *Dipylidiina*: rostellum with hooklets; suckers unarmed; genital pore marginal; genital organs simple or duplicated; uterus separating into ovisacs or atrophying, with the ova then free in parenchyma of link (*Dipylidium*, *Hymenolepis*, etc.).

Subfamily, *Davaineina*: rostellum and suckers armed; ova generally in ovisacs.

Subfamily, *Tæniina*: with rostellum and usually a double crown of hooklets; uterus with median longitudinal trunk and lateral branches (*Tænia*).

IV—*ECHINOBOTHRIDÆ*: scolex consisting of head and pedicle; head with two suckers and rostellum; pedicle with longitudinal rows of T-shaped hooks; genital apparatus as in *Tetraphyllidæ*, but with pore opening on surface of link.

V—*RHYNCHOBOTHRIDÆ*: scolex with head and pedicle; former with two or four bothridia and four retractile and armed projections; pedicle unarmed.

### I—*BOTHRIOCEPHALOIDEA*.

Family: *DIBOTHRIOCEPHALIDÆ*; Subfamily: *DIBOTHRIOCEPHALINÆ*;

Genus: *Dibothriocephalus*.

#### 1. *Dibothriocephalus latus* (Leuckart).

(*Tænia lata*; *bothriocephalus latus*; *dibothrium latum*; *bothriocephalus latissimus*; fish tapeworm; etc.)

DESCRIPTION.—Strobile two to ten meters or more in length (reported 20 in one or two cases); strobile yellowish; marked in ripe segments by brownish central rosette (uterus with ova) when specimen is soaked in water; head elongated almond-shape (2.-5. mm. long, and 0.71 mm. transversely), with two lateral grooves or bothridia as suckers; neck variable according to degree of contraction; 3000-4000 segments: the anterior links poorly defined, in their growth increasing slowly in length but markedly in breadth; ripe links back of middle of strobile measure 2.-4.

mm. long and 10.-12.-20. mm. wide, with opaque brownish rosette in middle line; terminal links shrunken and narrower than above in proportion to the length after discharge of ova; vagina and cirrus open in small prominence in midventral line near anterior border of link and just back of this a third opening (uterine); testes numerous, best seen toward the margins; uterus of a number of plicated tubes in form of rosette; ova brownish, ellipsoidal (68.-71. microm. long, 44.-45. microm. transversely), operculated.

FIG. 177.—*Dibothriocephalus latus*. (Leuckart.)

This parasite in its adult stage is most commonly met in the human intestine, but has been encountered also in dogs and cats. It is most common in parts of central Europe (Switzerland, northern part of Italy, southern Germany and this vicinity), along the Baltic borders, occasionally in Denmark and in the Netherlands, and British Islands. In Asia it has been met a few times in Turkestan and in Japan. The few examples which from time to time are reported from this country occur invariably in foreigners.

The strobile, the longest met in man, is generally found singly, the head attached in the upper part of the small intestine and the length trailing through the gut in a somewhat plicated fashion and not infrequently extending beyond the ileo-cecal valve. Unlike other large tapeworms of the human intestine ovulation takes place in this form, the eggs being discharged through the uterine opening without the necessity of destruction of the link, and large numbers are usually encountered in the fecal matter, where they are readily recognized on microscopic inspection. In the life-history of the parasite, these ova, being carried out with the fecal matter, require for their further development immersion in water. If thus favored, in about two weeks at a temperature of about 30° C. (longer time in cooler water) the operculum at the end of the eggs opens and permits the escape of a minute hexacanthous embryo, which is surrounded by a ciliated membrane and

FIG. 179.—Free swimming embryo of *dibothriocephalus latus*.  $\times 500$ . (Leuckart.)

FIG. 180.—Plerocercoid of *dibothriocephalus latus*: A, with head projected; B, head retracted. (Braun.)

which lives a free existence in the water for a time. It is not known how this embryo passes to the intermediate host, one or other of several fresh-water fishes, but it is probably swallowed; in event of failure

to attain this secondary host, it dies after some days. Within the fish it develops into a small worm-like larva (S. mm. long, 3. mm. thick), known as a *plerocercoid*, which, without a surrounding (adventitious) capsule, is found in the ovary, wall of the intestine, liver and other viscera, and in the muscular system. It possesses a slight vermicular movement. Essentially it is the anterior end of the future adult tapeworm. The head is generally invaginated, but may be caused to protrude if the specimen is placed for a time in warm water, when it will be found to present the characteristics above outlined for the adult head; unlike the common bladder-worms of many tapeworms the posterior part of this larva is not cystic. From experiments it has been found that under ordinary conditions these plerocercoids will retain their vitality in the flesh of the dead fish for about 18 days, that they are quickly killed in a saturated sodium chlorid solution, that they are comparatively resistant to cold but are soon destroyed by a heat above  $50^{\circ}\text{C}$ .– $53^{\circ}\text{C}$ . Transmission of the parasite to man is believed to be confined to the swallowing of the plerocercoid in the flesh of the infested fish imperfectly salted or cooked; although formerly it was believed if the ciliated embryo were taken into the human alimentary canal with unfiltered water, it was able to develop directly into the strobile. The fish most liable to contain the larval worms are fresh-water fish, as pike, turbot, perch, tench, grayling, etc. In countries where these fish abound it not infrequently happens

that certain parts, as the roe or liver, are eaten as delicacies very imperfectly cooked, such habits distinctly favoring the acquirement of the parasite, should the fish be infested.

The symptoms of parasitism by *dibothriocephalus latus*

FIG. 181.—*Dibothriocephalus cordatus*: adult. (Leuckart.)

FIG. 182.—Young specimens of *dibothriocephalus cordatus*; natural size. (Leuckart.)

FIG. 183.—Head and anterior segments of *dibothriocephalus cordatus*: A, seen from margin of strobile; B, seen from surface of strobile. (Leuckart.)

are for the most part quite similar to those occasioned by other tapeworms, *alimentary* and *nutritive* and *reflex nervous*. Usually the alimentary or local symptoms are the most pronounced, and proportionately more marked than in the case of infestation by the beef and the pork tapeworms. These may be

very trivial and be entirely neglected, however, although there is commonly some degree of abdominal discomfort, fullness, and a sense of weight, with now and again some little pain. Often the pains, irregularly intermittent in occurrence, are severe. Diarrhea alternating with constipation is common, and occasionally nausea and vomiting are noted. The appetite is apt to be capricious. In time some loss of weight and strength and a more or less striking and notable anemia may be expected, the latter being supposed to be due to the absorption of some toxic principle elaborated by the parasite or developing under conditions of its presence in the alimentary tract. The nervous phenomena are generally of little moment, but may exceptionally be pronounced. There may be nasal and anal pruritus, ocular disturbances, sometimes a functional and transitory strabismus, choreiform twitching, epileptiform seizures, headaches, mental hebetude, tinnitus, etc.

FIG. 184.—*Bothriocephalus mansoni*: A, after Leuckart; B, after Cobbold.

*Treatment* rests upon the general principles and measures detailed in the section devoted to treatment of tapeworm disease in general (p. 1353). For personal prophylaxis the individual should not be permitted to eat of the flesh of fish from infected districts except it be well cooked; and as a general measure to prevent

the infestation of the fish, human excreta should be kept from the drainage into lakes and rivers inhabited by fishes suitable for the plerocercoid stage.

2. *Dibothriocephalus cordatus* (Leuckart): A tapeworm of the same genus as the above, ordinarily parasitic in seals, has been reported as derived from the human intestine in at least a single instance (Greenland). It is a rather large tapeworm (strobile a yard or more—80.-115. cm.—in length) and is readily told by its large and heart-shaped head.

3. *Bothriocephalus Mansoni* (Cobbold): Thus far the adult characters of this parasite are not known, the larval form alone having been found. It has been met a number of times in the subcutaneous tissue, once in the pleural cavity, and a number of times passed by the urethra with bloody urine, from human beings (mainly Chinese and Japanese); and similar or identical plerocercoids are recorded from a number of mammals (J. Allen Smith has recently examined an example obtained from the subcutaneous tissue of the neck of a hog in China). It was originally regarded as a ligula; is a thick, flat, worm-shaped larva (varying up to 30. mm. in length and 3.-6.-12. mm. in thickness), not segmented, but with faint transverse striations; with a small, usually invaginated head showing two shallow shallow marginal sucker-like grooves. Nothing is known of its development or origin.

Genus: *Diplogonoporus*.

*Diplogonoporus grandis* (Blanchard).

(*Bothriocephalus* sp.; *Krabbea grandis*).

Strobile measures up to 10. m. in length; proglottids short and broad (10.-25. m. wide); number of segments unknown; head and neck unknown; double set of genital organs in each segment, arranged in two rows in the length of strobile; genital pores open in two longitudinal grooves on ventral surface; each uterus rosette-shaped, with several, usually two, loops on each side; ova brownish, operculated, oval, measure 63. microm. in length and 48.-50. microm. in width.

Ijima and Kuromoto have recorded two instances of infestation by this worm; the first subject having for some years been troubled with vague abdominal discomfort and pain, alternating periods of constipation and diarrhea, maldigestion and gradual loss of nutrition and moderate anemia; the second subject having but little disturbance and recognizing the existence of the parasite by the presence of the proglottids in the dejecta. In neither case was the head of the worm obtained, although long lengths of the strobile were passed after the administration of filix mas. The ova are to be carefully differentiated from those of *dibothriocephalus latus*, which they closely resemble, being, however, slightly smaller. Nothing is known of the intermediate host, but some kind of fish probably acts this rôle.

III—CYCLOPHYLLIDEA.<sup>1</sup>

Family: TÆNIIDÆ; Subfamily: DIPYLIDIINÆ; Genus: DIPYLIDIUM.

**Dipylidium caninum** (Leuckart).(*Tænia canina*; *t. moniliformis*; *t. cucumerina*; *t. elliptica*; *dipylidium cucumerinum*.)

Strobile 15–35. cm. long; head small, rhomboidal, with clavate rostellum surrounded by three or four crowns of hooklets (48–60); four large suckers with radially marked borders; neck very short; anterior links broad and short, middle ones as long as broad, fully developed ones longer than broad (6–7. : 2–3. mm.). The worm when fresh has a slightly reddish color. The links swell out in the middle so that the strobile has an appearance not unlike a chain of beads of melon-seeds. Genital pores on both margins of links (double); testes in large numbers, in middle substance of link, connecting by fine tubes to the median line where a vas deferens passes in tortuous course to each side to the cirrus pouch, a claviform organ opening at genital pore and containing a thread-like cirrus. Each half of the link contains an ovary, made up of ramifying tubes, and a yolk-gland, the ovarian canals uniting to form a simple oviduct, which near its beginning receives the vitelloguct. Vagina opens at genital pore behind the cirrus opening, is well dilated at inner end into receptaculum seminis. A single uterus is common to the two oviducts, consisting of a network of tubes in which the ova lie in groups filling small sacculi developed by their pressure, each containing 10 or 15 ova and surrounded by a reddish intermediate material which gives the color, above mentioned, to the worm. Ova spherical (43–50. microm.), with double wall and containing a hexacanthous embryo.

FIG. 185.—*Dipylidium caninum* (Leuckart, after Weinland.)

This worm is a common parasite of dogs and is regarded as identical with the worm formerly known as *tænia elliptica* of cats; in these animals it is widely distributed over the world. In occasional cases it has been known to infest the human intestine, almost always in children (24 cases, according to Braun). The parasite is usually without symptoms in human subjects and when these are present they are of the same general character as detailed in connection with the more common tapeworms. It is readily recognized by the shape and color of the links passed in the stools and by the fact that a genital pore is to be found on each lateral border of the link. The intermediate hosts are fleas (*pulex serraticeps*) and lice (*trichodectes canis*) of the dog, and the ordinary flea of man (*pulex irritans*). These insects presumably get the ova from the fecal matter adherent about the anus or on the coat of the dog; and the animal biting at infested fleas or lice transfers the *cysticercoid* (the invaginated scolex, differing from a true bladder-worm in that no true cystic change has taken place in the posterior part of the larva to form a bladder, and hence the larval mass is much more minute). Human beings probably acquire the cysticercoid in the crushing of infested insects between the fingers, which later, if unwashed, carry the larva adherent to the skin to the mouth; or possibly dogs having these larvae clinging to the lips, after having bitten infested insects, may transfer them to the hands of the human being by licking the hands.

Genus: *Hymenolepis*.1. *Hymenolepis nana* (von Sicbold).(*Tænia nana*; *t. ægyptica*; *dipylacanthus nana*; *hymenolepis murina*; dwarf tapeworm.)

DESCRIPTION.—Average length of strobile 10–15. mm. (may reach 25. mm.); head subglobular, measuring 0.25–0.30 mm. in transverse diameter; head provided with four large rounded suckers and a large rostellum retractile into an infundibulum; rostellum surrounded by a single crown of hooklets (24–30); neck rather long and

<sup>1</sup> The II, IV and V classes of tapeworms are not considered here because they are not found in human beings.

slender; about 150 proglottids, very small, broader than long; the largest, near the posterior end of strobile, measure 0.14–0.30 mm. long by 0.4–0.9 mm. broad, while the terminal links narrow slightly and lengthen, so as to give a rounded posterior extremity to the strobile. Genital pores all on the same (left) margin, near anterior end of margin of links; three spherical testes, in posterior part of segment near dorsal wall; vas deferens small, straight, slightly distended before reaching cirrus pouch; cirrus pouch club-shaped, near anterior end of segment. Vagina distended into prominent receptaculum seminis, in anterior part of segment; ovary bilobed, extending transversely just anterior to middle of segment; back of it the yolk-gland and between the two the "shell-gland"; uterus distended with ova occupies nearly the

FIG. 186.—*Hymenolepis nana*:  $\times 10$ . (Gould, after Leuckart.)

whole segment, obscuring the other parts (ova often free in parenchyma of segment). Ova round or oval, double-walled; outer diameter averaging 40. microm., but variable (30.: 32. microm. to 56.: 42. microm.); inner wall showing measurements ranging from 20.: 18. to 32.: 24. microm.; at each pole of inner membrane a small protuberance from which spring a number of clear, refractile threads which are distributed in a waving fashion through the substance intermediate to the outer and inner walls; within the egg a hexacanthous embryo slightly separated from the inner membrane.

This parasite, now regarded by most authorities as identical with *hymenolepis murina* of rats and mice, is an intestinal parasite of these animals and of man. It has a wide geographical distribution, being perhaps best known in Italy and neighboring parts of southern Europe. Recently a number of cases have been encountered in the eastern and southern states of

FIG. 187.—Head of *hymenolepis nana*: with rostellum retracted,  $\times 75$ ; A, an isolated hooklet,  $\times 300$ . (Gould, after Leuckart.)

this country, and there is some reason in the supposition that it will come to be regarded as one of the most common tapeworms of this portion of the world. It is most frequently met in children, especially in those of the poor and those living in poorly cared-for homes. The parasite inhabits the ileum, usually from the middle toward the ileo-cecal valve, and is commonly met in large numbers in the individual infested (sometimes a thousand or more.) The usual life-history is not finally established. For a long time certain cysticercoids met in

FIG. 188.—Ovum of *hymenolepis nana*,  $\times 300$ . (Gould, after Leuckart.)

the common meal-worm were suspected as representing the intermediate stage, but the evidence now held would refer these to another tapeworm; although it is not excluded that some such intermediate host may perhaps at times serve as a connecting link. However, it has been shown by Grassi that if the ova be fed to rats (best from one to three months old) the adult worm will develop in the intestine of the rat; and it has been found in such cases that the embryos having had the shell removed by the action of the upper digestive juices penetrate into the villi of the mucous membrane, and there become encysted as minute

cysticeroids, which later drop into the intestinal lumen and develop the adult worms. This would suggest the possibility of direct multiplication within the intestine of the definitive host, but this is a mistake. The ova are not affected by the juices of the lower intestinal canal and are passed from the original host without change and for their further progression must gain access to a second suitable host (rat, mouse, man) or perhaps to the original host of reinfecting himself with ova from his own intestine. The means of convection to the second host probably include unfiltered water tainted with human or murine dejecta, food to which rats or mice have had access, or in case of man the fingers soiled with fecal matter after scratching about the anus.

The symptoms caused by the parasite are of the same general nature as those induced by the common larger tapeworms; but in children, and when in large numbers, may be of marked severity and even terminate fatally. When present in but small numbers and in resistant individuals, the symptoms may be trivial and overlooked. In their severer manifestations, in addition to the intestinal discomfort and pain (sometimes severe) and irregular diarrhea, there may be marked nutritive disturbances with more or less severe anemia; and the nervous phenomena, as epileptiform convulsions, may be a marked feature of the case, continuing for years until the parasites are gotten rid of or perhaps until death. The presence of the parasite being suspected, the diagnosis may readily be confirmed by the discovery of the ova by microscopic examination of the fecal matter, large numbers being usually found where the parasites are present in any marked degree of infection.

The treatment is much as in other types of tapeworm disease; but male fern has proved most satisfactory among the common anthelmintics (p. 1353).

## 2. *Hymenolepis diminuta* (Rudolphi).

(*Tania diminuta*; *t. leptocephala*; *t. flavopunctata*;  
*hymenolepis flavopunctata*.)

DESCRIPTION.—Strobile 10.-60. mm. long; head small, globular, 0.2-0.6 mm. in width, with small pyriform rostellum devoid of hooklets, with four globose suckers situated close to apex; neck short; 800-1300 segments, broader than long, the largest near the posterior end of strobile measuring 3.5 mm. wide and 0.66 mm. long; genital pores all on left margins, in front of middle of margin; three testes (two on right, one on left) in each segment; vas deferens straight, distended before entering cirrus pouch; vagina after passing inward from genital pore distended into a prominent receptaculum seminis (which when filled with spermatozooids has a yellow color and causes the appearance of a yellow spot in the anterior part of the segments to the left of the median line, whence the name "*flavopunctata*") ; gravid uterus nearly fills segments, showing as transverse line when not ripe; two ovaries near middle of link, communicating by transverse canal, which receives canal from receptaculum seminis and communicates with transverse uterine canal. Ova round or slightly oval, yellowish, double-walled (outer diameter, 54.-86. microm., inner from 24.: 20. to 40.: 35. microm.); inner wall with slight protuberances at poles, layer of albuminous material between the walls. In man many of the segments are non-fertile; the gravid ones are slightly brownish in color from the ova contained and are larger than the non-fertile ones.

This worm has been found as a parasite of man, rats, and mice. It has been reported from this country (twice from Philadelphia; Leidy, 1884; Packard, 1896), from Brazil, France, Italy, and Sicily.

FIG. 189.—Head and neck of *hymenolepis diminuta*. (Braun after Zschokke.) Enlarged.

The cysticeroid of this species has been found in larval and adult meal-moths (*asopia farinalis*), earwigs, and several beetles, the first being regarded as the most important intermediate host. Experiments on man by feeding these cysticeroids have been followed in 15 days by the appearance of ova in the dejecta and by numerous specimens of the adult parasite after dosage with male fern. In the cases reported but few worms, perhaps only one, exist in the intestine of the individual host, the lower part

FIG. 190.—*Hymenolepis diminuta*: two proglottids somewhat magnified. (Braun, after Grassi.)

FIG. 191.—Ovum of *hymenolepis diminuta*. (Braun, after Grassi.)

of the intestine, from what little is known, being the favored habitat. Usually there are no symptoms, or at most no distinctive ones, from the presence of the worm. It is readily dislodged by practically any of the tenifuges, being sometimes passed spontaneously.

### 3. *Hymenolepis lanceolata* (Bloch),

(*t. lanceolata*, *drepanidotænia lanceolata*.)

One instance of a human being infested by this species is reported by Zschokke from Breslau, two examples having been obtained at different times from a 12-year-old boy. The parasite is found in geese and ducks in Europe, but is unknown in this country. The larval stage is believed to exist in certain crustaceans. The strobile ranges from 30. to 130. mm. in length, increasing in width directly from the head backward to close to the posterior end, where it again quickly narrows to a rounded extremity. The head is very small, has a retractile rostellum armed with a single row of about eight hooklets; four rounded suckers. Neck short. About 300 links; segments much broader than long; genital pore on one margin (right); and the rather prominent ovaries and uterus in opposite half of segment; three testes. Ova much like those of *h. diminuta*, double-walled, with albuminous substance between walls (outer diameter, 60.-100. microm.; inner wall measurements, 30.: 25. to 40.: 28. microm.).

Subfamily: DAVAINÆ; Genus: DAVAINÆ

### *Davainea madagascariensis* (Davaine).

(*Tænia madagascariensis*; *t. demerariensis*.)

Strobile 25.-30. cm. long; head small, with rostellum retractile into an infundibulum, rostellum armed with double crown of about 90 hooklets; head with four large globose suckers bordered by numerous small spines; 500-700 segments, the fully developed ones measuring 2. mm. long and 1.4 mm. broad; genital pore on one margin; about 50 testes in each link; uterus formed of a number of tubes, the ova in each thus appearing in separate groups (often free in parenchyma of link); oncosphere (embryo) hexacanthous, 8.-15. microm. long, surrounded by delicate double wall, the inner closely adherent to embryo, the outer showing at each pole a pointed projection. The worm has thus far only been found as a human parasite; intermediate stages unknown. It has been reported from Madagascar, Comores, Bangkok, Guiana, and Mauritius.

Subfamily: TÆNIINÆ; Genus: TÆNIA.

### 1. *Tænia saginata* (Goeze).

(*Tænia mediocanellata*; *t. inermis*; beef tapeworm.)

Average length, 3.-8. meters (in relaxed condition often reaching 10. meters), head tetragonal, pyriform, without hooklets or rostellum (in place of latter a central depression in center of frontal face, often slightly pigmented), with four cup-shaped suckers placed at the corners of frontal face, these provided with rather thick lips and often slightly pigmented at the border.; head measuring two millimeters in

transverse diameter at frontal face; neck rather long and slender; first segments very short and broader than long; the segments increasing in their development so as to become much longer than broad (almost cord-like at posterior extremity) and when fully ripe (near posterior extremity) of long quadrate shape, 18.-20. mm. long and 5.-7. mm. broad; genital pores in adjacent segments irregularly alternating upon opposite margins and situated a little back of the middle of the margin of each; gravid uterus showing a median longitudinal trunk with lateral single or dichotomously branching and slender diverticula (25-35 on each side); embryophore ovoid, nearly spherical, slightly brownish, 30.-40. microm. long and 20.-30. microm. transversely, with thick radially striated shell and containing granular hexacanthous embryo.

*Habitat and Transmission.*—This tapeworm, in its adult stage almost solely found in the small intestine of man, is widely disseminated over the world, especially in districts where beef is largely consumed, particularly when by habit of populace the flesh is not well preserved or thoroughly cooked. At present it is by far the most frequent tapeworm of man in this country, and is also the most common cestode of man in western Europe. It is a mistake to trust in the popular idea prevailing in the United States that of the large tapeworms met in man, most are derived from pork. The late Professor Leidy, to whom large numbers of worms were constantly being sent for opinion, informed the author of this work that all specimens sent him for examination during a period of 15 years were *tæniæ saginata*; and while in central Germany *tænia solium* has in previous periods been comparatively common, Heller has found in Holstein the beef tapeworm four times as prevalent as the pork worm.

FIG. 192.—*Tania saginata*. (Gould, after Leuckart.)

FIG. 193.—Head and neck of *tænia saginata*: A, retracted. B, extended. (Gould after Leuckart.)

The parasite is obtained from eating improperly cooked fresh beef containing the bladder-worm of the cestode. This, the *cysticercus bovis*, is a small spherical or ovoid vesicle, colorless and glistening, usually about half a centimeter in diameter (occasionally reaching or exceeding one centimeter), and surrounded by a thin connective-tissue capsule formed at the expense of the host. After separating the bladder from this envelope one may note a small, opaque, whitish point on one side of the cyst. This is the invaginated head of the future tape-worm, which can be expelled from the cyst by careful pressure of the latter between the thumb and finger or

FIG. 194.—Proglottid of *tænia saginata*.  $\times 2$  (Braun.)

may be caused to protrude by immersion in slightly warmed water; thus exposed, the head will be found to possess the characters of the future head of the adult tapeworm, with its neck faintly striated transversely (future segments) and with its posterior end distended into the cyst into

which the head was invaginated. This bladder-worm because of its small size and small numbers (usually) is often missed in inspections of slaughtered beef; it may be found in any part of the striated muscular system and sometimes in the solid viscera, but Hertwig has pointed out its special frequency in the muscles of the masseteric region, in the internal and external pterygoid muscles. It develops from the ingested ovum apparently in a period of about three or four weeks; as a rule, is not of long life in this stage, as experimentally produced cysticercosis of but a few months' duration has repeatedly shown numbers of dead and calcified specimens in the muscles of the experiment animals. There is no doubt of the statement that transmission of the parasite to man follows only when the meat eaten is imperfectly cooked, as it has been shown that brief periods of exposure (several minutes) to temperatures of  $45^{\circ}$ – $48^{\circ}$  C. will kill the larval parasite, and it is safe to say that well-roasted meat ( $70^{\circ}$  C.) cannot transmit the worm in vital condition. Moreover, while temporary drying of the flesh is by no means lethal to the bladder-worm (which while thus shrunken will again assume its vesicular appearance on soaking in water). Perroncito has found all cysticerci dead at the end of two weeks in a well dried and salted piece of veal. After eating noxious beef the subject requires from *seven to ten weeks* before manifesting evidence of the presence of a fully developed *tania saginata* by the passage from the anus of ripe segments of the worm.

These separated segments, usually single, may be found in the dejecta or may be passed in the interval between stools; they were formerly regarded as special intestinal parasites and spoken of as "cucumber-worms," "water-worms," etc.; they are yellowish-white in color, range up to about two centimeters in length, and are either distinctly quadrate and flat or are shrunken into nearly a cylindrical shape; they are usually quite active, having a mode of motion not unlike that of "measuring worms," and in this country among the ignorant there is a superstition that they will, if undisturbed, always crawl toward the nearest water (whence the name "water-worms"). Quite commonly they do gain access to water, but only in a passive convection with ordinary drainage, and when immersed may retain their vitality and activity for a number of days. Ferdinand Herff, of San Antonio, speaks of having found a number of actively moving proglottids of this parasite in the water of a well into which surface drainage carried the contents of a cesspool. If deposited on a dry surface they soon die and are disintegrated and the ova are scattered over the herbage, these not losing vitality for some time because of the protection which their thick shells afford against drying and the elements. Cattle eating the blades of grass thus acquire the embryos within their alimentary tubes, and later these penetrate the intestinal walls and gain access to suitable parts, where they are encysted as larvæ or bladder-worms.

The adult tapeworm in the human intestine has an undetermined duration of life; it is well known to persist for years, and Railliet quotes Wawurch in connection with a case known to have passed segments over a period of 35 years. The parasite is found invariably in the small intestine when discovered at autopsy; usually the head is fixed a short distance

below the pylorus among the villi, the strobile ranging loosely through the extent of the small bowel and only rarely found extending beyond the ileocecal valve. (Recently Shoemaker in Philadelphia found in the lumen of an appendix vermiformis which he removed from a young Syrian woman several actively motile segments of this parasite, although there was little reason to suppose their presence, the real agency in establishing the chronic appendicitis which existed.) Although not provided with hooklets as is the pork tapeworm, it is apparently more firmly fixed than the latter to the mucous membrane.<sup>1</sup> Usually but a single example of the beef tapeworm exists in one host, but cases are reported furnishing as many as five or six.

But little difficulty can be experienced in attempting to distinguish between this worm and the *tænia solium*, with which alone it is likely to be confused at first. As a rule, the strobile is considerably larger and longer; the segments are larger and more active in their movements, and are more likely to be discharged from the anus in the intervals between the stools; the uterus in each link is more highly branched than in case of the tapeworm of the hog; the head is not provided with hooklets; the ova are somewhat larger than those of the latter and a little less spherical. In examining a link for study of the arrangement of the uterus, it is usual to compress it between two glass slides in a small amount of a 1 per cent. solution of caustic potash, or in a 20 per cent. solution of acetic acid.

**Symptoms.**—The symptoms occasioned by the parasite are partly local and partly of a reflex nervous type, and are both often so trivial as to pass unnoted. The former are generally of the nature of an indefinite abdominal discomfort, of weight and fullness, of occasional indistinct pain, usually most marked at meal-times, capricious appetite, irregular periods of diarrhea alternating with constipation, occasional nausea and vomiting, slow loss of flesh and strength, and eventually a moderate degree of anemia. The nervous phenomena are also very variable and indefinite, such as nasal pruritus, slight vertigo, choreiform twitching and occasionally epileptiform convulsions, visual disturbances and restless sleep. When the parasite is suspected, the stools should be carefully watched for discharged proglottids and the patient instructed as to the appearance of these should they pass in the intervals from the anus upon the clothing. By microscopic examination occasionally the ova may be discovered, but probably the safer and almost as quick a recognition will be obtained by noting the links themselves as they appear.

The treatment of parasitism by this worm presents no special features differing from the treatment of tapeworms generally and will be discussed (p. 1353) in the latter connection.

## 2. *Tænia Solium* (Leuckart).

(*Tænia cucurbitina*; *t. dentata*; *cystotænia solium*; pork tapeworm.)

**DESCRIPTION.**—Average length of strobile, 2–3. meters, occasionally reaching twice this measurement; head more spherical than that of the *tænia mediocanellata*, but with a somewhat tetragonal shape given by the four rather prominent cup-like suckers with thick lips; head provided with a short thick rostellum bearing a double crown of hooklets (22–32 in number, usually 28); transverse diameter of head 0.6–1. mm.; neck rather thin and approaching one centimeter in length; about 800–900

<sup>1</sup> At least this is the opinion of Railliet, page 239 of his "Treatise on Medical Zoology," although it does not seem reasonable that the worm armed with suckers only should be more difficult to dislodge than the worm armed with suckers and hooklets. I cannot speak from my own experience, for I have never had a case of pork tapeworm.

proglottids; fairly developed links found unusually close to head; fully grown and ripe segments measure 10.-12. mm. long and 5.-6. mm. broad; regular alternation of genital pore on opposite margins of adjacent links, back of middle of margin; uterus consisting of a median longitudinal trunk with from seven to ten coarsely dendritic branches on each side; embryophore nearly spherical, light brownish, with thick radially marked shell and containing a granular hexacanthous embryo, measures 31.-36. microm.

*Habitat and Transmission.*—This parasite in its adult stage is practically limited to the small intestine of man in its occurrence. It is extremely rare in this country, popular impressions to the contrary notwithstanding; and is most frequently met with in Germany, France, Italy, and the British Islands. Because of the more careful meat inspection prevailing at present it is, however, decidedly less frequently met with than formerly. That it does occur occasionally among us is strongly indicated by the fact that the bladder-worm in pork is occasionally found in America; although the above statement as to its rarity is the experience of practically all American helminthologists. While the bladder-worm is occasionally encountered in other animals than the hog (and rarely in man), human beings obtain the intestinal parasites practically solely

from eating improperly cooked pork containing the cysticerci. The encysted larva, known as *cysticercus cellulosæ*, is generally when found in pork encountered in large numbers, commonly in the muscles and especially in those of the shoulder, neck, tongue, diaphragm, and loins, but often in any part of the muscular system and sometimes in the solid viscera and even in the central nervous system. It is somewhat larger than that of the beef tapeworm, is a pale, shining cyst of ovoid shape,

FIG. 195.—Head and neck, and ovum  $\times 300$ , of *tania solium*. Embryophore surrounded by vitellus. (Gould, after Leuckart.)

FIG. 196.—*Cysticercus cellulosæ*: A, with invaginated head, B, with evaginated head. (Leuckart.)

FIG. 197.—*Cysticercus cellulosæ*,  $\times 12$ . (Coplin and Bevan, after Leuckart.)

FIG. 198.—*Cysticercus cellulosæ* after digestion of the bladder,  $\times 10$ . (Leuckart.)

measuring from one-half to two centimeters in length, and from three to ten millimeters in transverse diameter; and as above described for cysticerci in general is surrounded by an additional thin connective-tissue wall derived from the surrounding tissues through inflammatory reaction. When picked out of such a situation there may be noted on one side of the cyst a small, slightly elevated spot of opaque white color, with a minute opening at the tip of the prominence. The white mass is the

invaginated head, the tiny opening the outer end of the canal of invagination; and by careful pressure or by immersion in warm water the head may be caused to protrude from its bed through the opening referred to, showing the characters belonging to the scolex of the adult worm. The actual relationship between the cysticercus and the developed *tænia solium* has frequently been demonstrated by feeding experiments. In pork there are usually large numbers of these cysticerci, the muscles of favored parts being literally riddled with the bladder-worms; many of which are usually found in a shrunken and calcified condition (dead). The duration of life in this larval stage encysted in pork is unknown, but probably varies between several months to several years. Young hogs (less than six months of age) are more apt to be infested than older ones, which seem to possess some degree of immunity against the larval worms; and as would readily be supposed, hogs which are not carefully stalled and fed, but which are allowed to roam about, often rooting about manure-heaps (in which in country districts human fecal material is apt to be deposited), are most likely to show infested flesh. As in case of the *cysticercus bovis* above mentioned, careful cooking and prolonged and thorough salting and drying of the meat will destroy the vitality of the bladder-worms; but they seem slightly more resistant to such influences than the cysticerci of beef. About two and one-half months or over are required for the development of the adult worm after the infested pork has been devoured; after which the ripe links may be found in the stools of the patients. They are readily known from those of the beef tapeworm by their smaller size, their less active movement, and by the coarser and less highly branched appearance of the uterus as seen in compressed links cleared with acetic acid, caustic potash solution, or glycerin. The ova are less frequently encountered in the stools than those of the beef tapeworm, being more apt to be retained in the ripe segment until after its discharge and disintegration.

The habitat of the strobile in the human intestine, as seen in cases discovered at autopsy, is similar to that noted for the *tænia saginata*; usually but a single specimen is found (whence the name "*solium*," "the solitary worm"), but occasionally several are encountered in the single host. The duration of its existence in the intestine is unknown, but instances of infested persons who passed links for years are common.

**Symptoms.**—The symptoms caused by this parasite are practically the same as those above detailed for the beef worm. Human cysticercosis is rare; when the bladder-worms occur in the musculature as is usually the case, there are no symptoms of their presence; in the rare cases where the encysted larva is seated in the membranes of the brain or in the central nervous system, irritative and compression nervous symptoms corresponding to the area involved are induced. In man the cysticercus seems to have a longer period of vitality than in the hog, cases extending over 15 to 20 years being recorded with undegenerated scolices found post-mortem in the cysts. The acquirement of this stage of the worm by man means, of course, his previous ingestion of the embryophore, possibly in eating vegetables (salads) grown in ground fertilized with human excrement, or from drinking unfiltered water into which latrines drain, or occasionally from coprophagism or by autoinfection (where the subject has been

the host of the intestinal worm and has transferred the ova to the mouth by some uncleanly habit, perhaps on the fingers soiled by fecal material).

The treatment of cases of parasitism by this worm is the same as outlined below (p. 1353) for the treatment of tapeworm disease generally.

### 3. *Tænia Echinococcus* (von Siebold).

(*Echinococcifer echinococcus*; *tænia nana*, v. Beneden; dog tapeworm.)

DESCRIPTION.—Strobile 2.5–5. mm. long; head small, subglobular, measuring in transverse diameter 0.3 mm., with a prominent rostellum with a double row of hooklets (28–50), with four prominent cup-shaped suckers; neck short and rather thick; three (sometimes four) proglottids, the last of which is commonly longer than the rest of the worm put together (about 15.–3. mm. long and 0.6 mm. wide); genital pore marginal, alternating; uterus consisting of a thick longitudinal median trunk with a few short lateral branches; embryophore spheroidal, with thin radially striated shell and containing a granular hexacanthous embryo; long diameter of embryophore, 30.–36. microm., transverse diameter, 25.–30. microm.

The parasite in its adult stage is met, usually in great numbers, in the upper part of the small intestine of dogs, wolves, and jackals, each with its

FIG. 199.—*Tænia echinococcus*: a, adult; b, head from echinococcus cyst. On left a detached hooklet, as seen in fluid from cyst. (Coplin and Bevan, after Leuckart.)

FIG. 200.—Hydatid cyst, showing daughter cysts. In the lower part of field is a whitish mass containing parts of the walls of ruptured daughter cysts. The thick wall of the mother cyst is well shown. From liver of man,  $\times \frac{3}{8}$ . (Coplin.)

head embedded among the villi; the ripe segments, when the intestine is laid open and immersed in fluid, floating out and giving the mucous surface the appearance of a coarse, shaggy velvet.

### *Hydatid Disease.*

The worm is of importance in human pathology because its larval stage, known as a *hydatid cyst*, is not infrequently met in the human body, although also encountered in a large range of the lower animals, as the ox, hog, horse, dog, cat, bear, panther, camel, etc., and occasionally in birds (turkeys).

As far as man is concerned, hydatid disease is fortunately rare except in a few localities where dogs are very numerous and are kept in unduly intimate relations with the human beings. Thus in Iceland and Australia,

where such conditions prevail, the disease is not uncommon. In Iceland the ratio is put by various authorities as 1 in 6 to 1 in 61 residents. In some parts of Germany it is not very rare. Thus in Rostock, during a period of 23 years, there was one case of hydatid disease to 1414 residents; in Upper Mecklenburg, one in 129,000 persons; and in Greifswald, one out of 75 autopsies disclosed the disease. In Manitoba, North America, where there are settlements of Icelanders, the disease is not very infrequent. A. H. Ferguson reports that between 45 and 50 subjects have been treated in Winnipeg since 1874, when the Icelandic immigration began. The disease is also occasionally encountered in India, as might be expected from the large numbers of dogs and their lack of proper

FIG. 201.—Daughter cyst from hydatid cyst, considerably enlarged. (Coplin.)

FIG. 202.—A group of daughter cysts from hydatid cysts. (Coplin.)

care in that country. While in the United States hydatid disease is occasionally met at autopsies, a large proportion of the subjects are foreigners, and presumably have acquired their parasite elsewhere than in this country.

Echinococcus disease is acquired solely through the swallowing of the embryophore of the *tænia echinococcus*; and this must, as above indicated, be practically always referred back to the dog as the original host. The transmission to man comes from eating food tainted with the excrement of the infested dog (as insufficiently cleansed green vegetables grown in soil in which dogs are permitted to deposit their excrement). Or it is possible that where dogs are allowed to roam about the house any food might become tainted by dust bearing ova; unfiltered water might well bear the ova. Probably a common transmission is directly from the dog; thus a dog, which in biting in the anal region because of itching may have had ova cling to the lips or the tongue, may later in licking its master's hand transfer these to the latter, whence they may be transferred to the mouth if the man neglect to wash his hand; or doubtless in many instances the ova become adherent to the hair of the dog while rolling over ground upon which the infected fecal matter has been scattered, and a human being may well have these embryophores carried to the mouth ignorantly, if after petting the dog the hands be not well washed. Conveyed in some such fashion to the human alimentary canal the embryo develops and

penetrates the wall, probably often being passively conveyed some distance in blood or lymph-streams which it may enter, and lodging in some more or less distant situation, where it becomes encysted. The most common site of the resulting hydatid is in the liver, the portal route being probably traversed in its convection, fully half of all hydatids met being found in this organ. After this range the kidneys, bladder, and genitals in about ten per cent.; intestinal canal, nine per cent.; bones, 3 1/2 per cent.; other organs, eight per cent. Of 85 cases collected by William Osler in Canada and this country up to 1891, the liver was the seat in 59—considerably over 50 per cent.

A description of the hydatid cyst has been detailed above in the section on hepatic diseases (p. 516), to which the reader is referred; consideration being there given also to the symptomatology and treatment of hepatic hydatids. No further description of echinococci located elsewhere need be given as they present identical features; and aside from symptoms of the purely local involvement nothing need be added in the symptomatology. When situated in the lungs and pleura the evidences of local tumor, respiratory disturbances and perhaps cardiac labor, the peculiar hydatid fremitus heard on auscultation, and the possible detection of hooklets or of daughter-cysts in the sputum or in fluid obtained from the pleural cavity, would lead to recognition. In case of involvement of the urinary organs the appearance of hooklets in the urine should constitute the certain feature of diagnosis. The symptoms of hydatids of the brain are those of brain tumors, the disease being more frequent on the right side. When absorption of the contents of a hydatid cyst is impossible, usually after rupture or puncture, a rather marked and troublesome urticarial eruption is often met.

#### *Occasional Tæniæ of Other Types.*

4—Braun mentions the occurrence of the cysticercus (*cysticercus tenuicollis*) of *t. marginata* in man, but acknowledges the uncertainty of diagnosis. The adult worm is a common parasite of the dog in this country and elsewhere. The cysticerci, among the largest of bladder-worms, are not infrequently found in sheep and cattle, often in the subserous tissues of the peritoneum. The size of the cyst and the slender neck of the evaginated head should lead to suspicion as to the nature; the head possesses four suckers and 36–38 hooklets.

5—Von Linstow in 1900 described under the name *tænia africana* a tænia obtained from a negro soldier in Africa which presents the following features: strobile over 1.3 meters long; head with apical suckorial depression and four suckers at angles of frontal face (diameter of central sucker, 0.16 mm., of ordinary suckers 0.63 mm.); transverse diameter of head, 1.38 mm.; neck very short, somewhat broader than head; about 600 segments; terminal segments 7. mm. long by 12.–15. mm. broad; genital pore marginal, irregularly alternating, situated in middle of margin of link; testes very numerous, filling the whole interior substance of link; vas deferens very tortuous; cirrus pouch pyriform and thick-walled; cirrus bristled; vagina similarly beset with bristles; receptaculum spindle-shaped; ovary large, paired, made up of radially arranged, unbranched, and non-communicating club-shaped tubes; vitellogene in posterior part of link; between it and ovary the "shell-gland"; uterus consisting of median longitudinal trunk with 15–24 undivided branches on each side; embryophore spherical (31.–34. microm.) or oval (39. by 34. microm.), with thick radially striated wall and containing hexacanthous embryo (hooklets of latter 7.8 microm. in length). The intermediate stage is unknown, but the cysticercus is believed to exist in the zebu.

6—In 1896 Ward described under the name *tænia confusa* a large tapeworm of which he encountered two incomplete specimens, given him by a physician in Lincoln, Nebraska, having been passed at different times from the bowel of a human subject. The head and neck were not obtained. Estimated number of segments 700–800; segments always longer than broad; terminal links 35. mm. long by 4.–5.

mm. broad; genital pore irregularly alternating, placed back of middle of margin of link; testes numerous; vas deferens somewhat tortuous; cirrus pouch thick-walled, long, club-shaped, cirrus bristled; receptaculum seminis subglobular; ovary small, paired, each half somewhat bean-shaped; vitelline gland small, trilobed; "shell-gland" globular; uterus composed of median longitudinal trunk with 14-18 short, divided branches on each side; embryophores oval (30. microm, long, 30. microm. transversely), shell thick, radially striated. Braun suggests this is possibly a variety of *tania solium*.

**Treatment of Tapeworm Diseases.**—There is, perhaps, no morbid condition which has brought more opprobrium upon the regular profession and more "grist to the mill" for advertisers and those who use secret remedies than tapeworm, and to our humiliation it must be said that these persons do seem to have more success in getting rid of tapeworm promptly than we do. There are, I think, two reasons why this is so. In the first place, it is certain that they do not use different remedies from those commonly in use by the profession, but they give larger doses. In the second place, they see a larger number of cases and develop a sort of specialty which, like all specialties, produces greater skill in treatment. In order that a tapeworm may be successfully removed it is necessary that it shall be of a certain size; so that, if a large part of the worm has been brought away by medicine, it is useless to give anything more until the remaining part increases sufficiently in size.

It is sometimes useful to know the exact course pursued in a given successful case. Thus, in such a case the patient was fasted for 29 hours. Twelve hours after fasting began he was given one ounce of castor oil. Twenty-four hours after fasting began he was given 1 1/2 drams (5.55 c.c.) of oleoresin of male fern. In 5 hours more he was given another ounce of oil. The worm came away entire in a mass.

There are half a dozen remedies for tapeworm, and they are all good. I think that the two best are probably the ethereal extract of male fern and kousso flowers. Some prefer the first of these, while others prefer the second. In my hands kousso has been decidedly the most efficient—that is, having failed with everything else and having succeeded with *kousso*, it has naturally become the remedy with which I usually begin the treatment. It is the dried flowers and immature fruit of the *brayera anthelmintica*, a tree native to Abyssinia.

Patients require some preparation before any remedy is employed. In all cases they should be kept absolutely quiet during treatment. They should eat nothing from breakfast time of one day until the next morning, during which time the bowels should be moved by a saline cathartic; when 1 ounce (30 gm.) of kousso and 8 ounces (240 c.c.) of water are to be taken. A more pleasant way is to give 75 grains (5 gm.) in a glass of white wine every half-hour until four doses are taken. If at the end of six hours no movement of the bowels has taken place, a promptly acting aperient, as a dose of oil, compound jalap powder, or elaterium, is taken, but generally kousso requires no purgative after it. The worm is usually discharged entire. Of course, one is never certain that this is the case unless the head is found. At the same time, it does not follow because the head cannot be found that it has not been passed, for it is very small, and may be lost in the discharges. In the *tania solium* the head is about the size of a small pin's head; in the *mediocanellata*

it is a little larger, and in the bothriocephalus it is still larger. If the head has not been removed, it is certain that in from 10 to 16 weeks the worm will grow out again and begin to discharge links. Kouso is said to have induced miscarriage; it should not, therefore, be given to pregnant women. Instead of kouso, the resin which it contains, called koussir, may be given, but I have had no experience with it. The dose is from 20 to 40 grains (1.33 to 2.66 gm.), inclosed in a wafer. The fluid extract is also efficient in dose of  $1/2$  a fluidounce (15 c.c.).

The next remedy in efficiency is the ethereal extract of the rhizome of *aspidium filix mas*, or male fern, whose active principle—an oleoresin—is extracted by ether. The preparation of the patient is about the same as for kouso. The dose of the ethereal extract is from 2 to 2  $1/2$  drams (8 to 10 c.c.), followed in a couple of hours by a purgative. It is a dark, thick liquid, bitter, slightly acrid, and nauseous. Instead of the ethereal extract of male fern the oleoresin may be given in a gelatin capsule. The dose is from 1  $1/2$  to 2 fluidrams (3.88 to 7.4 gm.). Two hours later a dose of purgative medicine should be administered. An important point to be borne in mind is the varying quality of these drugs, and that they deteriorate with age.

The third remedy, in order of efficiency, is the bark of the root of the pomegranate. This has been given in the shape of a decoction, from 2 to 4 ounces (60 to 120 c.c.) to the pint (0.5 liter). Boil the bark half an hour, strain, and drink. The fluid extract is more convenient in the dose of from 45 minims to 2 fluidrams (3 to 8 c.c.). Two hours later a purgative should be given. An alkaloid is obtained from pomegranate, named pelletierine, in honor of the chemist, Pelletier. This is sold in a single dose from 8 to 25 grains (0.5 to 1.6 gm.). When first introduced, it was vaunted as a "sure cure," but the experience of practitioners has not been uniform, and success has been by no means inviolable. I have been successful with it.

Kamala, the hair of the *rotlera tinctoria*, is said to be very efficient in tapeworm, but I have had no experience with it. It is given in doses of from 1 to 2 drams (4 to 8 gm.) suspended in syrup, repeated in from eight to ten hours if it does not purge. The fluid extract is also given in doses of  $1/2$  a dram to 1 dram (2 to 4 c.c.). It is purgative, sometimes drastically so. It may also cause nausea and vomiting.

Another efficient remedy is the oil of turpentine. It is, however, apt to produce symptoms so unpleasant that it should be last used. The dose is from 1 ounce to 2 ounces (30 to 60 c.c.), mixed with twice that amount of castor oil—a horrid dose; but if others fail, it may be tried.

Still another is pumpkin-seed. There are two ways in which it may be given. Three or 4 ounces (30 to 120 gm.) of the seeds may be crushed in a mortar with water, then strained, and the emulsion taken fasting, after a day's dieting. A few hours later a brisk purge should be taken. Second, the seeds may be made into an electuary which is almost as pleasant as sugar candy, and often is about as effectual. I should place these different remedies in the order of their efficiency as follows: kouso, male fern, pomegranate, kamala, turpentine, and lastly, pumpkin-seed.

Combinations are sometimes very efficient. The following is recommended by Strümpell:

R	Granati corticis radices. . . . .	3 iv-v (120 to 150 gm.)
	Aquæ . . . . .	Oij (1000 c.c.)
	Macerate for 24 hours and boil until it is reduced to five fluid-ounces (150 c.c.)	
	Add:	
	Oleoresinæ filicis . . . . .	gr. lxxv (5 gm.).

The whole amount is to be taken in three or four doses as close together as possible.

Thymol, in doses of 10 grains (0.66 gm.) three times a day in a wafer, has been recommended. Another method is to give five grains (0.33 gm.) every hour with or without preparation. Papain, juice of *carica papaya*, is given in doses of from 1 to 10 grains (0.066 to 0.66 gm.).

*Prophylaxis* is of the greatest importance. Great attention should be paid to the cooking of meats, especially of large joints, in order that they may be thoroughly "done." Rare meats should not be eaten.

## B—NEMATHELMINTHES (ROUND WORMS.)

The nematelmintes, or round worms, embrace three orders: *acanthocephala*, *gordiidae*, and *nematoda*. All of these include numerous parasitic organisms, few in fact being free-living; but the *acanthocephala* and *gordiidae* are not known as parasites of man, and may therefore be placed aside from further consideration here.

### NEMATODA.

The nematode worms, like the other orders of the round worms, are unsegmented, elongate, circular or nearly so in their transverse sections, cylindrical or more or less delicately fusiform and tapering toward each end. They are with but few exceptions parasitic and include important examples parasitic in man.

They are covered with a firm and rather transparent cuticle of a hyaloid or fibrillar and non-cellular type, which is believed to be a product of the cellular coverings of the early or larval stages, which is apt to be finely striated transversely (ringed) and which may bear in fixed positions papillæ, tubercles, bristles, spines or hook-like armature, or vesicular or wing-like expansions and folds. The cuticle extends into the oral cavity and is carried as the lining along the esophagus; a delicate continuation with pores moreover extends through the intestine, and at the posterior end of the canal forms the full lining of the rectum and is continuous at the anus with the external cuticular substance. The deep layer of this cuticle, known as the *hypoderm*, is a soft, fibrillar, nucleated, but not cellular structure, internally in close contact with the muscular wall of the worm, and along certain lines in the length of the worm is accumulated in considerable amount so as to form longitudinal ridges projecting internally toward the body cavity. These thickened lines, known as the *longitudinal lines* of the round worms, can often be recognized from the exterior as slightly depressed lines of a more opaque appearance than the rest of the surface. There are usually four, two larger ones, one along each side (lateral lines), and two in the median plane (one dorsal and one ventral), the former usually the more marked; occasionally intermediate lines of the same character, but much less pronounced, are seen between each median and lateral line. These thickenings of the hypoderm, as seen in transverse sections of the animal, separate the muscular layer into four lateromedian fields; and accommodate special structures which extend longitudinally in the worm (each lateral thickening inclosing one of the two longitudinal excretory canals and two lateral nerve trunks; each median carrying one nerve trunk).

The muscular layer forms the bulk of the thickness of the body wall; is in close relation externally with the inner surface of the hypoderm and internally with the so-called body-cavity. It is made up of numerous muscle cells which have their peripheral substance transversely striated and the internal material made up of a soft, reticulated protoplasm in which is embedded a fairly prominent nucleus.

They are of a fusiform shape (sometimes almost bladder-like, with the body much more prominent than the narrow ends), with one end in contact with the deeper layer of the cuticle and the length of the cell extending longitudinally and somewhat obliquely toward the body-cavity, inclining toward one of the lines to receive innervation from one or other of the longitudinal nerve trunks inclosed in the latter structures. According to the number of muscle cells to be seen in the transverse section of the worm in each of the fields between the median and lateral longitudinal lines, the nematodes are often divided into the *polymyariæ* (numerous cells in each of the latero-median fields) and the *meromyariæ* (two muscle cells in each latero-median field); those forms in which the fields are not well separated from each other sometimes being considered as forming a third group, the *holomyariæ*.

The alimentary system of the nematodes is a comparatively simple one. At the anterior extremity of the worm is the oral orifice, a round or transversely oval aperture, about which are often developed definite lips, papillæ (sensory), bristles or chitinous tooth-like armatures. The oral cavity is usually somewhat globular, lined with the internally continued cuticle, and at its deeper part (which may be specially developed as a buccal cavity or vestibule) there may be a chitinous armature of lance-like or spine-like elements. The muscular, suctorial esophagus, with triangular or triradiate lumen, is generally of a long flask shape or cylindrical; often at its posterior extremity it shows special lobes or "valves," which may also present special chitinous structures as an armature. The intestine proper is a long, straight, unbranched, thin-walled tube reaching from the esophagus to near the posterior extremity of the worm. It lies in the so-called body-cavity, held in position by strands of the body-wall derived from the longitudinal lines, mostly the lateral ones. In transverse section this tube is generally flattened dorso-ventrally. The wall is made up of cylindrical or cuboidal cells placed on a basement membrane and internally covered by a very thin and porous continuation of the cuticle continued from the front and hind ends of the gut. Close to the posterior end the tube loses its cellular structure, the cuticular lining becoming more pronounced; this portion is spoken of as the rectum. The anal orifice is usually situated close to the tail on the ventral side of the worm, is generally a transverse aperture, at times with well-marked lips and often with papillæ at its border or about it. In the male sex the rectum forms a *cloaca* with the sexual apparatus; but in the females is isolated from the latter. As appendages to the digestive apparatus may be found in some examples special unicellular glands opening into the esophagus or oral cavity (*esophageal and head glands*) or into the anal lumen (*anal glands*).

The excretory (supposed) apparatus consists of two longitudinal tubes lying in the tissues of the lateral longitudinal lines of the body wall near to the body-cavity, these beginning blindly posteriorly (in a few forms having communication with the body-cavity) and extending anteriorly close to the head, where they pass ventrally and unite in a common tube which opens on the ventro-median line upon the external surface of the worm. These are supposed to carry off waste fluid material from the body wall and to some extent from the body-cavity. Perhaps here, too, may be placed the "*erivical glands*," large unicellular glands situated along the esophagus, with a duct opening on each side to the exterior in a more or less marked lateral papilla.

The nervous system consists briefly of a ring containing ganglionic cells encircling the anterior end of the esophagus or depth of the oral cavity, sending six trunks of small size anteriorly into the head end of the worm and four or six posteriorly. The larger of the latter extend in the tissues of the median longitudinal lines; and either one or two smaller ones in each of the lateral longitudinal lines. Commissures exist about the opening of the excretory duct and in the male about the cloaca; while commissural and muscular branches are given off in the length of each of these trunks. In a few free-living forms eye-spots exist; but in the parasitic ones these are not present, the only sensory apparatus being the papillæ and bristles (oral, anal, or sexual) which exist in variable number and position in the different forms.

There is no definite blood-circulatory system, but the so-called body-cavity probably serves in a measure the same purpose, it being filled with a plasma which in some forms may contain a few cells and which bathes the alimentary and sexual tubes within the cavity and the inner surface of the body-wall.

The nematodes almost invariably have the sexes separate. The male has a simple tubular testis, plicated along the intestine and continuing as a somewhat narrower vas deferens (sometimes with a special dilatation, the *seminal vesicle*) to the posterior extremity of the worm, where it opens with the rectum into the cloaca. On the dorsal side of the latter, inclosed in tubular extensions of the wall (sheaths) are one or two chitinous spicules (penis), projectile and retractile through the action of strands of muscle attached to the base; which, when extended and entered into the vagina of the female, serve to hold the vulvar orifice open for the reception of the seminal elements and which also in some measure serve for attaching the male and female in coition. As an additional feature in the male, not infrequently the cuticular layer, including "rays" of the muscular wall, at the posterior end is expanded so as to form a pocket or "bursa" about the cloacal opening; this musculo-cuticular expansion being applied about the body of the female in coition for pur-

pose of prehension. The female apparatus is similarly arranged as one or two tubes (ovary and uterus) folded along the intestine in the body-cavity. The vulvar opening, guarded by rather prominent lips, often bearing sense papillæ, is generally situated about the middle of the length of the worm, or anterior to this (sometimes posterior) on the ventral side. From this there extends internally a short vaginal tube directly continuous with the single uterine and ovarian tube in the smaller forms, or dividing into the double (anterior and posterior) uterine tube (the far end of which serves as an ovary) in the larger forms. These tubes, as above stated, range in a plicated fashion along the intestine within the body-cavity. Generally the female is readily distinguished from the male by being of larger size and by the fact that the posterior end terminates more pointedly (that of the male being curved or flared out into the copulatory bursa above described).

The life-history of the nematode worms is extremely varied. They are oviparous or ovoviviparous. As parasites they are to be found in many possible situations in the economy of the host, as the alimentary canal, urinary and genital passages (as this paper is being written Dr. Powell of the Methodist Hospital of this city has brought to the writer a fully developed male *heterakis perspicillum*, inclosed in the albumen of a chicken's egg, the worm having evidently passed from its natural habitat in the fowl's intestine by way of the cloaca into the oviduct and there become included in the egg before the formation of the shell-membranes and shell), respiratory passages, blood-vessels, body-cavities or general tissues; and much complication may be met in connection with the different life-stages and with the transmission of the parasites to their hosts. Among the numerous possibilities the following may be outlined as examples. The embryos may develop within the shell-membrane either within the parent or after oviposition within the body of the host; in some forms may escape from the membrane as larvæ and develop directly in the host into the adult parasite (as perhaps occasionally in case of *oxyuris vermicularis*); or may remain as larvæ in the host to be passively transferred to a second host before development into adult form (as in case of *trichinella spiralis*, transferred as encysted larvæ in the muscle of the first host when this is devoured by the second host); or the larvæ being expelled from the host may pass a period as free animals, in which case sometimes (as in case of *strongyloides intestinalis*) a second generation intervenes (alternation of generations) before the animal again becomes parasitic. The ova of some of these worms are passed to the exterior without evidence of development of the embryo and may require for development that they be taken up by a second host in whom development occurs (as is probably the case with the common whip-worm); or may develop only as embryos within the shell-membrane before entering the second host, or again may incubate outside of the body and the larvæ with more or less intermediate development reach some fixed stage and thus await transference to the second host for their full growth and organization (as in case of *uncinaria*). While thus complicated it is to be noted that the intermediate hosts, so essential for the intermediate stages of the flukes and tapeworms, are in these parasites practically absent, the original or the second definitive host being sufficient for the embryonic and larval forms or a free period existing for their development, in most instances.

The following outlined classification, somewhat modified from Braun, may be offered for this large and important group:

- Family 1—ENOPLIDÆ: only free-living forms, commonly marine; sometimes with single bulb; fine hairs and bristles about mouth sometimes; often eyes and mouth armature. Genera: *Enoplus*, *Dorylaimus*, etc.
- Family 2—ANGUILLULIDÆ: mostly free, in water, earth, fermenting or macerating materials; here too a number of parasites in plants and rarely in animals; usually very small and especially characterized by fact that esophagus has two swellings (double bulb); many with a chitinous spine in oral cavity, or teeth; two equal male spicules; often a copulatory bursa; female posterior extremity pointed; vulva in middle of body-length. Genera: *Anguillula*, *Rhabditis*, etc.
- Family 3—ANGIOSTOMIDÆ: characterized by alternation of free-living generation with separate sexes and parasitic parthenogenetic female generation (Heterogony). Genera: *Strongyloides*, *Angiostoma*, *Allantonema*, etc.
- Family 4—GNATHOSTOMIDÆ: a small group including *Gnathostoma* or *Cheiracanthus*, representatives of which live in the stomach of vertebrates, especially mammals; characterized by numerous branching spines, either generally over the surface or only over surface of anterior portion of the body.
- Family 5—FILARIIDÆ: very long, filiform nematodes; oral orifice with papillæ or with two lips; esophagus thin, cylindrical, without bulb; four pairs of preanal papillæ and one unpaired; one or two unequal spicules in male; vulva usually in anterior half of body; generally ovoviviparous. Genera: *Filaria*, *Spiroptera*, *Dispharagus*, etc.

Family 6—TRICHOTRACHELIDÆ: characterized by a beaded esophagus, small oral orifice devoid of papillæ, anterior part of body very slender and filiform; posterior portion more or less thick and bearing the reproductive organs; male spicule single or absent; only one ovary; vulva at border between the anterior slender and posterior thicker part of body. Genera: *Trichinella*, *Trichiuris*, *Trichosoma*, etc.

Family 7—STRONGYLIDÆ: a very large group embracing a number of genera; characterized by possession of six oral papillæ; armature of chitinous teeth or spines frequent; esophagus flask-shaped; male with copulatory bursa and one or two spicules; for the most part small worms. Genera: *Eustrongylus*, *Strongylus*, *Syngamus*, *Sclerosoma*, *Uncinaria*, etc.

Family 8—ASCARIDÆ: mouth with three papillæ, one dorsal and two ventral; esophagus with bulb; male with one or two spicules; ovary double. Genera: *Ascaris*, *Oxyuris*, *Heterakis*.

#### Family: ANGUILLULIDÆ.

This family includes a number of small nematodes with thin, smooth cuticle, filiform, with a small mouth sometimes followed by a vestibule in which there may be a tooth-like armature, and this followed by an esophagus with two bulbous swellings (in the posterior one of which there may or may not be some form of chitinous armature). The males usually have the posterior end flared out into a copulatory bursa, and two equal spicules; the female has the posterior end pointed, with vulva back of the middle of the worm, and a double ovary; they are ovoviviparous.

For the most part they live in water, earth, fermenting matters, and in plants; and are occasionally accidental parasites in man. Thus several instances of the discovery of the common "vinegar eel" (*anguillula aceti*) in the human urine have been recorded; it is quite possible that, in some of these, mistakes have been made concerning the real parasitism, the urine perhaps having been placed before examination in some container in which previously vinegar or fermenting wine had been kept, the worms having been really living in some remaining portion of such material.

The *rhabditis pellio* reported by Schneider as occurring in the bloody and purulent urine of a woman with pyelonephritis was probably introduced into the vagina in bathing the genitals with unclean water, lived and multiplied there, examples being from time to time swept out with the urine, in which it was noted that they soon died. Similar cases have been published by Peiper and by Baginsky. The male of this worm is 0.8–1.05 mm. long; the female, 0.9–1.3 mm. The posterior end of the male has a heart-shaped or leaf-shaped copulatory bursa with from seven to ten muscular rays on either side, unequal spicules. The female has a pointed tail, vulva back of the middle of the body length. The ova within the uterine tube measures 60. : 35. microm.

The form known as *rhabditis niellyi*, found as the larva of an unknown nematode in vesicles in the skin of a boy by Nielly, is usually placed in this family, but it should be recalled here that rhabditiform larvæ of other round worms, as of uncinariæ, gain access to their host through the skin, and it may well be that Nielly's case and other instances of larval rhabditiform worms in the skin (mostly in lower animals) are but examples of other nematodes passing to a new host.

Occasionally some of the anguillulidæ naturally living in vegetables have been found in the vomit of persons who have eaten of the infested vegetables, as in the case recorded by Botkin where the anguillula of onions (*anguillulina putrefaciens*) was thus met.

#### Family: ANGIOSTOMIDÆ;

##### Genus: *Strongyloides*.

#### *Strongyloides intestinalis* (Grassi).

(*Anguillula intestinalis* et *stercoralis*; *leptodera intestinalis* et *stercoralis*; *pseudorhabditis stercoralis*; *rhabdonema strongyloides*; *rhabdonema intestinale*.)

Living as two different (heterogonous) generations; the first dioic and free; the second parasitic as parthenogenetic females. The parasitic form lives in the upper intestinal tract of man; 2.5 mm. long; cylindrical, with pointed tail end; smooth cuticle; simple mouth with four (3?) lips; long, slender cylindrical esophagus, reaching one-quarter of the length of the worm; anus close to tail; vulva at posterior third; containing yellowish-green oval ova (50.–58. : 30.–34. microm.); larvæ develop in intestine (at first 200.–240. microm. in length, but increase to two or three times this length) and are passed in the fecal material. The larvæ differ essentially from the parent in having an esophagus with two bulbs (rhabditiform). In the discharged feces at suitable temperature (about 30 °C.) these develop with one moulting of the cuticle to a free-living generation with separate sexes (at lower temperature are apt to remain at least in part asexual). In this free sexual generation the worms are smooth, cylindrical, and tapering, with pointed tail end; mouth as in parasitic form;

esophagus rhabditiform (two bulbs) with its anterior portion long and with the posterior pyriform and containing a Y-shaped chitinous armature; anus at base of tail; male with tail curved and two spicules, body length 0.7 mm.; female 1. mm. long, with straight pointed tail, vulva a little back of middle; ova few, yellowish, ellipsoid, thin-shelled, 70. : 45. microm., sometimes hatching in uterus. The larvæ of this generation look much as their free parents, are at first 0.22 mm. in length, but grow to 0.55 mm., then moult and assume a filariform or strongyloid character like that of the parasitic grandparent. In unknown manner these gain access to the intestine of a new host or shortly die.

The above outline follows that known for the tropical *strongyloides*; it is said that in the European examples the intermediate generation with separate sexes fails, that the rhabditiform larvæ of the parasitic worms pass with moulting to the condition of the strongyloid larvæ and these, if introduced into the intestine of the next host, directly develop into the parasitic females as above.

The worm is commonly spoken of as *strongyloides intestinalis* when one refers to the parasitic parthenogenetic females and their larval offspring; as *strongyloides stercoralis* in the free form having separate sexes. The parasite was first met in the stools of persons suffering from Cochin-China diarrhea, and was supposed to be the cause of this affection; and at one time, too, was suspected of being in causal relation to Asiatic cholera. Both these views are erroneous, the worm probably having no direct pathological significance; although perhaps, when present in large numbers, it is capable of aiding in keeping up the intestinal irritation of a diarrheal affection caused by some other original influence. The parthenogenetic females are found in the upper part of the small intestine, burrowed in the crypts or a little way in the mucous membrane. Here they deposit their ova. These retained in the crypts or between the folds rapidly incubate and give origin to the larvæ found in the stools. These are usually found in great numbers, scarcely a bit of the fecal matter but contains at least two or three of the young worms in ordinary cases. They are readily observed with low powers of magnification in thin layers of the fecal

FIG. 203.—*Strongyloides intestinalis*: on the left a gravid female from human intestine (natural size, 2.5 mm.). In the middle a rhabditiform larva from fresh fecal matter,  $\times 120$ ; to the right a filariform larva from culture,  $\times 120$ . (Braun.)

matter, actively wriggling. In autopsies there are occasionally found a few sexually developed examples of the intermediate generation (*s. stercoralis*) in the intestine of the cadaver; but it is probable that these develop after the death of the host from the intestinal larvæ in the same manner that they usually follow after ordinary discharge to the exterior.

Nothing is known as to the mode of transmission to the second host, but presumably unfiltered water or unclean vegetables (uncooked) which may have been grown in soil watered with fecal infusions (as is rather common in China, Japan, and elsewhere) may bear the second generation of larvæ to the intestine of the next person. The worm is found widely distributed in Indo-China, the East Indies, Africa, Europe, and in both North and South America. Few cases have been reported from this country, but it is not an infrequent parasite, at least in our Southern States, where the writer has encountered it a number of times, invariably without notable symptoms.

It may be expelled without much difficulty by the use of the ethereal extract of male fern; and in case of infested persons who for some reason decline treatment, or in whom perhaps treatment temporarily fails, the stools should as a matter of precaution be disinfected to prevent the dissemination of the parasite.

#### Family: GNATHOSOMIDÆ.

This family, generally parasitic in the stomach of a few vertebrates as cats, hogs, is easily recognized by the existence of spines set in the posterior border of the transverse rings or striations of the cuticle, either over the entire worm or only over the anterior portion.

One single example is known to have existed parasitically in man, that found by Levinson, derived from a swelling of the skin of the breast of a young woman in Siam and known as *gnathosoma siamense*. Only one female worm was obtained from this case, although as many as five or six specimens were obtained, but subsequently lost, from several other cases. This female example was 9. mm. long and 1. mm. thick; the anterior extremity was slightly narrowed and the oral transverse opening guarded by two prominent lips, about which were eight circles of spines; the anterior portion of the specimen was beset with three-branched spines (middle branch largest) in front, becoming smaller and simple toward the end of the first third of the body length, back of which the cuticle was free from spines; vulva back of the middle of length.

#### Family: FILARIIDÆ;

##### Genus: *Filaria*.

#### 1—*Filaria bancrofti* (Cobbold).

(*Trichina cystica*; *filaria sanguinis hominis*; *filaria sanguinis hominis ægyptica*; *f. wuchereri*, *f. sanguinis hominum*; *f. sanguinis hominis nocturna*; *f. nocturna*.)

*Male*: colorless; 40. mm. long, 0.1 mm. thick; filiform; anterior end slightly clubbed, the head being a little thicker than the neck; posterior end curved, but not spiral; anus close to tail on ventral side, with three pairs of small preanal papillæ and same number of postanal papillæ; unequal spicules. *Female*: brownish; 76.-80. mm. long, 0.2-0.3 mm. thick; extremities rounded; vulva 1.27 mm. back of anterior extremity, anus 0.28 mm. anterior to posterior extremity; nearly the whole of the body is occupied by the two uterine tubes in which may be seen the ova and already developed larval filariæ. *Larvæ*: covered by a delicate sheath-like membrane, 130.-300. microm. in length, 7.-11. microm. thick.

Bancroft's filaria, the common form of human blood filaria, is met in most tropical countries. It occurs in the West Indian islands, in our own Southern States (where it was first demonstrated by Dr. John Guitéras, and later by a number of observers), and in South America. It is encountered frequently in India, China, and Japan, in the East Indian

islands and the South Sea islands, in Australia, commonly in Africa, and has even been met in southern Europe (Spain). The worm was first known only as the larva found in the circulating blood, no recognition being made of the species *f. diurna*, *f. perstans* and others later described as separate species by Manson. From the fact that these larvæ were met in the blood of infested individuals, the name *filaria sanguinis hominis* was first attached; but later, when the adults were recognized, it was found that the proper habitat of the worm in man is in one of the lymph passages, usually one of the large lymph vessels of the trunk, as in the groins, the pelvis, or thoracic duct; although as errant forms they are also to be found in subcutaneous lymph vessels, and even in the heart and blood-vessels. In such situation are usually found two worms,

FIG. 204.—Larval *filaria bancrofti* in blood. (Coplin.)

male and female, intimately coiled together and probably living thus for long periods and producing their larvæ. The female generally gives birth to the larvæ (occasionally ova), in large numbers, each inclosed in a so-called "sheath" (the shell-membrane). These are carried along the lymph vessels by the current and eventually are poured into the blood-vessels, each larva being probably capable of several months of life in the blood. The establishment of a positive diagnosis of filariasis is made by the discovery of these larvæ in the blood of the subject examined. They are readily detected with ordinary laboratory powers of the microscope in thin moist films of the fresh blood made just as in examination for malarial parasites, each larva being about as thick as the diameter of a red blood cell, and about forty times as long. They are nicely demonstrated with the sheath stained by drying a film of blood over the fumes of acetic or osmic acid and then staining with hematoxylin and eosin or carmine and methylene blue. In the fresh blood they are seen to have an active, wriggling movement, but because of their inclosure in the sac-like sheath they accomplish but little progression by their activity. They may be obtained at any hour from the interior blood; but show a peculiar periodicity in the peripheral blood, that drawn as in ordinary clinical examinations from the subcutaneous tissues only showing their presence when taken at night (best between dusk and midnight). While no certain knowledge is had explanatory of this periodicity it probably does not rest with periodicity in the life of the worm, but is rather due to a variation in caliber of the peripheral capillaries at night and in day. From the tonicity of the walls of the capillaries and their surrounding tissues in the waking hours of the subject, probably the capillary lumen is too narrow for the easy progression of these larvæ; while in the relaxation from fatigue, and in sleep, it may become sufficiently wide to allow the worm fair opportunity to be borne along with the blood. In support of such an idea stands the fact that if the habits of the infested individual be changed so that he

sleep in day and be awake and active at night, after a short period of indifference the larvæ are to be found in the peripheral blood only in the day. While in the blood the larvæ retain their sheaths and are only passively carried in the blood stream; were it otherwise they could probably actively progress at any hour through the finest blood channels, and could in all likelihood be found in the peripheral blood at all hours, and perhaps might penetrate the vessel walls and tissues of the host. It has repeatedly been noted that in blood preparations after the cells disintegrate and give off their hemoglobin, the plasma thus becoming thicker (although not coagulated), the larvæ are able by their active movements to break through the sheath (which is somewhat fixed by the denser plasma) and then are actively progressive, each showing on close examination a small boring apparatus at the head end.

The further life-history of these larvæ is not certainly established; but it is known that at least some are removed from the infested subject by mosquitoes of the genus *Culex* in withdrawal of blood by these insects. It has been observed that in the stomach of the mosquito, as the blood disintegrates and the plasma thickens, the larvæ, just as in the blood-film alluded to, escape from their sheaths and penetrate the walls of the stomach to bore into the thoracic muscles of the gnat. Here they grow to an intermediate size, reaching as much as 1.5 mm. in length. It was generally believed that the larvæ are next, with the death of the infested gnat, freed into the water upon which commonly the mosquito has died, and that they are transferred with this to the alimentary canal of the next host, boring through the walls of the digestive tube and attaining one of the abdominal or pelvic lymphatics. This idea is by no means abandoned; but it is known that larvæ experimentally kept in water die in the course of a few days, and attempts to infect monkeys with water containing the larvæ have failed. On the other hand, it is well established that the larvæ after growth in the muscles of the gnat, may travel and get into the proboscis; and it is thought quite possible that if the *Culex* at such times should bite a fresh human subject these larvæ may readily gain access to the wound and thus enter the new host. Strong analogy exists in the established similar mode of transmission of *f. immitis* of the dog by mosquitoes shown by Noé; and the present attitude favors this view.

**Pathology and Symptomatology.**—The symptoms of filariasis, aside from the presence of the larvæ in the blood, vary much in individual cases. It is well known that the infested persons, with numerous larval filariæ in their blood, may for years show no symptoms and be apparently in excellent health. Doubtless in such cases the parent worms are located in some portion of the lymphatic circulation which they do not occlude (as the receptaculum chyli) or in such part where free anastomosis prevents serious fault in the lymph flow. If, however, the parasites should occasion obstruction and cause stoppage of the lymph circulation, then in a limited or extensive portion of the body, according to the lymphatic area affected, there follows dilatation of the lymph vessels. This may result in rupture of the distended vessels and lymph edema; or a lymph fistula may develop to the external surface of the body or into one of the body cavities or hollow viscera. Not infrequently such fistula opens into a

ureter or the urinary bladder, the urine becoming milky from the lymph admixture (chyluria); and at times in the development of the fistula some of the small blood-vessels may also be broken into and blood is added (hematochyluria). The distention of the lymphatics may involve the lymph glands; thus those of the inguinal region sometimes form tumor-like masses of a peculiar boggy quality ("varicose glands"), giving on palpation the sensation of interior small solid areas, occasionally growing to half the size of a fist, and requiring to be differentiated from hernia. Along with such conditions the tissues about the dilated lymph vessels and passages become hyperplastic, especially in the skin, where the sometimes enormous thickening of the corium known as elephantiasis (the possibility of a combined or secondary bacterial infection in the production of which should be held in mind) is occasioned. This last is usually met in the skin of the lower members and about the genitals, but is occasionally seen elsewhere. These changes are essentially permanent, and for this reason not every case showing elephantiasis, lymph edema, varicose glands, lymph-fistula, or chyluria need necessarily show the presence of the filarial larvæ in the blood, all of the parent and larval parasites having perhaps died—moreover, lymph obstruction with any of the above secondary results may arise, of course, from other than parasite cause; yet it is safe to say that in infested districts the majority of such conditions as above mentioned should be regarded as due to existing or previous presence of filarial parasites. In addition, there are likely to develop some blood changes, eosinophilia and more or less reduction in the number of red cells, enlargement of the general lymphatics and of the spleen, some indefinite febrile disturbances, more or less alteration of nutrition, together with possible inflammatory changes of the peritoneum, bladder, pelvis of the kidney or of the latter organ itself.

The mechanism of the obstructive phenomena and their results are thus outlined by Manson:

"A parent filaria is lodged in the left thoracic duct. In some way not yet understood it injures the walls of the vessel, causing ulceration or inflammatory thickening. In time this lesion leads to stenosis of the duct. *Pari passu* with the development of the stenosis the thoracic duct on the distal side of the stricture dilates owing to the rising lymph. After a time the stricture becomes so narrow that the lymph and chyle no longer find their way past it to the left subclavian vein. They seek, however, to reach the blood by another route; a retrograde movement down the thoracic duct sets in, and so, by way of the pelvic lymphatics in the walls of the abdomen and the anastomosis between these and the lymphatics of the upper part of the body, the chyle from the intestines and the lymph from the lower extremities find their way into the circulation by the right thoracic duct. Possibly there are other routes, as by the lymphatics of the esophagus, diaphragm, and back. It is certain, however, that a frequent course pursued is that described, which is much the same as that pursued by the blood in the case of obstructed portal circulation. To accommodate this diverted chyle and lymph, the lymphatics by which they pass become enlarged and in many places varicose. The tendency to varicosity is very evident in such places as the scrotum, mucous membrane of the bladder, or wherever the lymphatics are abundant and feebly supported. In many instances these varices, when superficial, can be seen or felt and their nature readily recognized. If the inguino-femoral glands are involved, the varicose groin glands, so characteristic of filaria infection, are produced. Sometimes the varix is apparent on the surface of the abdomen even, as in a case related by Sir William Roberts and in another by Havelhing. That these varices are really part of an anastomosis conveying chyle from the abdominal viscera to the blood is proved by the nature of their contents, which are usually milky-white or slightly red-tinted chyle—not clear and limpid lymph, such as comes from the legs. As the lacteals are the only source of chyle, these chylous contents of the varicose lymphatics must have come from that source,

and the route followed must have been the retrograde one described. Now, if the lymphatics of the bladder happen to be involved in the compensatory anastomosis, and if they give way, as the lymphatics of the scrotum so frequently do in similar circumstances, the result is a leakage of chyle in the bladder, and chyluria. It is evident from this that the embryo filariæ, although they are generally present in the blood and the urine in chyluria, have nothing whatever to do with its production. This is further proved by the fact that in some few cases of genuine and persistent tropical chyluria no embryo filaria can be found either in blood or urine. Proper treatment of chyluria is in principle the same as the treatment of acquired varix in any accessible region. This should consist of rest, elevation, lowering of the tension in the lymphatic vessels by the use of saline purgatives, limited and appropriate food, and abstinence from fluids as much as possible. Certain drugs have been vaunted as specifics for chyluria. Temporary recovery from time to time is the rule, and the drug which was being used at the time the urine cleared spontaneously from the healing of the rupture in the varix of the bladder is often credited with the cure. I cannot understand how a drug introduced by the mouth can possibly cause the closure of a gaping varix in the bladder."

Besides *f. bancrofti* reference may be made at this point to the following species of filariæ, the larvæ of which are to be met in the blood and liable to be confused with those of the ordinary form of human blood filariæ:

2—*Filaria diurna* (*f. sanguinis hominis*, var. *major*): a larval filaria found by Manson in the blood of negroes in West Africa, and differentiated by this observer from the larvæ of *f. bancrofti* by its presence in the peripheral blood in the day rather than at night, and by the fact that its intestine is not as granular as that of *f. bancrofti*. It is of the same size and general appearance as the latter, however. Manson has suggested this as the larval form of *f. loa*. In the few cases in which it was seen it presented no special symptomatology. It seems quite possible that this species is identical with *f. bancrofti*, the time of appearance in the peripheral blood being perhaps dependent rather upon conditions of the host than of the parasite, the less granular condition of the intestine being scarcely enough to justify the idea of specific difference.

3—*Filaria perstans* (*f. sanguinis hominis*, var. *minor*): This form was met as the larva by Manson in the blood of negroes along the west coast of Africa and by him erected into a separate species. It is distinguished from the ordinary filariæ of human blood by the fact that it is present in the peripheral blood at all times, without diurnal or nocturnal periodicity; is smaller; as seen in the blood has no sheath and is actively progressive; has its posterior end truncated and abruptly rounded; and the boring spicule at the head end is more prominent than that of *f. bancrofti*. The adult parasites, subsequently recognized, inhabit the mesenteric and retroperitoneal tissues. The parasite is apparently of little or no pathogenic importance, as the hosts present no symptoms or important lesions thus far referable to the worms or their embryos. The male reaches a length of 45. mm. and is 0.06 mm. in thickness; the female is about twice as long and as thick as the male. The head end is rounded. The tail of the male is curled, and is marked by four pairs of preanal and one pair of postanal papillæ; spicules unequal; a pair of small cuticular appendages at the tip of the tail. Vagina 0.6 mm. from the head end; tail with cuticular appendages at tip as in male; one anal papilla.

The intermediate hosts are as yet unknown.

4—*Filaria demarquayi*: Manson gave this name to certain larval filariæ found in the blood of natives of the West Indies and New Guinea, which look like those of *f. bancrofti* but are only about half as large. The larvæ are apparently ensheathed, but of this Manson is not sure; they were found in the peripheral blood both in day and in the night. The adult female only has been met, reaching 80. mm. in length and 0.25 mm. in thickness. It was found in the mesentery of a nation of St. Lucia by Galgey and described by Daniels and Ozzard. Nothing is known of the intermediate host; and the specific isolation of the parasite is as yet not without question. It is not known to be of pathogenic importance.

5—*Filaria ozzardi*: a larval form obtained from the blood of Caribs of British Guiana and established by Manson as a separate species; resemble the larvæ of *f. perstans*; measure 0.173–0.240 mm. in length and 0.0043–0.005 mm. thick; have no sheath and are actively progressive in the fresh blood preparations; have blunt tails (sharp-tailed forms also found in the blood of the same patients and supposed to represent another phase of the same parasite). Manson states that more recently Daniels has found at autopsy in several Caribs, known to have shown these larvæ in the blood in lifetime, numerous adults in the mesentery and fat at the base of the mesentery (and in one case in the subpericardial fat). These were 7.5 cm. in length and very slender (about one-third as thick as *f. bancrofti*), head somewhat club-shaped and without papillæ; tail of male coiled and showing one projecting spicule.

6—*Filaria magalhæsi*: At autopsy in the heart of a child in Rio Janeiro Magalhães found two sexually mature filarial worms, male and female, to which the above name has been applied. *Male*: 83. mm. long and from 0.28 to 0.4 mm. thick, with thick finely transversely striated cuticle, rounded head end without papillæ, posterior end with double curl and four large pairs of preanal and of postanal papillæ, with one (probably two unequal) spicule, anus 0.11 mm. anterior to tail, mouth round and unarmed. *Female*: 155 mm. long, 0.6–0.8 mm. thick, with cuticle a little more coarsely striated than in male; head-end as in male; tail slender, ending bluntly; vulva 2.5 mm. from anterior end; anus 0.13 mm. in front of tail; two ovaries, with the ova contained measuring 38. microm. long and 14. microm. wide, the larvæ 300–350. microm. in length.

**Treatment of Filariasis.**—There are no established remedial measures in case of these forms of filarial infection. Thymol has been lauded as almost a specific and has at times seemed to have given excellent results, but in many other cases it has been apparently of no value. So, too, benzoic acid and benzoate of soda have been recommended for the destruction of the parasites, but are of not more promise than the thymol. At best treatment has most to deal with the effects of the parasites in the way of the elephantiasis, lymph edema, fistulæ, chyluria, etc., and of course, the above drugs can have no value in such relation. Such conditions must be met individually and symptomatically. Elephantiasis is at times to be dealt with surgically, as in case of elephantiasis of such restricted regions as the scrotum, or of the female genitalia. It may be dealt with in cases of general involvement of the skin of the limbs by elevation of the member, application of pressure by bandage from foot upward, and perhaps some value may be realized from the internal administration of iodid of potash. Inasmuch as there is reason to believe that the dermal thickening of elephantiasis is, at least in the early stages of the inflammation, in part due to associated infection of the skin by various common bacteria of the surface of the body, there is reason in employing internal antiseptics (as methylene blue or ichthyol) or applications of ichthyol or other antiseptics to the surface beneath the bandages advised. Treatment of chyluria or hematochyluria demands rest in the recumbent position, the lowering of lymphatic tension by saline purgatives, appropriate food, and limitation of fluids; such measures being appropriate also in connection with the pressure treatment of elephantiasis and in that of all of the mechanically induced lesions.

As measures of prophylaxis the careful screening of infested individuals from mosquitoes, particularly at night, all efforts to destroy mosquitoes and prevent their breeding and entering human habitations, and the careful filtration and boiling of water used by inhabitants of infested districts (in recognition of the possibility of correctness of the old theory of water transference of the larvæ) should all be practised—such measures much more than attempted remedy of existing cases holding out promise of valuable results.

#### 7—*Filaria medinensis* (Linneus).

(*Vena medinensis*; *dracunculus Persarum*; *gordius medinensis*; *filaria dracunculus*; *f. athiopica*; *dracunculus medinensis*, Guinea-worm.)

Only the female certainly known; whitish or yellowish; 50–80. cm. or more in length, 0.5–1.7 mm. thick; cylindrical; anterior end rounded; oral orifice terminal; small, with two lips back of which are two lateral and four submedian papillæ, posterior extremity curved into a hook and terminating in a blunt point; intestine missing (probably atrophied by pressure of gravid uterus) up to esophagus; vulva

and vaginal tube not recognized; nearly the whole body occupied by the double uterus full of larvæ and ova in various stages of development. Males probably represented by the small worms found by Charles in an autopsy on a native in Lahore, in whom in the subperitoneal tissue he encountered two female Guinea-worms each having a small worm about four centimeters in length attached about 14 centimeters back of the head end; it is from this believed that males are much smaller than females and that after coition they perish and are lost. Larvæ in uterus measure 0.5-0.75 mm. in length, slightly tapering toward the head extremity and gradually tapering from the middle to a long fine straight posterior extremity, finely striated transversely, somewhat flattened laterally; escaping to the exterior of host through the mouth of the parent by rupture of uterine sac when the mother worm comes to the surface of the body of the infested individual.

The Guinea-worm, known of old as the "fiery serpent" of the children of Israel in their wandering through the wilderness and mentioned in the ancient writings of other races, occurs in India, Persia, Turkestan,

in Egypt, and in fact all through tropical Africa, especially on the west coast. It has been introduced with negroes from Africa into this country, but has not taken permanent hold in the western hemisphere save in a few isolated localities in South America. It has been found occasionally in cattle, horses, the dog, jackal, leopard, and wild cat; but it is most common in man. It occurs without reference to race or age, is more common among males, but probably only because of some difference in exposure from habits; and generally is most frequently seen during the wet season and in the succeeding hot months of the year. Its usual habitat in the host is in the subcutaneous tissue of the lower extremities, down near the ankles, but it has been found in the trunk, in the face, and about the eyes and in the tongue, and elsewhere. It does not remain in one locality, but wanders through the tissue, usually causing some minor itching as it travels; and after maturation, which is reached after some months or a year or more after entrance of the larval worm, it coils itself in

FIG. 205.—*Filaria medinensis*: a, anterior extremity; O, mouth; P, papilla; b, female, reduced to less than half normal adult size; c, larvæ, enlarged. (Braun, after Claus.)

some locality, as about the ankles, and there occasions a red and painful tumefaction. Probably, as above suggested, in the original infestation both a male and a female larva enter the host; after coition it is thought the male dies and is absorbed and the female continues to grow, developing an enormous number of larvæ in the uterus, pressure from the distended uterine sac causing the atrophy of the other structures internally and being largely responsible for the size of the mature worm. After several days the swelling, which may be as big as a pigeon's egg, becomes vesicular at the top and breaks down into an ulcer. When

moisture is applied over this ulcerated tip (either water purposely dripped upon it or incidentally applied when the host is wading) the worm seems to be stimulated to discharge the larvæ, and the head end is slightly protruded through a small opening in the midst of the ulcer. The uterine sac seems to be forced through the oral orifice, breaks, and from it escapes a milky fluid abounding in actively moving larvæ. Some days may elapse before the entire discharge of the latter, the worm coincidentally shriveling and eventually spontaneously passing out from the tissue.

Nothing is really certainly known as to the life-history of the larvæ. It has been definitely shown that they may be directly passed with the water into which they have escaped to the next host and reach full development in such individual; but whether this is the rule is not established. Manson and others believe that, having escaped from the host into water, they enter the bodies of certain minute water arthropods (*cyclops*), therein moulting several times, becoming cylindrical, losing the delicate tail, and developing a small tripartite tail appendage. Whether the larvæ enter the next human host ordinarily with the water into the intestine (either free or inclosed in the arthropods), or whether they penetrate the skin of some individual who may be wading in water containing them, is not known. It is known that in clean water they are not of long life, dying in five or six days; in muddy water they live for several months as free-swimming larvæ; and when parasitic in *cyclops* are still more enduring.

There is rarely more than one parasite of the species in one host, although there have been placed on record as many as 50. The symptoms occasioned are practically entirely localized to the place of escape of the worm and under conditions of cleanliness after the removal of the parasite entirely disappear. Occasionally, in the height of the local inflammation, there may be a slight febrile general state induced, but this is not of importance; however, should the worm be broken in an endeavor to drag it out, suppuration and more or less septic absorption with general symptoms may ensue.

**Treatment.**—Attempts to destroy the worm before its maturation and pointing are practically useless with means at present known; and the treatment is limited to the safe withdrawal of the worm and antiseptic dressing of the sore occasioned. The natives are in the habit of allowing water to drip over the ulcerated surface to cause the protrusion of the head of the worm; this is then fastened to a small stick, which is bound loosely to the surface by a well-moistened bandage. From time to time, several times daily, a turn is taken upon the stick, thus winding the protruding part upon it until finally the entire length is safely and without breakage withdrawn. A more excellent method has been suggested by a French surgeon, Emily, who injects with a fine hypodermic needle a little corrosive sublimate solution into the head end of the worm, which kills the parasite and allows it to be more readily withdrawn. Or if this cannot be done he would inject a small amount of the bichlorid solution into the swollen tissue about the worm, which is also likely to destroy the worm, and then cuts down upon it and carefully extracts it. Faulkner has said that he has been able to expel the worm entire within an hour by applying one pole of the constant current over the tumefied area.

It is impossible to be specific as to prophylaxis; but at least with our present knowledge it is advisable to refrain from the use of water for drinking which has not been boiled or well filtered, and lest perhaps the larvæ enter the host through the skin it would be well to refrain from wading in muddy water in countries where the parasite is known to exist.

#### 8—*Filaria loa* (Guyot).

(*Filaria oculi*; *dracunculus oculi*; *d. loa*; *f. subconjunctivalis*; *f. lachrymalis*.)

*Male*: length, 20.–30. mm.; width, 0.3–0.4 mm. whitish or yellowish; cuticle not striated but, except at extremities, beset with numerous irregularly placed protuberances; anterior end as a truncated cone; at base of cone, dorsally and ventrally, a small papilla; posterior end slightly curved ventrally, pointed; mouth unarmed; anus 82. microm. in front of tail; three pairs of prominent preanal papillæ, two pairs of smaller postanal papillæ; two unequal sexual spicules. *Female*: 30.–40. mm. or more long, 0.5 mm. thick; surface and anterior end as in male; posterior end straight and tapering, round at tip; vulva at end of first fourth of body; double uterine tube nearly filling the body, the ends of tubes as ovaries; the uterus filled with ova and larvæ (253.–262. microm. in length) with rounded head ends and long pointed tails.

This worm is, as far as now known, confined to Western Africa; it has been known in America, having been conveyed in negro slaves to this country, but has never become permanent here. The adults live and wander through the subcutaneous tissues, especially about the face, nose, and eyes, and have been especially found in the subconjunctival tissue. Crawling in the skin, the worms cause considerable itching and burning pain; and in the eyelids and conjunctivæ induce more or less troublesome inflammation and swelling. The adults are known to persist for months or even several years in these situations in the host; but, as a rule, there are only a few present in one individual. The mode of escape of the larvæ from the host and their subsequent history are unknown. The treatment is limited to the removal of the parasite by surgical methods, as the clipping of an opening in the conjunctiva and withdrawal of the worm cautiously by means of suitable forceps.

#### *Occasional or Accidental Filaria in Man.*

9—*Filaria immitis* (*f. canis cordis*; *f. papillosa*, *hæmatica canis domestici*.)

*Male*: 12.–18. cm. in length, 0.7–0.9 mm. in thickness; filiform; whitish; rounded head end, and posterior end pointed and coiled spirally; oral orifice round, unarmed, terminal, with six small papillæ around it; anus close to tail, with three pairs of large preanal papillæ and one pair of smaller postanal papillæ (by some a larger number recognized); feebly developed lateral cuticular wings at tail end; two unequal spicules. *Female*: 25.–30. cm. in length, 1.–1.3 mm. in thickness; anterior end as in male; posterior end tapering to obtuse point, straight; vulva 7. mm. from anterior end; viviparous. *Larvæ*: 285.–295. microm. long, 5. microm. in thickness, with finely tapering and pointed tail.

This worm is commonly met in the heart and larger blood-vessels of the dog; and has a wide distribution in the body. Bowlby has described its occurrence in considerable numbers in the body of an Arab in the portal vein. The worm is of considerable interest, too, because of the proven convection of the larvæ from one dog to another by mosquitoes (Grassi and Noë).

10—*Filaria oculi humani* (*f. lentis*); Several instances of the occurrence of small worms, apparently filariæ, in the lens have been recorded by ophthalmologists, ranging from 1. to 12. mm. in length. It is very questionable whether a definite species exists, the above name having been coined without sufficiently careful examination of any of these parasites; which may well be of different species and probably errant examples of known filariæ.

11—*Filaria hominis oris*: Under this name Leidy described a male (?) filaria which he found preserved in alcohol in the collection of the Philadelphia Academy of Natural Sciences, labeled "from the mouth of a child," but without any further record. It was 14. cm. long, 0.16 mm. in thickness, head end rounded, with mouth

round and simple; posterior end obtuse, furnished with a short curved epidermal hooklet 0.05 mm. in length.

12—*Filaria restiformis*: Leidy has proposed this name for a filaria, a single specimen of which was submitted to him having been passed *via* the urethra from a young man in West Virginia, the urine just before and for a few days after passage of the parasite being milky, slightly bloody and rich in mucus. It was 65. cm. long, 1.5 mm. thick; nearly cylindrical; red when fresh; with smooth, shining, and tough cuticle; head end rounded, without appendages; posterior end not tapering and tail bluntly rounded, incurved, and without appendages; mouth terminal, round, unarmed, without papillæ; no evident anus or genital aperture; straight cylindrical intestine apparently ending blindly; generative organs unobserved. Leidy regarded it as merely an accidental parasite of man, but was unable to identify it with known species and hence proposed the above terminology.

13—*Filaria peritonei hominis* (*f. conjunctiva*; *f. inermis*): Thus far the female only is known. Length about 16. cm.; thickness 0.4–0.5 mm.; whitish to brownish; filiform; extremities slightly tapering, posterior more than anterior; posterior end terminated by an incurved point; cuticle striated transversely and showing longitudinal lines; head without papillæ; mouth small, round, unarmed; anus 0.3 mm. from tail; vulva 0.05–0.1 mm. back of mouth; ova developing in uterus to larvæ, 350. microm. long, with finely tapering and pointed tail.

This worm is known to occur in the horse and the ass, probably more frequently than has been supposed, as there is some chance of its being confused with *f. equina*; in man it is doubtless but an accidental parasite. It is suspected as being identical with a filaria (*f. palpebralis*) obtained from a small cyst in the upper eyelid of a boy in Palermo by Pace; and Railliet suggests that it may represent the adult stage of some form of *f. oculi humani*. It has been found three times in man, once in the eye by Dubini, encysted in the folds of the gastrosplenic omentum by Babes, and by Addario in a pea-sized tumor of the ocular bulb.

14—*Filaria labialis*: Pane gave this name to a filaria (female only found) obtained from a small pustule on the inner side of the upper lip of a Neapolitan. It was about 30. mm. long; anterior end slightly tapering, with small terminal mouth about which were four papillæ; posterior end tapering, but a little bulbous at the tip; anus 0.5 mm. in front of tail; vulva 2.5 mm. anterior to anus; double uterus, the posterior tube of which is apparently rudimentary.

15—*Filaria lymphatica* (*Hamularia lymphatica*; *f. hominis bronchialis*): This worm as originally described (male) was found by Treutler in the bronchial lymphatic glands of a phthisical subject; length, 26 mm., brownish blotched with white, almost transparent posteriorly, filiform, slightly compressed laterally; with two spicules. Instances supposed to be of the same type have since been recorded by Blanchard, Brera, and v. Linstow. Braun regards the worm as identical with *f. equina*, a common parasite of the peritoneal and pleural serous membranes in the horse; but the data in hand from the original case are too meager to permit this view to definitely prevail.

16, etc.—Leuckart has found in several small cystic tumors from the subcutaneous tissue of negroes of the west coast of Africa numerous filariæ, male and female, occurring in tangled masses in a fluid in the interior, this fluid containing numerous larvæ, like those of *f. bancrofti*. The males measured 30.–35. cm. long; the females, 60.–70. cm. Similar instances have been found in Africa by Labadie-Lagrave, Deguy, and Prout. Leuckart describes the worm under the term *f. volvulus* (*volvulans*, Railliet?).

A small filaria measuring 1. mm. long and 0.03 mm. thick, with mature alimentary and sexual apparatus, was found in the blood of a Roumanian by Sarcan and termed *f. romanorum-orientalis*.

Kolb has recorded the discovery of a filaria bearing some similarity to *f. medinensis* free in the peritoneal cavity of a negro in eastern Africa, under the name *f. kilimariæ*.

FIG. 206.—*Filaria immitis*: natural size; to left, male; to right, female. (Railliet.)

Family: TRICHOTRACHELIDÆ;

Genus: *Trichiuris*.***Trichiuris trichiura* (Leuckart).**(*Ascaris trichiura*; *trichocephalus trichiurus*; *trichocephalus hominis*;  
*trichocephalus dispar*; whip-worm.)

*Male*: 35.-45. mm. long; whitish; anterior three-fifths slender and thread-like; posterior two-fifths thicker, cylindrical, terminally rounded and curled; anus terminal; single spicule in a tubular sheath containing small spinules. *Female*: 35.-50. mm. long; shape as in male for front and body; posterior extremity straight, bluntly pointed terminally; vulva at beginning of thick posterior portion of body; ova brown, oval, thick-walled with a colorless shining button-like protuberance at each pole (50.-54. microm. long; 23. microm. broad).

This parasite, commonly known as the "whip-worm" because of the shape (the anterior filiform end suggesting the lash, the posterior thicker part the handle of the whip), is a very common and widely distributed parasite of man, finding its habitat in the large intestine, where the worms are found adhering to the wall by the anterior ends, which are buried a short distance in the tissues of the mucous membrane. It is one of the most common intestinal parasites in this country, although but little attention is given it and few records are to be had. The ova are

FIG. 207.—*Trichiuris trichiura*, natural size: A, male; B, female.

discharged with the fecal matter from the intestine, and in water or moist earth the embryo develops within the shell, but does not escape to free larval life. The thick shell affords considerable protection and the embryo may live for months before destruction, thus incased. Probably with water or food the developed ova are introduced into the intestine of the next host, where in about a month or less the fully matured adult worms will

FIG. 208.—Ovum of *trichiuris trichiura*.

be found. The parasite is of little pathological importance; there are not often more than a dozen present in one host, and apparently they do but little damage and practically never give rise to appreciable symptoms of their presence. Doubtless some little irritation and a very slight loss of blood from the lesions occasioned in the mucous membrane of the cecum and colon may result, but these are not of sufficient gravity to be noted. It is a somewhat difficult worm to dislodge with the ordinary parasitocides, probably yielding more readily to male fern than to other drugs of this class.

Genus: *Trichinella*.***Trichinella Spiralis* (Owen).**(*Trichina spiralis*.)

*Male*: Length, 1.4-1.6 mm.; thickness 0.04 mm.; cylindrical; anterior end tapering, posterior end gradually and slightly thickening and terminating in bifid extremity with two lateral somewhat conical tail appendages; cloacal aperture between these, which form a sort of bursa; back of cloacal aperture two pairs of papillae. *Female*: 3.-4. mm. long; anterior end as in male; posterior end nearly of same thickness to tail, which is rounded; anus terminal; vulva at anterior fifth of body; viviparous. *Larvæ*: when born, 90.-100. microm. in length, obtuse anteriorly, posteriorly prolonged to a pointed tail; when encysted as "muscle trichinæ" the larvæ measure about 1. mm. long and 0.04 mm. in thickness, tapering anteriorly, more thick and obtuse posteriorly, with complete organization as in the adult and showing the characters of the different sexes.

This important parasite in its adult, sexual stage infests for a brief period the intestinal tract of man and a number of animals (mainly mammals), gives origin to a large number of larval worms after which the adults die; the larvæ make their way into the muscles of the same host

FIG. 209.—*Trichinella spiralis*: a, gravid female "intestinal trichina"; E, embryos; G, vulva; Ov, ovary; b, adult male "intestinal trichina"; T, testicles; c, young larva; d, larva in musculature; e, encapsulated larva in muscle. (Braun, after Claus)

and pass an indefinite encysted stage in this situation until transferred to the next host by the ingestion of the infested flesh by the latter. The species was first established by Owen in 1835, from encysted larvæ in the muscles of human anatomical subjects; in 1846 Leidy announced the discovery of the encysted larvæ in pork; but it was not until 1860, mainly through Zenker, that the full relation with the intestinal form and the development of the worm were understood.

Besides in man the worm is commonly found in the hog (domestic and wild), in rats, and in mice; it has also been met in rabbits, guinea-pigs, cow, sheep, horse, dog, cat, fox, martin, badger, bear, raccoon, mole, skunk, hedgehog, hippopotamus, hamster, and in birds as hen, pigeon, and duck. It is most common in man, hog, rat, guinea-pig, and rabbit.

Man commonly acquires trichiniasis by eating infected ham insufficiently cooked. The capsules are digested and the trichinæ set free; they

FIG. 210.—Section of human muscle containing encysted *trichinella spiralis*; parasite and its cyst cut in section, and but a part of the larval worm shown; about upper pole a local fat deposit.

pass into the small intestine and there develop into the sexually mature worms, attaining maturity about the third day; of these the males die after fertilization, while the females adhere to the mucous membrane, or may perforate the intestinal wall and may find their way into the mesentery and lymphatic glands of the mesentery. Each of these gives birth to large numbers of larvæ; the young brood is carried away from the bowel or mesentery in the lymph stream, and is distributed partly through the blood and lymph streams and partly by active migration. Before birth the young trichinæ are from 0.09 to 0.1 mm. (0.0035 to 0.0393 inch) long, growing slightly during migration, say from 0.12 to 0.16 mm. (0.0047 to 0.0063 inch). Their favorite seat of lodgment is the striated muscular tissue, within the striped muscular fasciculus itself, or between the muscular fasciculi and parallel to them. In nine or ten days after infection

the first brood reaches its destination, to be followed by others, since the intestinal trichinæ continue to produce young throughout a life of seven weeks. A single worm, it is said, may bring forth from 8,000 to 10,000.

The young trichinæ begin to be encysted in the muscle about the second or third week after infection, by which time the parasite has grown to 0.8 mm. (0.0314 inch) in length. Each one arranges itself in a spiral, of which the outline is oval, and becomes surrounded by a capsule of corresponding shape, the worm cyst lying with the long axis parallel to the direction of the muscular fibers. The cyst is transparent, 0.4 mm. (0.0157 inch) long, and 0.25 mm. (0.0098 inch) wide. After from five to eight months calcification may even involve the inclosed trichina itself. On the other hand, the capsule may undergo fatty degeneration and calcifications, a pathological change which takes place at times early, at others only after the lapse of years. The encapsulated trichina remains living and capable of development for a long time—according to Damman, in hogs eleven years, while in man they have remained living 25, 27, 30, and 40 years after infection. It has been shown by Zenker that the encysting is not a necessary condition to the mature development of young trichinæ.

Human infection having been conclusively shown to be due to the eating of raw pork infested with trichinæ, it is not at once evident how swine become infected. It is well known that the rats which infest slaughter

houses are infected in large numbers, but it is plain also that they may acquire trichinæ by eating pork. The two probably contribute mutually to the perpetuation of the disease.

As to the distribution of the trichiniasis: most epidemics have been in Germany. Even in America, where there have been two or three epidemics, it has been in German immigrant communities. Apparently it is rather the imperfect cooking of the pork which is responsible, for although a larger percentage of American pork appears to be infected than German, yet, as already stated, the disease is much more infrequent in America than in Germany. It is to be remembered that while thorough cooking effectually destroys the parasites, the requisite heat may fail to reach the interior of large masses of meat containing viable larvæ.

**Symptoms.**—The immigration of numerous active parasites in muscular tissue is followed by intense irritation, manifested at first by fever and muscular pain. The latter is especially severe during motion. The acts of chewing, swallowing, and breathing are particularly difficult, because of the pain excited by these acts. In the early stage of the disease diarrhea is quite common, so that certain epidemics have been mistaken for typhoid fever and as often also for rheumatism. In the very beginning of the immigration into the muscles edema has sometimes been observed. The more general and thorough the invasion, the more intense the symptoms. Very high fever, delirium, infiltration of the lungs, and fatty degeneration of the liver have been observed. Death may take place either from exhaustion as the result of extreme irritation, or later in the disease from the same cause preceded by anemia and gradual loss of strength. Usually, however, improvement sets in about the fourth or fifth week, though convalescence in bad cases is slow, and many weeks elapse before recovery is complete.

**Diagnosis.**—It is usually the unexpectedness of the disease which leads to delay in diagnosis. The resemblance of the symptoms to those of *typhoid fever* and *muscular rheumatism* has been referred to, yet in the presence of a possible cause—as, for example, a German picnic or other feasting occasion where the favorite ham or sausage has formed part of the feast—such symptoms should immediately excite suspicion. The discovery by Thomas R. Brown in 1897<sup>1</sup> that eosinophilia is constantly associated with trichiniasis is important and, when present, is confirmatory of the existence of the disease. A differential blood count should therefore be made in suspected cases. When doubt exists, the harpoon, designed for obtaining samples of muscle for examination, should be unhesitatingly used, under ether or local anesthesia, and the part removed carefully examined under the microscope.

**Treatment.**—Salting of the pork, while causing the death of a few of the encysted larval trichinæ, is insufficient to destroy any large proportion unless prolonged much more than is usually practised; smoking is also lethal to the larvæ, but insufficient to guarantee the death of all; cold storage is of little or no value; but an exposure to heat of 70° C., as should be assured in thorough cooking, is known to be uniformly fatal to any remaining parasites and should render the infested flesh innocuous.

<sup>1</sup> "Johns Hopkins Hospital Bulletin," April, 1897.

However, it must be remembered that heat does not well penetrate to the interior of large masses of meat; and nothing but certainty of the thoroughness of cooking can be relied upon; and imperfectly cooked pork is more apt to be eaten than well cooked when hams are boiled entire.

Here, as so often elsewhere, an "ounce of prevention is worth a pound of cure." Such prevention consists in thorough official inspection of all pork brought to market, because cooking may fail of its purpose for the reasons already mentioned. For a similar reason swine should be grain-fed, rather than allowed to feed on offal. It is doubtful whether any direct measures can be used for arresting the disease after the muscles have once been invaded. It is a simple conflict for the mastery between the strength of the patient and the life of the trichinæ. In the majority of cases the former triumphs, though death is not infrequent from the causes named. If the disease is recognized early, the alimentary canal should be treated with vermicides and purgatives, with a view to getting rid of all the sexually mature worms which may happen to remain there, since it will be remembered that successive broods develop from the same mother-worm while in the intestinal tract. Glycerin, given in a tablespoonful (30 c.c.) dose hourly, is said to destroy the trichinæ. Benzine, in 1 to 2-dram (4 to 8 gm.) doses in capsules, and picric acid in dose of from 5 to 8 grains (0. to 0.5 gm.), are also recommended, but are regarded as less reliable. To relieve the pains, hypodermic injections of morphin, 1/4 grain (0.0165 gm.), or warm baths may be used. Restoratives and stimulants should be given to keep up strength.

Family: STRONGYLIDÆ;

Genus: *Eustrongylus*.

*Eustrongylus gigas* (Rudolphi).

(*Ascaris canis et martis*; *a. visceralis et renalis*; *strongylus gigas*; *s. renalis*; *eustr. visceralis*.)

*Male*: red in color; 14.-40. cm. in length, 4.-6. mm. thick; slightly tapering anteriorly; mouth terminal, with a hexagonal orifice surrounded by six lips bearing papillæ; cuticle thin and transparent, finely striated transversely; about 150 papillæ along the longitudinal lines laterally (best marked near middle of body length); caudal extremity with an oval plate-like expansion serving as a bursa (transverse diameter the longer), its margin bearing small papillæ and slightly indented dorsally and ventrally; single sexual spicule. *Female*: general appearance and head end as in male; 20.-100. cm. in length and 5.-12. mm. thick; caudal extremity obtuse, straight, with anus subterminal; vulva 50.-70. mm. posterior to mouth; single ovarian and uterine tube plicated from near anterior end along the intestine nearly to anus, then returning to vulva near anterior end. Ova brown, ellipsoid, with thick shell marked by external cribriform depressions, 64.-48. microm. long and 40.-44. microm. broad.

This worm, more common in the dog (and also found in other animals as seal, otter, wolf, horse, cow, martin, and skunk), has been recorded a number of times as a parasite of man, although in most cases with some reservation as to the correctness of diagnosis. It is the largest of the nematodes and has its habitat in the pelvis of the kidney, where one or several of the parasites may exist. It has been known, too, to be free in the abdominal cavity, and is said to have in rare instances been found in the liver and in the pleural cavity (in lower animals). Little is known of its life-history. At the time of oviposition the interior of the ova

is segmented. Passed with the urine into water or moist earth outside the host, a larval worm develops in the course of five or six months in winter and probably much more rapidly in summer; this remains for a long time living within the shell, apparently several years. If removed experimentally from the ovum it soon dies in pure water, but may be kept alive for a longer time in albuminous fluids. As yet no successful transference of the larval worm has been accomplished experimentally, and in consequence it is thought that in nature it passes to some intermediate host, possibly some fish.

In its usual habitat the worm causes considerable dilatation of the renal pelvis, and sometimes the whole kidney becomes reduced to a thin hydronephrotic sac, in which in the midst of a red and bloody urinous

FIG. 211.—*Eustrongylus gigas*: female, natural size, in kidney of dog. (Railliet.)

fluid the parasites are found. In man the worm has not been recognized antemortem, having only accidentally been observed in autopsies; and this is also usual in case of infestation of the lower animals. However, in the dog the urine often becomes notably bloody, the animal sometimes whines as if in pain, the gait becomes tremulous, the bark altered, the animal becoming depressed and showing nervous symptoms which have been confused with those of rabies. The diagnosis must, of course, rest upon the discovery of the characteristic ova in the urine; and the only treatment, should a safe conclusion as to the presence of the worm in one or other renal pelvis be arrived at, would rest with the enucleation of the worm or of the entire kidney by surgical procedure. Thus far but one kidney has been found infested in a single host, although, of course, care should be exercised to exclude the possibility of a bilateral infestation.

Genus: *Strongylus*.

1—*Strongylus apri* (Gmelin): (*gordius pulmonalis apri*; *ascaris apri*; *strongylus suis*; *s. paradoxus*; *s. elongatus*; *s. longevaginatus*; *metastrongylus paradoxus*):

*Male*: 12.-25. mm. long, cylindrical; white to brownish; mouth terminal, with six lips, two lateral the largest; copulatory bursa bilobed, with five muscular rays in each lobe; two spicules, 4. mm. long, slender. *Female*: up to 50. mm. long; posterior end terminated by a mucronate, ventrally curved tail; anus subterminal; vulva close in front of anus. Ova within uterus elliptical, 50.-100. microm. long, 39.-72 microm. broad; embryo developed at oviposition; and larvæ quickly escape within the mucus of bronchial tubes infested, 220.-350. microm. long and 10.-12. microm. thick.

This worm is comparatively common in the bronchial tubes of the hog in this

FIG. 212.—*Eustrongylus gigas*: male, natural size. (Braun, after Railliet.)

FIG. 213.—Ova of *eustrongylus gigas*:  $\times 250$ . (Braun after Railliet.)

FIG. 214.—*Strongylus apri*: A, tail of female, enlarged; B, tail of male, showing bursa and sexual spicules; C, male (left), and female (right), in natural size. (Braun, after Railliet.)

country as well as in Europe; it has also been recorded from Japan. Large numbers of the worms exist commonly in the single host and the presence of these adults together with many larval worms are in the hog apt to set up a troublesome bronchitis and bronchopneumonia which may be fatal, at least to young hogs. The cases recorded in man have occasioned the same type of lesions and symptoms; their identification with this species being probable but not absolutely certain.

2—*Trichostrongylus instabilis* (Railliet): In 1895 Loos described under this name certain very small examples found by him by microscopic examination of the intestinal contents at autopsy of natives of the Egyptian lowlands. Later he found

the same worm in the intestinal contents of a camel; and a worm regarded as identical has been encountered in a Japanese by Ogata. The following description is given by Loos: *Male*: 4.-5. mm. long, thickest near posterior end (0.07 mm.); anteriorly tapering and at head end measuring in thickness only 9. microm.; esophagus occupies about one-sixth of body length; two single-cell esophageal glands on dorsal side of esophagus, one back of the other; copulatory bursa two-lobed, with asymmetrical muscular rays; two spicules; cuticle thin, finely striated transversely; excretory pore 0.19 mm. from anterior end. *Female*: 5.6-7. mm. long; greatest body thickness about posterior third (0.09 mm.); anteriorly tapering to a thickness of 10. microm. at head; posterior end with a rapidly tapering and pointed tail; anus 0.097 mm. anterior to tail; vulva at level of posterior fifth of body length; double uterus and ovarian tube. Ova thin-walled, oval, highly granular interiorly, measure 63. : 41 microm.

Loos does not regard the parasite as of pathological significance because of the small size of the mouth, the usually small number of parasites present, and the small size of the parasites. Ijima, reporting Ogata's case, questions whether the worms, in this instance found to the number of about two hundred, may not, however, have had some harmful influence.

Genus: *Uncinaria*.

*Uncinaria duodenalis* (Dubini).

(*Anchylostoma duodenale*; *strongylus quadridentatus*; *dochmius anchylostomum*; *sclerostoma duodenale*; *strongylus duodenalis*; *dochmius duodenalis*; European or old-world hook-worm).

*Male*: whitish or blotched posteriorly with brownish, when intestine contains blood; 8.-10. mm. long; cuticle finely striated transversely; tapering to a blunt point anteriorly and with head curved upon dorsum so as to give a slightly hooked anterior end; on each side of median line on ventral side of oral border two hook-like chitinous teeth and on dorsal border on each side of median line one less curved chitinous tooth; with a dorsal conical tooth extending along back of oral cavity from base of cavity; in oral cavity about esophageal opening a delicate armature consisting of two dorsal and two ventral lancet-like pieces; posteriorly the body ends in an

FIG. 215.—Ova of *uncinaria duodenalis*.

FIG. 216.—Anterior end, showing mouth parts of *uncinaria duodenalis* (dorsal view).

FIG. 217.—Tail, with expanded bursa, of male *uncinaria duodenalis*.

abruptly pointed tail in a copulatory bursal expansion of the cuticle, this having one dorsal and two lateral lobes; in folds of bursa one dorsal subdivided muscular ray each division ending tridigitately, and on each side symmetrically an undivided dorso-lateral, a divided lateral, undivided latero-ventral, subdivided ventral and undivided small subventral muscular rays; cloacal aperture superterminal; two equal spicules. *Female*: General appearance and anteriorly like male; 12.-18. mm. long; posteriorly tapering to a finely pointed tail; anus subterminal; vulva about posterior third of body length; two uterine and ovarian tubes. Ova: colorless, elliptical, thin-shelled, 50.-60. : 39. microm.

This important parasite of man has a wide distribution in tropical and subtropical countries, but probably properly belongs to such localities in the older hemisphere as southern Europe (especially Italy, Switzerland, and Austria), the Mediterranean borders of Africa, southern Asia, and the eastern archipelago. It is found also in the tropical and subtropical regions of America, but here has been much confused with the American species of hook-worm recently recognized as a separate species. As im-

ported cases, perhaps occasionally giving rise to small endemic foci, it has been met in the cooler parts of the United States.

Its habitat is in the duodenum, jejunum, and upper part of the ileum of man, where it is found in numbers varying from a few to considerably more than a thousand. With its strong armature it attaches itself to the intestinal mucous membrane producing a small excavation, and thus fixed, sucks the nutrient juices, lymph and blood, from the mucosa. Through the agency of certain glands situated in the anterior end the worm produces a substance inhibiting blood coagulation; and thus from the tiny lesions produced by the worm, which are frequently forsaken for fresh situations, considerable bloody oozing takes place. From this factor, as well probably from nutritive faults following upon the intestinal disturbances induced and perhaps also from some undiscovered toxic influences, there results a loss of bodily weight and strength and an anemia which in its severer forms ranks among the pernicious anemias. Fatal cases are not infrequent. When from the first but few parasites are present there may be practically no symptoms appreciated (unless the parasites are but a complication of other serious disturbance as malaria, the anemic results of which they are likely to accentuate, or unless the host be quite young or a weakling). In severer grades of infestation, discomfort and actual pain in the abdomen, nausea, altered appetite (often *kakophagism*), and alternating diarrhea and constipation are apt to be noted. In course of time flesh and strength are lost, the patient becomes dull and slothful; the young do not develop with the usual vigor; and an anemia of varying grade comes to be appreciated (miner's anemia, tunnel anemia, etc.). This latter may be profound in loss and change of the red cells, is apt to show in its typical appearance some increase in the eosinophilic leukocytes, and a comparatively low hemoglobin proportion. With the severer anemia, and probably largely secondary to this, arise wide-spread degenerations, mainly fatty in type, involving almost any of the body structures, but especially noteworthy in the important parenchymatous structures as the wall of the heart, the liver, and kidneys. These in turn give further manifestations of disease; the urine becomes albuminous, the circulation becomes feeble, and a cachectic type of dropsy is apt to develop; and eventually, if no relief be afforded, the patient may die, as in any severe anemia, from exhaustion, intercurrent affection, or, perhaps, accidental terminal hemorrhage. The course of the case is apt to be a prolonged one, the parasites often persisting in the host for years.

The affection, known as *uncinariasis* or *anchylostomiasis*, is readily recognized from the general picture and the discovery of the ova of the worms in the stool, these being very numerous in the dejecta from subjects of even moderate infestation. They are readily determined by means of the ordinary laboratory powers of the microscope in thin layers of fecal matter, diluted if needed with a drop of water.

Of the life-history of the parasite it is known that the larvæ escape from the ova within from 24 to 48 hours at a temperature of 25° C. or therabouts in the fecal matter, in moist soil or in dirty water. The incubation goes on best in fair access to air, and therefore the most favorable situation is in moist sandy soil. When first emerged the larva measures

about 0.2 mm. in length, is obtuse anteriorly, and posteriorly tapers to a finely pointed tail and shows a rhabditiform type of esophagus. In 48-72 hours a moulting occurs, the larva having grown in size, but preserving its structural features unchanged; a second moulting follows about the fifth day, the larva remaining, however, in the old cuticle (so-called "encystment") and assuming the adult type of esophagus. In this encysted stage it is still motile and now lives well in water or moist soil for several months, eventually dying or gaining access to a fresh host. From actual personal experience and from experimentation on man and dogs, Loos has established the fact that at this stage the parasite may pass into the human host by penetration of the skin. Should the moisture containing these larvæ come in contact with the skin, as about the feet of persons walking barefooted on the wet and infested sand, or wading in infested water, the larval worms attack the exposed surface, rapidly penetrating the skin and leaving their mantles (old cuticle) behind. In so doing, if there be many of the larvæ entering, considerable irritation and consequent mild inflammation may be induced. It is supposed that this feature is the origin of certain inflammatory skin affections common in tropical regions and known as "ground itch," "water itch" and by other local terms; probably only a portion of cases of such affections depends upon this cause, as there are doubtless many other possible irritants which may act in a similar manner, and, moreover, it is probable that much of the inflammatory mischief is caused and prolonged in these cases by bacteria of one or other sort conveyed by the larval worms to the subcutaneous tissues. From the position of entrance into the skin the larvæ make their way, probably largely by passive convection by the blood and lymph, to the lungs. Here they penetrate to the air-passages, where it is thought they undergo another ecdysis, or moulting. They are still minute; are supposed to be carried by the bronchial mucus upward to the mouth and then to be swallowed, thus gaining their proper habitat and growing into adult size and sexual ability in the upper part of the intestine.

While this mode of infestation may be regarded as established, the older belief that the encysted larvæ are transmitted to the host by direct ingestion in dirty water or on unclean vegetables, or in dirt (in kakophagism), etc., cannot be as yet excluded, and must be kept in mind in considerations as to prophylaxis.

Genus: *Necator*.

*Necator Americanus* (Stiles).

(*Uncinaria americana*; *anchylostoma americanum*.)

*Male*: differs from *uncinaria duodenalis* in being of smaller size (6.-9. mm. long and more slender than *u. duodenalis*), in the smaller size and more conical shape of the head, in having no hooklets on the oral rim, but instead on each side a large ventral and smaller dorsal chitinous lip extending from the rim toward the median line; in a greater prominence and projection into the oral cavity of the dorsal conical tooth; in the smaller size of the copulatory bursa, its dorsal lobe being subdivided and the ventral margin being extended so as to form an indefinite ventral lobe and showing the dorsal muscular ray of the bursa divided, each division ending in a bipartite tip. *Female*: differs from *u. duodenalis* in being shorter and more slender (8.-15. mm. long), with similar differences of the anterior end as above outlined for male; vulva just in front of the middle of body length instead of at posterior third, as in *u. duodenalis*. Ova somewhat larger than those of *u. duodenalis* (68.-70. : 38.-40. microm.), but otherwise similar.

*Necator americanus*, originally established as a species of *uncinaria* by Stiles, but subsequently determined as generically distinct and given the name now used, is found especially in tropical and subtropical America, and in the West Indian islands; and prior to 1902, when the species was established, was probably often confused with *uncinaria duodenalis*. The latter is also met in imported instances and has been encountered not infrequently either alone or in association with the American form; but is scarcely to be regarded as properly an American parasite, especially since it is almost certain that many of the records of its occurrence in America are based by mistake upon *necator americanus*. The two worms are analogous in their influences and the term *uncinariasis* is usually employed to indicate the state of infestation

FIG. 218.—Ova of *necator americanus*.

FIG. 219.—Anterior end, showing mouth parts, of *necator americanus* (dorsal view).

FIG. 220.—Tail, with expanded bursa, of male *necator americanus*.

by *necator americanus* or *uncinaria duodenalis* more or less indifferently. The worm in question is very common in our own Southern States, where it is apparently responsible for a group of anemic conditions in the inefficient, undernourished, pallid, and complaining classes of population known by various contemptuous terms in different localities, as "poor white trash," "crackers," "sand-lickers," "dirt-eaters," etc. The conditions produced by the American hook-worm are comparable to those caused by the old-world form, but are probably less intense for a given degree of infection in the individual host. The affection in this country has long been popularly known as dirt-eaters' disease, sand-lappers' disease, mountain anemia, etc.

**Treatment of Uncinariasis.**—For the expulsion of the parasites, thymol is perhaps the most efficient remedy. It is given in large doses of the undissolved drug with precautions as below indicated, reliance being had upon its slow and partial solution in the intestine in close contact with the parasites, thus directly influencing the latter, but not being sufficiently dissolved to afford ease of serious absorption and intoxication of the host. The patient is prepared the day prior to the administration by a mild catharsis and by taking but a light evening meal or none. The following morning thymol is given in capsule or cachet, in three doses an hour apart of 0.6–2. g. (9–30. grains) each, making from 1.8 to 6. grams in all. During the period in which the drug is in the alimentary canal oils, alcoholics, and other solvents of thymol are withheld to prevent massive solution and absorption of the substance. Within an hour after

the last dose, if free purgation has not meanwhile taken place, a purgative (an ordinary saline) is administered; and the stools are to be closely examined for the discharged worms. In the course of a week or ten days, if examination of the dejecta continue to show the presence of ova, the above procedure may be repeated. Sometimes mental wandering, dizziness, and faintness appear as toxic symptoms from absorption of thymol, but usually rest in bed, a little weak coffee, and a small amount of hot bouillon after purgation has begun allay these symptoms. Male fern is strongly recommended by a number of European writers for the old-world hook-worm; but the writer's experience with the American form would indicate the greater efficiency of thymol. Filmaron, the non-toxic active principle of filix mas, has been recommended by Nagel.

As measures of prophylaxis there should be recommended the use of only boiled or well-filtered water for drinking purposes, thorough cleanliness of all vegetable food which has been grown in suspicious soils and which is eaten uncooked, together with refraining from going barefooted and wading in dirty water or mud in infested districts. The drainage of soils contaminated by the dejecta of infected persons, together with its exposure to the sun by plowing, should also be considered; and the stools of infested persons should be disinfected before disposal.

Genus: *Physaloptera*.

*Physaloptera caucasica*: v. Linstow has described under this name a worm obtained from the human intestine and submitted to him from the collection of the Imperial Academy of Sciences in St. Petersburg. As far as is known, the specimens were all obtained from a single individual. *Male*: 14.2 mm. long, 0.71 mm. thick; cuticle smooth, swollen into a prominent ring which incloses the mouth; latter with two lateral lips which in the submedian lines bear four small papillæ; two slender teeth at oral orifice; posterior end tapering to a blunt-pointed tail provided with a bursa formed by lateral alar expansions of the cuticle, this bursa being large and rounded anteriorly, but narrowing posteriorly so as to give the tail somewhat of the shape of an arrow; four pairs of petiolated papillæ on each side supporting the bursa, two sessile papillæ in front of cloacal aperture and four in two rows back of aperture, and six in the tail; spicules unequal. *Female*: 27. mm. long, 1.14 mm. thick; anteriorly and general appearance as in male; tail rounded; vulva at anterior sixth of body length; ova thick-shelled; measure 57. : 39. microm.

Family: ASCARIDÆ;

Genus: *Ascaris*.

1—*Ascaris lumbricoides* (Leuckart).

(Maw-worm; common round worm of children.)

*Male*: whitish to reddish-yellow; 15.-17. cm. long, 3.-3.5 mm. thick; elongate, fusiform; cuticle finely ringed; oral orifice terminal, with three lips (one dorsal and the other two meeting in median ventral line), each with fine denticulations on margins; at base of superior lip two papillæ, one only at base of other two lips; posterior end terminating conically, curved ventrally, with two slightly curved, short, equal spicules projecting from subventral cloaca; 70.-75. papillæ on ventral face of posterior end, of which seven pairs are postanal. *Female*: 20.-25. cm. long, 5.-5.5 mm. thick; anterior end and general appearance as in male; posterior end tapering, ending in conical, pointed, straight tail; vulva at level of first third of body length (in a slightly depressed annular band); anus subterminal. Ova ellipsoidal, 50.-75. microm. long and 40.-58. microm. broad; thick-shelled; stained yellowish from fecal matter when found in dejecta, but colorless in uterus; covered with a mammilated albuminous envelope.

FIG. 221.—Anterior extremity of *ascaris lumbricoides*: A, seen from front; B, seen from dorsal surface. (Railliet.)

This worm has a world-wide distribution, its habitat being in the small intestine of man. It is more common in the young, but may occur in persons of any age. The number in a single host is usually small, two to six or eight, but in rare instances there have been reported some hundreds from one individual; and Cruveilhier found in the small intestine of a young idiot girl great masses of the worms, the number of which he estimated at about one thousand.

The presence of but a few of the parasites may pass unnoticed; but even where the parasites are but few there may result in children severe nervous disturbances, either reflex from intestinal irritation or possibly from absorption of some toxic material elaborated by the worms or generated in the intestine in their presence, as epileptiform attacks, cerebral congestion and headache, vertigo, chorea, ocular disturbances, or manifold hysterical manifestations. Capricious appetite, nausea, indefinite abdominal pains, symptoms of maldigestion, restless sleep are often complained of; occasionally swelling and congestion of the lachrymal papillæ, undue lachrymation, itching about the eyes, itching and swelling of the fingers are encountered. The worms possess active motility and not infrequently wander from their proper habitat, either up or down the canal and perhaps into some of the collateral passages. Thus, the writer some years since met an instance in which an adult ascaris was found in the cavity of a periappendiceal abscess, the worm having penetrated the appendix and escaped through a perforation in its distal end into the abscess cavity, having probably had much to do with the appendicitis and perforation of the wall. Not infrequently they wander to the rectum and spontaneously pass from the anus. They have been found in the biliary duct, producing obstructive jaundice; in the pancreatic duct; in the stomach, whence they are commonly expelled by vomiting excited by their presence and movements. A specimen was formerly in the collection of the University of Pennsylvania, in which the worm, having been thus carried from the stomach to the pharynx, had been retracted into the larynx in

FIG. 222.—*Ascaris lumbricoides*: to left, male in lateral aspect; to right, female, ventral aspect, natural size. (Railliet.)

the deep inspiration following the retching, obstructing the lumen and causing the death of the child. Bunches of these worms have been known to cause intestinal obstruction; and occasionally at such positions of

obstruction perforation of the wall has taken place and the parasites have been found in the abdominal cavity.

The ordinary life-history is about as follows: The ovum, after discharge in the fecal matter, slowly develops in water or moist earth, the larval worm being retained within the shell and preserved for months from destruction by the resistant shell; it is transferred directly to the alimentary canal of the next host with unclean water or food, there quickly freed from its wall by the action of the digestive juices, and developing to adult stage in the course of about five weeks.

The recognition of the presence of these parasites, while perhaps suggested by the presence of the more common symptoms above indicated, is only established by the discovery in the stools of the host of the ova or by the recognized passage of one or more worms.

FIG. 223.—*A*, Ovum of *ascaris texana* drawn from specimen in uterus; *B*, ovum of *ascaris lumbricoides* drawn for comparison from examples taken from uterus of formaldehyd specimen.

**Treatment.**—The remedy which has been most satisfactory in my hands is santonin in combination with calomel. Powders containing santonin and calomel, of each 1 or 2 grains (0.066 to 0.132 gm.), may be prescribed rubbed up with sugar of milk. One is given night and morning until the bowels are freely moved. The santonin may color the urine and produce yellow vision, or xanthopsia, but I have never seen harmful results in a large experience, though poisoning, manifested by convulsion, is said to have been produced. For very young children the dose may be reduced to  $\frac{1}{4}$  to  $\frac{1}{2}$  grain (0.0165 to 0.033 gm.). The worm tablets extensively advertised usually contain santonin as their basis. There is an official troche, U. S. P., containing  $\frac{1}{2}$  grain (0.033 gm.) of santonin. Santonica, or Levant wormseed, whence santonin is derived, is no longer used. What is known as wormseed oil, the oil of chenopodium, another excellent remedy for round worm, is derived from the *chenopodium anthelminticum*, or American wormseed. The

dose is 10 minims (0.65 c.c.) to a child of five years, on a lump of sugar or in emulsion—before breakfast, dinner, and supper for two days—followed by a purge, of which none is more suitable for children than calomel, itself a vermicide.

FIG. 224.—Lips of *ascaris texana* (camera lucida drawing from compressed specimen): *a*, superior lip; *b*, inferior lips, the left overlying the right; *c*, pulpa; *d*, denticulate anterior margin of superior and right inferior lips; *e*, keel of superior lip on inner surface; *f*, interlabium.

The prophylactic measures are principally the careful filtration or boiling of all water used for drinking purposes, and thorough cleanliness of all uncooked food.

FIG. 225.—*Ascaris canis*: A, male; B, female; C, anterior extremity, enlarged and shown from dorsum to exhibit the lateral wing-like cuticular expansions, D, same showing in profile. (Railliet.)

2—Leuckart in 1876 gave the name *ascaris maritima* to a single undeveloped female ascaris obtained some years before by Paff from the vomit of a child in the northern part of Greenland. It has not since been observed and Railliet suggests its relation with *ascaris transfuga* of the brown bear. The specimen was 43. mm. in length, 1 mm. thick, with but poorly developed lips, a crest-like expansion of the cuticle at the anterior end; posterior end drawn into a fine point.

3—*Ascaris texana*: In 1904 Smith and Goeth described under this name an ascaris obtained from the dejecta of a man in San Antonio, Texas. Two females, badly preserved, alone constituted the material for study. The man had passed numbers of the parasites over a period of some years, had had no pathological consequences as far as known from their presence, but had been unable after many attempts with vermifuges to rid himself of the worms. The specimens measured 50.-60. mm. in length, 1.-1.5 mm. in thickness; colorless to slightly yellowish; tapering gradually to anterior end; mouth terminal; superior lip the largest, margins of lips denticulate; interlabia present; no cuticular expansion at either end; posterior end conical ending in a mucronate tail slightly curved dorsally; anus subterminal; papillæ at posterior end present, but indeterminate in material examined; vulva not surely located, but apparently 20. mm. back of oral lips; ova within uterus colorless, oval, 60. : 40. microm., with thick wall without external envelope or markings, segmented in uterus.

The species is as yet doubtful, until male specimens and other fresh material is obtained for further study; but probably the worm is but an accidental parasite of man, being seemingly most closely allied to known species parasitic in birds and reptiles.

4—*Ascaris canis* (*lumbricus canis*; *ascaris teres*; *a. caniculæ*; *a. cati*; *a. canis et felis*; *a. tricuspidata*; *a. felis*; *a. werneri*; *a. marginata*; *a. mystax*; *a. alata*; *fusaria mystax*): This worm, the common round worm of dogs and cats, has occasionally been encountered as a parasite of the intestine of man, in Germany, England, Denmark, and in this country. *Male*: whitish or slightly brownish; 40.-60. mm. long. 1. mm. thick; anterior end usually curved, with lateral cuticular expansions making the end look somewhat arrow-like; mouth terminal, with three nearly equal lips with denticulate margins; at base of superior lip two papillæ, on inferior lips one ordinary and two minute papillæ; posterior end curled and with lateral cuticular alar expansions, and on each side of cloacal aperture 26 papillæ of which five are post-anal. *Female*: 120.-180. mm. long; anterior end and general appearance as in male; posterior end straight, terminating obtusely; vulva at anterior fourth of body length; anus subterminal. Ova almost spherical; 68.-72. microm.; thin-shelled; with thin albuminous envelope showing an alveolated surface.

The general life-history and effects of this parasite are similar to those outlined for *ascaris lumbricoides*.

#### Genus: *Oxyuris*.

#### *Oxyuris vermicularis* (Leuckart).

(*Ascaris vermicularis*; *fusaria vermicularis*; pin-worm; thread-worm; seat-worm.)

*Male*: whitish; 3.-5. mm. long, 0.3-0.4 mm. thick; cuticle transversely striated and at head end showing a vesicular swelling along the dorsal and ventral median lines; lateral lines distinct; mouth terminal, with three retractile lips; esophagus with distinct bulb; posterior end conical, curved ventrally, with six pairs of papillæ and slight cuticular expansion on each side; one spicule hooked at free end. *Female*: 10. mm. long, 0.6 mm. thick; anterior end and general appearance as in male; posterior end straight; extended to a long mucronate tail; anus 2. mm. in front of tail; vulva at anterior third of body length. Ova oval, flattened on one side, 50.: 16.-20. microm.; thin-shelled; colorless with embryo developed at oviposition.

This worm is an extremely common parasite of man, of practically world-wide occurrence, having its proper habitat in the lower end of the ileum and the cecum. It is especially frequent in children, but is also found in individuals of any age. The worms usually are in large numbers in the individual host; and are possessed of considerable activity, wandering from their natural habitat so that occasionally they are found in the upper end of the small intestine and have been known to get into the stomach and be vomited, but more commonly passing downward to the rectum, and spontaneously crawling from the anus. They are not as apt to be found in errant positions as *ascaris lumbricoides*, but in this respect much that has been said of the latter is true also of the present type. A specimen recently brought into the pathological laboratory of the University of Pennsylvania shows in a catarrhal appendix large numbers of the parasites. It was long thought that the entire evolution of the worm from the ovum to adult stage takes place in the original host, and Vix has actually

seen the larval worms after emergence from the egg in the rectal mucus; but that this takes place, save exceptionally, is no longer held. It is believed that the ova with the developed embryos within are scattered after defecation over vegetables and fruit, being strongly resistant for some time at least to the effects of drying; or they may become adherent to the nails and fingers of the host when the latter, because of the intolerable itching about the anus, scratches himself.

It is thought possible, too, that they may be transferred from the fecal mass to food-stuffs by flies. Ingested with foods they are directly swallowed. Upon the hands of one host they may readily be transferred to the hands of a second human being and thus endanger the latter. From the fingers they may be transferred to the mouth, or perhaps, may be carried into the nose, when the habit of nose-picking exists; and in the nasal mucus the larvæ may emerge from the shell and later be swallowed. It is not likely that they are transferred by water, soon dying in the latter fluid. If the eggs have been swallowed, the larvæ probably emerge from the shells in the stomach and upper intestine. Here they undergo several moults before maturation, copulate, and the females become gravid. The males after copulation apparently soon die and are carried off in the intestinal contents, explaining the comparative rarity of the latter among samples obtained. The females in their wanderings lodge for the most part about the ileo-cecal region, where most of the ova are deposited; but are apt to continue moving slowly along the gut to the rectum, continuing to deposit their eggs. Their duration in the intestine is apparently at least some months; and the common persistence of parasitism in spite of treatment argues for the ease and frequency of self-infection by the host.

FIG. 226.—*Oxyuris vermicularis*: to the left, female; to right, male (considerably enlarged). A, anus; O, mouth; v, vulva. (Braun, after Claus.)

When in small numbers but little disturbance is ordinarily occasioned, but nervous symptoms, much as outlined in connection with *ascaris lumbricoides*,

may be induced. The greatest common inconvenience is occasioned by their movements and the irritation of the mucous membrane of the rectum, inducing a proctitis and troublesome pruritus. Sometimes, especially at night, the worms spontaneously escape from the anus and may be found in the bedclothes; or they have been known to crawl into the genital canal of females, where they may set up a vaginal catarrh and by the itching occasioned lead children to take up the habit of masturbation.

**Treatment.**—Some perseverance is commonly necessary to get rid of the thread-worm. I usually prescribe the same powder of santolin

FIG. 228.—Parasitic bodies, ova and larva met in human feces; color approximate only.

and calomel as for the round worm—*i. e.*, from 1 to 2 grains (0.066 to 0.132 gm.) of each—but at the same time order nightly injections into the rectum of vermicides, of which there are many—the infusion of quassia, of aloes, lime-water, vinegar, corrosive sublimate (1 to 5000), salt and water. The injection should be retained for some time, and to this end the buttocks should be raised, or the child may be placed on its hands and knees. Only as much should be introduced—from 2 to 4 ounces (60 to 120 c.c.)—as can be conveniently retained. Too large a quantity is promptly rejected.

Stools from infested individuals require to be disinfected before disposition; the anal region, especially in children, should be well washed after every defecation; and under no circumstances should the infested person be permitted to scratch about the anus lest the ova of the pin-worms become adherent to the nails, and through careless and uncleanly habit be transferred to the nose or mouth. Cleanliness and prevention of self-infestation, if persevered in will eventually be followed by the natural death and disappearance of the parasites; it is safe to say in all cases of very protracted presence of these pin-worms that in some way these essentials have not been fully maintained.

### III—ARTHROPODA.

Arthropods are bilaterally symmetrical, segmented animals whose segments do not correspond, but vary in their structure, and which primitively bear upon each segment a pair of jointed appendages. The segments are often more or less fused, thus forming special body-regions (head, thorax, and abdomen) which may themselves be more or less fused together as well. The covering of these animals is a comparatively thick and strong cuticle which remains pliable between the segments of the body and of the jointed appendages, but which commonly becomes hard and shell-like from chitinous or calcareous material directly over the different body segments and internodes of the jointed appendages. This arrangement requires that in the growth of the individual the firm external covering should from time to time be shed, such changes taking place periodically and being known as moults. While each segment in the primitive animal is provided with a pair of jointed appendages, these in the individual species are often lost from this or that part of the body, or may remain rudimentary and inconspicuous, or may take on special features of structure from the assumption of special function which causes their wide departure from the original and common type used for locomotion. They are usually best preserved for the latter purpose in the thoracic region; in the other parts of the body various types are developed. Thus they may serve as sensory organs, as in the palpi; for respiration as branchiæ; for mastication or other oral purposes as the mandibles and maxillæ; for sexual purposes as the ovipositors, etc. The arthropods commonly reproduce by ovulation, the development of the embryo to the adult often showing more or less complicated metamorphoses. The general organization, while presenting broad analogies in the different types, has a wide range of variation, many forms exhibiting high and complex structure in their different systems to adapt them for

the special environments of their lives; and can scarcely find place in a work of the limitations of the present volume. The entire group includes the largest number of known types of animal existence, the greater portion being free-living, existing in water or air-breathing, a comparatively small proportion being of importance from their parasitic character. Five classes are recognized: *Crustacea*, *Protracheata*, *Arachnoidea*, *Myriapoda*, and *Insecta*. While a large number are of medical interest because the individual species may serve as intermediate host or transmitter of definite animal or vegetable parasites, the true parasitic forms thus far met in man are limited to the Arachnoids and the Insects.

#### A—ARACHNOIDEA.

Among a number of arachnoids of more or less importance as parasites of man, either transitorily or permanently, the following species may be selected for brief mention.

##### Order: ACARINA (MITES, TICKS).

1. *Sarcoptes* or *acarus scabiei*—the itch insect. This is the most frequently met of the arachnide parasites. Its oval, nearly circular little body, provided with horns and bristles, is barely visible to the naked eye under favorable circumstances, the male being from 0.2 to 0.3 mm. (0.0078 to

FIG. 229.—*Acarus scabiei*: A, female, dorsal view; B, portion of human epidermis, showing burrows with contained ova and young acarians. (Gould, after Leuckart.)

0.00118 inch) by 0.145 to 0.19 mm. (0.0057 to 0.0074 inch); the female, from 0.33 to 0.45 mm. (0.0129 to 0.0177 inch) by 0.25 to 0.35 mm. (0.0098 to 0.0137 inch).

The female lies at the end of a burrow in the epidermis, in situations where the skin is most delicate, as between the fingers, at the elbows, and under the knees, in the groin, and on the penis, very seldom in the face, but in any delicate part. In this burrow, some millimeters to a centimeter long, the female deposits her eggs. The male is seldom seen, dying after copulation, and the female after depositing her eggs. The eggs hatch in from four to eight days, and in about 14 days the larvæ are sufficiently matured to make their own burrows. The disease is communicated by personal contact or by clothing.

**Symptoms.**—These are first an intense itching which incites to scratching, which, in turn, causes excoriations, papules, vesicles, and pustules.

**Diagnosis.**—The diagnostic feature is the shining little vesicle readily recognized by a moderate magnifier in the webs of the fingers, though it is often obscured and obliterated by the eruption and marks caused by scratching.

FIG. 230.—*Demodex folliculorum*: from dog, enlarged. (Braun, after Mèguin.)

**Treatment.**—This is very simple. Sulphur ointment is a prompt specific. The body should be first bathed thoroughly with soft soap, and then as thoroughly anointed with the ointment, which should be allowed to remain until the next day, when there should be another bath, followed by another vigorous application of the ointment. Three or four days of this treatment should suffice. An ointment of naphthol, one dram to the ounce (4 gm. to 30 gm.) is recommended.

2. *Demodex folliculorum*, a minute parasite from 0.3 to 0.4 mm. (0.0118 to 0.0157 inch) long, which resides in the sebaceous follicles, with the grease of which it can sometimes be squeezed out. It is oftenest met on the face and nose. It is said to be present in about 50 per cent. of persons, but this is probably exaggerated. It usually gives rise to no symptoms, but is said sometimes to be the cause of obstruction of the follicles and produces thus the little worm-like accumulations of fat which may be squeezed out of the follicles, and which cause inflammation and acne.

**Treatment.**—Acne is well treated by a lotion of corrosive sublimate, 2 to 1000, and it may be by its effect on the demodex that it is useful.

3. *Leptus autumnalis*, or harvest bug, is a minute red parasite, from 0.3 to 0.5 mm. (0.0118 to 0.0196 inch) long, which has three pairs of legs, with rows of bristles upon its back and belly. It prevails in summer on grasses and plants, attaches itself to the skin of man and animals by its hooklets, and gives rise to irritation.

**Treatment.**—It is successfully destroyed by sulphur ointment and corrosive sublimate, 2 to 1000.

Order: LINGUATULIDA (PENTASTOMES).

The pentastomes include the *pentastomum tænioides*, or *linguacula rhinaria*, and the *pentastomum constrictum*, or *porcephalus constrictus*.

FIG. 231.—*Leptus autumnalis*: enlarged. (Braun.)

1. The *pentastomum tænioides* is a lancet-shaped worm-like animal, already described in connection with parasites of the liver. The male, white in color, is 18 to 20 mm. (0.72 to 0.8 inch) long, 3 to 4 mm. (0.12 to 0.16 inch) wide in the anterior part and 0.5 mm. (0.02 inch) in the posterior part. The female is 8 to 13 mm. (0.32 to 0.52 inch) long, anteriorly 8 to 10 mm. (0.32 to 0.4 inch) wide and posteriorly 2 mm. (0.08 inch) and yel-

low in color. The adult infests the frontal sinuses and nostrils of the dog, more rarely of the horse, and has been found in the nostrils of man.

2. The *pentastomum constrictum* has as yet been met only in the larval state. It is milk-white in color, with golden-yellow hooklets, 13 mm. (0.5118 inch) long and 2.2 mm. (0.0866 inch) wide, provided with 23 rings. It has been found by Pruner encysted in the liver of two negroes in Cairo, by Bilharz in two instances encysted in the liver and mucosa of the bowel, and by Aitken in the liver and lungs of an English soldier in the West Indies.

### B—INSECTA.

In this enormous class, too, a small proportion, embracing, however, a large number of individual species, are of interest as parasites either temporarily at some period in their existence or permanently. Moreover, many are important as conveyers of one or other type of parasitic or infectious disease in man and the higher animals. Of the parasitic forms brief mention may here be permitted the follow-

FIG. 232.—*Linguatula rhinaria* (*pentastomum tanioides*): female, natural size. (Braun.)

FIG. 233.—*Linguatula rhinaria* (*pentastomum tanioides*); larva, enlarged. (Braun, after Leuckart.)

### Order: HEMIPTERA.

#### Family: *Pediculidæ* (Lice).

1. The *pediculus capitis*, or head-louse. The male is from 1 to 1.5 mm. (0.0393 to 0.059 inch) long, the female from 1.8 to 2 mm. (0.0708 to 0.0757 inch) long. The color varies somewhat with the races. In the white it is gray with a dark border, in the negro and Chinamen darker. Its eggs are 0.6 mm. (0.0236 inch) long, of which the female lays about 50, which mature in about a week, and in 18 days are ready to reproduce. The eggs are attached to the hairs, and are easily visible, being known as nits.

The head-louse is found the world over, upon the hairy heads of men and sometimes in other parts of the body where there are hairs. Even when they are quite numerous they may produce no symptoms. Generally, however, they cause itching and scratching, especially when the louse bores deep into the skin and produces pustular dermatitis, with resulting crusts and scabs in which the hair becomes matted and tangled, forming the *plica polonica*, so called from its frequency in Poland.

2. The *pediculus vestimenti*, or body-louse, is considerably larger, being

from two to five mm. (0.1574 to 0.1968 inch) long and whitish-gray in color, the back part of the body being wider than the thorax. Its eggs are from 0.7 to 0.9 mm. (0.275 to 0.0354 inch) long, and about 70 are laid by the female. It lives on the clothing, in which it deposits its eggs, about the neck, back, and abdomen. The puncture incident to sucking is

FIG. 234.—Ovum of head-louse glued to hair:  $\times 70$ . (Braun.)

FIG. 235.—*Pediculus capitis*:  $\times 15$ . (Braun.)

often covered by a hemorrhagic point. It, too, causes itching and scratching, with irritation and inflammation of the skin, and in old cases a roughness and pigmentation causing dark spots and a condition known as *morbus errorum* or vagabond's disease, which has been mistaken for Addison's disease.

FIG. 236.—*Pediculus vestimentorum*:  $\times 10$ , circa. (Braun.)

FIG. 237.—*Phthirus inguinalis*. (Braun.)

3. The *pediculus pubis*, *phthirus inguinalis*, or crab-louse, is smaller than the head-louse, grayish-yellow or grayish-white, the male being from 0.8 to 1 mm. (0.0314 to 0.0393 inch) long, the female 1.12 mm. (0.0441 inch) long. The eggs are pear-shaped, from 0.8 to 0.9 mm. (0.0314 to 0.0354

inch) long, and from 0.4 to 0.5 mm. (0.0157 to 0.0196 inch) wide. They infest the parts of the body covered by shorter hairs, such as the pubis, axilla, and eyebrows. The *pediculus pubis* does not wander so much as the *pediculus capitis* or *vestimenti*, but adheres more closely to the skin and therefore removal is often with difficulty.

These lice rarely give rise to symptoms.

**Treatment of Pediculosis.**—For the head lice: The hair should be cut short and burned, the head thoroughly washed with soap and water, and then anointed with mercurial ointment or washed with tincture of cocculus indicus, or with coal-oil or turpentine, or carbolic acid, 1 to 50. Cocculus indicus is to be preferred because of its freedom from odor. The washing should be repeated for several days in succession.

The treatment for the crab-louse is the same, but, as mentioned, it adheres firmly to the skin, and it is generally necessary to pick off the individual louse.

To get rid of the body-louse the clothing, if not too valuable, should be burned, but may be boiled, or, when this is not admissible, treated by superheated steam.

The itching promptly disappears with its cause, but, if necessary, it may be allayed by a warm bath to which 4 or 5 ounces (120 to 150 gm.) of sodium bicarbonate are added.

Repeated bathing with soft soap should be done until it is absolutely certain that the parasite and its ova are removed.

4. The *cimex lectularius*, or common bed-bug. This familiar insect is reddish-brown, oval in shape, from four to five mm. (0.0574 to 0.1967 inch) long, and three mm. (0.1181 inch) wide. The female lays three or four times a year about 50 eggs, 1.12 mm. (0.0441 inch) long, which require about 11 months for their perfect development to the sexually ripe condition. They live in the crevices of beds, floors, and rafters, in furniture, behind wash-boards and wall-paper, in the habitations of man. During the day they lie concealed; at night they wander in search of the blood of the human being, which they draw by means of a long proboscis. The peculiar odor of the insect is due to a secretion of a special organ with which the bug is provided.

Human beings are variously susceptible to the bite of the bed-bug, some being quite indifferent to it, others being, as it were, special favorites of the little creature.

**Treatment.**—The irritation is confined to the moment of the bite. The aim to be sought is the extermination of the insect. This is often difficult when a thorough lodgment is secured, and it is often necessary that all wall-paper should be removed as well as loose woodwork. Bedsteads should be thoroughly scalded and then treated with the following: Two tablespoonfuls of metallic mercury should be thoroughly beaten up with the white of one egg until a froth is attained. Apply freely with a small paint-brush, filling in carefully all cracks and crevices. The pest is less apt to invade iron bedsteads, but even these must not be neglected, for they, too, in careless hands, may become infested. Solution of corrosive sublimate, 2 to 1000, may also be applied in the same manner.

Order: DIPTERA.

Suborder: APHANIPTERA (Fleas).

1. The *pulex irritans*, or common flea. Of these little creatures, the male is from 2 to 2.5 mm. (0.0787 to 0.1181 inch) long, the female as much as four mm. (0.1574 inch), red or dark-brown in color. It is also highly capricious in its tastes, disturbing some persons not at all, others seriously.

FIG. 238.—*Pulex irritans*:  $\times 14$ . (Braun.)FIG. 239.—Larva of *pulex irritans* (Gould.)

It is not a parasite of man, and invades him usually because of its great abundance in certain places and countries. Though of world-wide distribution, it is more troublesome in hot countries where cleanliness of household, city, and person is a matter of indifference. The eggs are not

FIG. 240.—*Sarcopsylla (pulex) penetrans*: gravid female, enlarged. (Braun, after Moniez.)FIG. 241.—*Sarcopsylla (pulex) penetrans*: young female, enlarged. (Braun, after Moniez.)

laid on human beings, but in the cracks of boards, sweepings, and wooden spit-boxes.

**Treatment.**—The essential oils applied to the infested parts cause the retreat of fleas when applied.

2. The *pulex penetrans*, or sand-flea or jigger. The female buries herself in the skin of human beings as well as of dogs, swine, and other mammals, producing painful irritation, circumscribed swelling, and even suppuration. It especially attacks the feet. It prevails in tropical countries, especially in Central and South America. The eggs are land-hatched.

**Treatment.**—The flea may be picked out with a needle, after which the essential oils are rubbed in on the parts to keep it away.

Suborder: BRACHYCERA\* (Flies).

*Myiasis.*—The diptera also contribute to parasites through their larvæ, which are deposited sometimes in open sores which have been neglected and sometimes in the nasal passages and cavities—the ear, pharynx, vagina, etc. The condition is called myiasis, from the Greek *μύια*, a fly.

The most common of these is *myiasis vulnecrum*, in which an ulcer becomes filled with maggots, which are the larvæ of the blue-bottle or common flesh-fly, *sarcophaga carnaria*.

*Myiasis narium, aurium, conjunctivæ, vaginæ*, etc., are due to the *lucilia macellaria*, whose larva is deposited in these situations usually when they are diseased, and may produce serious mischief, perforating mucous membrane and even cartilage. The larvæ of the

FIG. 242.—Larva of *lucilia macellaria*:  $\times 4$ . (Braun, after Conel.)

FIG. 243.—Larva of *musca vomitoria* (*calliphora vomitoria*): below, of natural size; above, enlarged. (Leuckart)

FIG. 244.—Larva of *dermatobia cyaniventris* ("Macaque worm"): to left, natural size; to right, enlarged. (Braun, after Blanchard.)

FIG. 245.—Larva of *anthomyia canicularis*, enlarged. Rarely found in the stool. (Gould.)

*lucilia nobilis* have also been found in the auditory passages, producing ringing of the ears as a symptom. The larvæ of *sarcophaga magnifica* have been found in ulcers and other situations, throughout Europe, and especially in Russia.

*Cutaneous myiosis* is commonly due to the larva of the *hypoderma bovis* or bot fly, the female of which lays her eggs on the skin of cattle and sheep, in which the larva bores its way and forms the gad boil, about as large as a pigeon's egg. Rarely in tropical countries this happens in the skin of man. Cutaneous myiosis is sometimes caused by the larva of the *musca vomitoria*, one of the domestic flies. More frequently it causes internal myiosis, having been swallowed and again discharged by vomiting.

In the tropics the macaque or moyaquil worm, the larva of a dermatobia, is not uncommon. More rarely dipterous larvæ are found in the feces, including those of the common house-fly and the *trichomyza fusca*, which has also been vomited.

## SECTION XIV.

### SUMMARY OF SYMPTOMS FOLLOWING OVERDOSES OF POISONS.

(Alphabetically Arranged.)

**ACONITE** (*Monkshood; Wolfsbane; Blue Rocket*).—All parts poisonous. The tincture may be mistaken for sherry or whisky; it has an exceedingly acrid taste.

**Symptoms.**—These appear quickly, and consist of an acrid taste in the mouth, a feeling of warmth in the stomach, followed by a tingling sensation throughout the body; muscular weakness, pulse weak and slow at first, later rapid and running; respirations slow and shallow; vomiting may be present, but is rare; the skin is cold and clammy and exceedingly pale; death may be gradual, from respiratory failure, or it may be sudden as a result of any movement of the body which throws any strain upon the heart. The mind is clear to the last.

**Treatment.**—Stomach-tube or emetics if seen early; recumbent posture, with feet elevated, not allowing the patient to arise for any cause. Stimulants freely, such as ammonia, ether, digitalis, atropin, and strychnin. External heat about the body, and artificial respiration for two hours.

**ALCOHOL.**—Taken in the form of spirituous beverages. Acute alcoholic poisoning. A brief period of excitement, with flushing of the face, followed by unconsciousness, stertorous breathing, rapid and, finally, weak pulse, vomiting, a subnormal temperature, delirium, complete muscular relaxation, at times convulsions; the pupils are usually dilated. Recovery commonly takes place in a day or two, but remissions may occur. Odor of alcohol on the breath.

**Treatment.**—Evacuation of stomach by pump; emetics, like apomorphin,  $\frac{1}{10}$  grain (0.0064 gm.); washing out the stomach. If coma and total relaxation is present, use external heat and stimulation by ammonia, atropin, caffein, digitalis, strychnin, or faradic current to muscles of respiration applied by passing an electric brush rapidly over the surface.

**DELIRIUM TREMENS.**—Delirium, with hallucinations; great restlessness and insomnia; slight fever, pulse rapid and soft.

**Treatment.**—Withdrawal of alcohol; hyoscin hydrobromid  $\frac{1}{100}$  grain (0.00064 gm.) hypodermically every two hours until patient is fully under its influence; bromids in full doses, or chloral, provided that the heart is not weak; aided by a cold bath to induce sleep; nourishing food and stimulation if the condition demands it, even by alcohol.

**AMMONIA.**—Taken by mistake or with suicidal intent in the form of "household ammonia," water of ammonia, spirit of hartshorn, and in liniments.

**Symptoms.**—At once, burning pain in the mouth, throat, esophagus, and stomach; the lips and tongue are intensely swollen and inflamed; vomiting of blood-tinged mucus, suffocative cough, with rapidly increasing dyspnea. The face is pale, pulse is rapid and thready, and collapse soon develops. Death may follow at once as the result of spasm or edema of the glottis, or some days later, from the violent gastro-enteritis and stricture of the esophagus.

**Diagnosis.**—Odor of ammonia on the breath, vapors of the corresponding salt when a rod dipped in hydrochloric acid is held before the mouth, together with the sudden onset of the symptoms.

**Treatment.**—Neutralization with vinegar, orange-juice, lemon-juice, or some other dilute acid, as soon as possible. If the patient lives, administer milk and bland oils to soothe the inflamed mucous membrane. Give morphin to relieve pain, stimulants to overcome depression, and apply external heat to maintain bodily temperature. Tracheotomy should be performed if there is danger of death from edema of the glottis.

**ANTIMONY.**—Taken as a tartar emetic, the tartrate of antimony and potassium. A heavy, white, odorless, slowly soluble powder having a sweetish, metallic taste; charring to redness upon heating.

**Symptoms.**—Metallic taste in the mouth, muscular relaxation, skin moist and relaxed, severe nausea and gastric distress followed by violent vomiting, and purging of, first, the normal contents of the bowel and later of serous material containing small shreds of mucous membrane. Cramps in the abdomen and in the muscles of the arms and legs occur as the result of the abstraction of water from the tissues by the violent purging. At the same time, symptoms of collapse appear—cold, clammy skin, feeble, shallow respirations, weak, thready pulse, subnormal temperature, coma and death.

**Treatment.**—Tannic acid as the chemical antidote, followed by washing out the stomach; recumbent posture with the head low, not allowing the patient to raise the head; external heat, stimulants, opium for the pain and demulcent drinks, such as bland oils, mucilages and albumin water, to soothe the inflamed mucous membrane.

**ARSENIC.**—Used in the form of arsenous acid in rat-poisons, in fly-paper, and to preserve stuffed birds and animals. Paris green, used as potato-bug poison, is an arsenite of copper, hence the symptoms are similar. Arsenous acid, or white arsenic, is an odorless, tasteless, white powder, quite heavy, and but slowly soluble in water.

**Symptoms.**—These appear usually in the course of an hour, and are those of violent gastro-enteritis, so severe as to suggest Asiatic cholera. Burning pain in the throat and stomach, persistent vomiting of brown matter streaked with blood, though the vomited matter may be green from bile. Purging is very severe; the stools, after the passage of the normal contents of the bowel, are serous as in antimonial poisoning, but

contain larger flakes of mucous membrane and blood. The urine is scanty, concentrated, and contains albumin. Great prostration accompanies these symptoms and the patient dies in collapse in one or two days. If the patient survives so long, there is usually an intermission in the symptoms about the third day which in a few hours is followed by a return of the symptoms. Nervous symptoms may appear. The poisoning resembles cholera morbus and Asiatic cholera.

**Treatment.**—An emetic if seen early, wash out the stomach, external heat and stimulants. The best antidote is the official ferri hydroxidum cum magnesii oxido, or ferri hydroxidum. These should be freshly prepared. In the absence of these official preparations, any liquid preparation of iron may be used by diluting with water, then adding a dilute solution of ammonia, strain out the precipitate, wash it free of ammonia while on the strainer, then dilute with fresh water and administer freely.

**ATROPIN** (*Belladonna*).—The deadly nightshade. Used as a mydriatic and in liniments. The leaves impart a narcotic odor to the tincture, but recognition depends upon the physiological effect.

**Symptoms.**—Face flushed, skin hot and dry, throat dry, pupils widely dilated, pulse rapid and bounding, respirations quickened and deepened; if the dose has been large there may be active, talkative delirium. An erythematous or scarlatiniform rash is sometimes present. The urine contains the alkaloid, hence it will cause dilatation of the pupil if dropped into the eye of an animal.

**Treatment.**—Tannic acid as a chemical antidote, followed by the stomach-tube or emetics. Morphin, physostigmin or pilocarpin as physiological antagonists. External heat and stimulants if the patient goes into collapse.

**BELLADONNA.**— See Atropin.

**BROMIN.**—A dark red, very heavy liquid, emitting reddish vapors resembling chlorin.

The fumes, when inhaled, cause convulsive cough, bloody expectoration, dyspnea, and spasm of the glottis.

**Treatment.**—Fresh, moist air and cautious inhalations of ammonia.

**BROMISM.**—The symptoms of chronic gastro-intestinal disturbance, such as fetor of the breath, anorexia, diarrhea; great depression of all the functions, especially the sexual function, with languor and mental apathy. A general eruption of acne is an early sign.

**Treatment.**—Stop the administration and aid elimination.

**CARBONIC ACID GAS.**—The choke damp or after-damp of miners. May be accidentally inhaled in overcrowded rooms, in fermenting vats, over lime-kilns, or wherever the products of complete combustion cannot escape.

**Symptoms.**—Headache, dizziness, noises in the ears, a sense of tightness across the chest, great drowsiness, loss of muscular power, followed

by symptoms of asphyxia; coma, tumultuous heart action, stertorous breathing, cyanosis, possibly convulsions and sometimes delirium.

**Treatment.**—Fresh air, if need be; artificial respiration, kept up steadily and unceasingly; ammonia by inhalation; oxygen, if obtainable; cold douche to the head and chest, with external heat and stimulation as occasion requires.

CARBONIC OXID (*Carbon Monoxid*) is formed during the incomplete combustion of carbon, and is a direct poison, while carbonic acid gas, the product of complete combustion, kills merely by exclusion of oxygen.

**Symptoms.**—The same as in carbonic acid poisoning.

**Treatment** as for carbonic acid gas.

CAUSTIC POTASH OR SODA.—Taken in the form of “lye.”

**Symptoms.**—An acrid, burning taste, the burning extending down to the stomach, followed by vomiting, purging, and collapse. The mucous membrane of the mouth shows evidence of corrosion. Convulsions may occur. Stricture of the esophagus may follow recovery from the acute symptoms.

**Treatment.**—Dilute vegetable acids, such as vinegar, lemon-juice, or orange-juice, to neutralize. Demulcent drinks, such as bland oils, mucilages, milk, or white of egg. Opium or morphin for the pain. External heat and stimulants. The stomach-tube should not be used. If the patient lives, the resulting stricture of the esophagus may require dilatation.

CHEESE POISONING.—Decayed cheese owes its poisonous properties probably to tyrotoxinon.

**Symptoms.**—Violent vomiting and purging; pain in abdomen; tongue first coated white, later red and dry; pulse weak and irregular; face is first pale, later cyanotic. The poisoning, while severe, rarely causes death.

**Treatment.**—The stomach-tube may be used if vomiting has not been free; subsequent lavage; opium and demulcent drinks to relieve pain and irritation; stimulants.

CHLORAL.—A popular somnifacient and sedative. Occurs in delicate crystals with characteristic odor and acrid, burning taste.

**Symptoms.**—Shortly after swallowing a poisonous dose of chloral, the patient becomes drowsy and gradually passes into a state of coma, from which he cannot be aroused. Respirations are slow and labored at first, later shallow and feeble; the pulse is feeble and shallow; the face may be white, livid, or cyanotic; the skin is relaxed, cold, and clammy; the pupils, at first contracted, later become widely dilated; there is complete muscular relaxation and abolition of reflexes; the temperature is lowered more than by any other toxic agent.

**Treatment.**—An emetic if seen early, or use the stomach-pump. The maintenance of bodily temperature is of the utmost importance. Rouse the patient, and employ artificial respiration with the faradic current and by other methods usually employed. The head should be kept lower than the feet, and the patient should not be allowed to raise the head or body for any reason. Stimulants should be given in full doses.

**CHLOROFORM.**—Identified by its peculiar ethereal odor and sweet, pungent taste; a heavy, volatile, non-inflammable liquid, not miscible with water.

**Symptoms.**—First stage of narcosis, excitement, struggling, a flushed face, contracted pupils, lessened sensibility to pain. Second stage, muscular relaxation, loss of sensibility, unconsciousness, reflexes abolished, temperature subnormal, respiration slow, pupils dilated, pulse slow. Third stage, that of paralysis, in which the pulse is irregular and weak, respiration fails, skin becomes cyanotic. Death, which results primarily from vasomotor paralysis with secondary respiratory paralysis and cardiac failure, may occur in any stage.

If the drug has been swallowed, the patient experiences an intense burning pain in the mouth, throat, and stomach, vomiting and purging, followed by the symptoms of narcosis enumerated above.

**Treatment.**—In case of accident during anesthesia, the patient should be held head downward; employ artificial respiration; rhythmical traction of the tongue by grasping it with a forceps and pulling it out of the mouth and upward about 14 times a minute; bandages to the extremities, and compression of the abdomen by means of a compress and bandage to confine the blood to vital centers; external heat; strychnin and other stimulants hypodermically; adrenalin chlorid intravenously or by hypodermoclysis. The faradic current may be used by sweeping the electrode over the chest to promote respiration. When swallowed, the stomach-tube or emetics should be used prior to the treatment above.

**COCAIN.**—Solution used as a local anesthetic, particularly in eye surgery.

**Symptoms.**—Vertigo, headache, paroxysmal dyspnea, rapid weak pulse, elevated temperature, mental excitement, blindness, delirium, coma, and convulsions. Some of these may be caused by the local application of solutions to mucous membranes. The pupil is dilated, but the power of accommodation remains in part.

**Treatment.**—Nitrite of amyl, stimulants, atropin, caffein, and ammonia. Wash out the stomach or administer an emetic if the drug has been swallowed. Death is unusual.

**CONIUM** (*Poison Hemlock; Common or Spotted Hemlock*).—Not a native of this country, hence cases of poisoning must be restricted to the use of the preparations. The plant and some of the preparations have a peculiar odor, resembling the urine of mice.

**Symptoms.**—Loss of muscular power, first felt in the legs, going on to complete paralysis which creeps up toward the trunk, the arms being less rapidly affected. The muscles of respiration become involved eventually, the patient becomes cyanotic, and death results from asphyxia. The pupils are dilated, the skin is relaxed and clammy and ptosis is a prominent symptom. Sometimes delirium, coma and convulsions are prominent from the first.

**Treatment.**—Stomach-pump or emetics; tannic acid; stimulants, particularly strychnin; external heat; artificial respiration.

**COPPER.**—The sulphate, blue stone or blue vitriol, is used in the arts. Recognized by its crystalline, shape, blue color, and acrid, metallic taste. Articles of food are frequently prepared in imperfectly cleansed copper kettles; a bright piece of steel, such as a knife, will show a deposit of metallic copper a few minutes after immersion in a liquid containing copper. Verdigris (subacetate) is another source.

**Symptoms.**—An astringent, metallic taste in the mouth; pain in the stomach and abdomen; violent vomiting of a greenish or bluish liquid; profuse purging of the normal contents of the bowel, later mucus and blood, accompanied by tenesmus; jaundice, respiratory failure, collapse, coma, and death.

**Treatment.**—Stomach-pump and emetics if vomiting has not already emptied the stomach; yellow prussiate of potassium (potassium ferrocyanid) as the chemical antidote; demulcents, such as bland oils, white of egg, and milk; opium for the pain; external heat and stimulants.

**DIGITALIS** (*Foxglove*).—A native of Europe. The tincture has a distinct odor of tea, the drug itself lacking a narcotic odor.

**Symptoms.**—Nausea, vomiting, pain, with or without diarrhea; headache, often severe, occasionally delirium and convulsions; the skin is cold and clammy; the pupils are dilated; the pulse at first slow and full, later becomes dicrotic or shuttle-like and difficult to count, while the heart-beat is irregular and tumultuous; the patient may show an inclination to somnolence, which may deepen into coma; death may not result for several days or it may occur suddenly following a muscular exertion.

**Treatment.**—Emetics or the stomach-pump may be used early; tannic acid as the chemical antidote; aconite may be used early as the physiological antagonist; external heat; horizontal position for several days after active symptoms have subsided; stimulants, such as ammonia, ether, atropin and strychnin, may be used in the later stages to combat collapse.

**ERGOT.**—Used to produce abortion.

**Symptoms of Acute Poisoning.**—Giddiness; pain in the stomach; thirst; nausea; vomiting; cardiac oppression; numbness and tingling of fingers and toes, extending along the limbs; cramp; dyspnea; coldness of the body, especially the limbs; great anxiety; delirium; coma and convulsions are among the symptoms which may be produced.

**Treatment.**—Emetics or stomach-tube. Stimulants and external heat as necessary. Nitroglycerin may be administered by the mouth.

*Chronic ergotism* occurs as a result of eating bread made from grain contaminated with the fungus. *Early symptoms* are gastric pain, general depression, nausea, occasionally vomiting; sometimes diarrhea, at others constipation, dizziness, insomnia, and lack of energy. *Subsequent symptoms* may take one or both of two courses: (1) Gangrenous ergotism characterized by patches of anesthesia, with a sensation of coldness of the parts affected, or by a burning sensation with redness of the skin. This usually occurs in the fingers and toes, and is followed by dry gangrene which may advance as far as the elbows or knees, but rarely affects the trunk. (2) Spasmodic ergotism characterized by paresthesias of various kinds;

sometimes there is complete anesthesia. Motor disturbances follow: twitchings, spastic muscular contractions attended with great pain, paralyses, and disturbance of the special senses.

**FISH-POISONING.**—Tainted fish probably contains ptomains, while several kinds of fish are constantly poisonous.

**Symptoms.**—Vomiting, profuse purging, thirst, great pain in the abdomen and in the head, with subsequent collapse and death in some instances.

**Treatment.**—Emetic or stomach-pump if vomiting has not occurred, stimulants, external heat, and artificial respiration if required.

**HYDROCHLORIC ACID.**—See Mineral Acids.

**HYDROCYANIC ACID** (*Prussic Acid*).—The pure acid is an exceedingly poisonous gas. In medicine it is employed as a 2 per cent. aqueous solution. Contained in oil of bitter almonds distilled from the seed; not found in the artificial or the purified natural product. Its salt, the cyanid of potassium, is employed as a quickly acting poison for the destruction of animals. Contained also in cherry-laurel water.

**Symptoms.**—The patient may drop dead almost immediately after a large dose of the poison has been swallowed. When smaller doses have been taken there is first difficult respiration, slow pulse, dizziness, impeded locomotion, a sense of constriction and heaviness in the head, progressive intellectual confusion, followed by tetanic convulsions, involuntary evacuations of urine and feces, with ejaculations of semen, dilated pupils, in turn succeeded by asphyxia, collapse, general paralysis, and death.

The odor of hydrocyanic acid about the body, the wide-staring eyes, the clinched teeth covered with froth, and the cyanotic face are diagnostic of death by this poison.

**Treatment.**—Stomach-pump or emetics, stimulants, artificial respiration, rapidly interrupted current applied by means of an electric brush swept quickly over the chest, alternate hot and cold douche. If the patient survives for 20 minutes or half an hour, the chances are in favor of his recovery.

**IODIN.**—May be taken by mistake; the tincture has the odor of iodine, which somewhat resembles chlorin.

**Symptoms.**—Metallic taste in the mouth, salivation, great pain in esophagus, stomach, and abdomen, followed by violent vomiting and purging. Face pale, pulse rapid, running, and feeble; urine suppressed; death occurs from respiratory paralysis. The presence of iodine is detected by the blue color of the vomited material if starch has been present.

**Treatment.**—Boiled starch (arrowroot or flour), as a chemical antidote; emetics and stomach-pump; opium or morphin for the pain; external heat, stimulants, and demulcent drinks.

**IODOFORM.**—Rarely taken internally, but toxic symptoms may appear when used freely as an antiseptic dressing.

**Symptoms.**—In mild cases, malaise, nausea, vomiting, headache, anorexia, followed by cerebral excitement, insomnia, fever, erythematous

rashes on the skin; small, rapid pulse; hematuria, or retention of urine, and in severe cases maniacal delirium, coma, and at times death.

**Treatment.**—Soullier advocates sodium bicarbonate to unite with the iodine and so aid in its elimination. External heat, stimulants. Emetics may be used if the drug has been swallowed.

**LEAD.**—Taken most frequently as sugar of lead (acetate), or in the form of Goulard's solution (subacetate), lead water (subacetate), white lead (carbonate).

**Symptoms of Acute Poisoning.**—After the acetate has been swallowed, the patient complains of a sweet, metallic taste in the mouth, a feeling of constriction in the esophagus, followed by vomiting of white, opaque masses; great thirst; cramps in the calves of the legs, occasionally paralysis; constipation or diarrhea, the feces being black, due to the formation of lead sulphid; great prostration, coma, and death.

**Treatment.**—Emetics and the stomach-pump. Magnesium or sodium sulphate in large quantities as chemical antidotes. Opium or morphin for the pain. External heat. Stimulants. Demulcent drinks.

**Chronic Poisoning.**—Obstinate constipation, with colicky pains centering around the umbilicus; abdominal walls retracted and hard; a blue line on the gums, due to a deposit of lead sulphid; the tongue is coated; the appetite diminished; pulse hard and tense; bilateral wrist-drop, due to peripheral neuritis, with paralysis of the extensor muscles of the forearm; arthralgia, especially of the knee-joints, less frequently involving the elbows and shoulders; cerebral disturbances—headache, vertigo, insomnia, delirium, epileptiform convulsions.

**Treatment.**—Remove the cause; promote elimination by the administration of potassium iodid in full doses, and by the use of hot baths; opium or morphin for the pain and to relax the spasm of the intestine caused by the lead; strychnin in full doses with electricity, massage, fresh air, and good food to overcome paralysis and increase general nutrition.

**MEAT POISONING.**—*Vide* Ptomain Poisoning.

**MERCURY** (*Corrosive Sublimate; Bichlorid of Mercury; Mercuric Chlorid, or the Perchlorid*).—Used in aqueous solution as bed-bug poison, as an insecticide, to preserve specimens, and as an antiseptic surgical dressing.

**Symptoms of Acute Poisoning.**—Acrid, metallic taste in the mouth, followed by burning pain in the esophagus, stomach and abdomen; the mucous membrane of mouth and pharynx is white and swollen; severe vomiting of the stomach contents mixed with shreds of mucous membrane and blood; violent purging accompanied by severe tenesmus, the stools being watery and blood-streaked; urine scanty or suppressed; profound prostration, collapse, and death.

**Treatment.**—White of egg as the chemical antidote; wash out the stomach or give emetics if vomiting is not profuse; external heat; opium for the pain; demulcent drinks; stimulants.

**Chronic Poisoning.**—**Symptoms.**—Increased salivation; swelling and tenderness of the gums when the jaws are snapped together; fetid breath;

nausea, vomiting and diarrhea may be present at intervals; loss of flesh and strength; anemia; skin eruptions; nervous disorders—tremors, psychical disturbances, choreic movements, hallucinations, mania, and paralyses as a result of peripheral neuritis.

**Treatment.**—Remove the cause; aid elimination; administer stimulants, good food and tonics; combat other symptoms as necessity arises.

#### MINERAL ACIDS.

**HYDROCHLORIC ACID** (*Muriatic Acid; Spirit of Salt*).

**Symptoms.**—Similar to those mentioned under sulphuric acid, though the acid is not so powerful and leaves no distinctive stain. It may be recognized by its odor and by the white fumes formed when the gaseous acid comes into contact with ammonia. Medicinally and in the arts hydrochloric acid is used in aqueous solution, the commercial variety tinted yellow from a trace of iron.

**Treatment.**—Same as for sulphuric acid.

**NITRIC ACID** (*Aqua fortis*).—A colorless, moderately heavy liquid of peculiar and characteristic odor, staining organic tissues yellow.

**Symptoms.**—The same as those mentioned under sulphuric acid, though the characteristic yellow stain may be found on the lips.

**Treatment.**—As for sulphuric acid.

**SULPHURIC ACID** (*Vitriol; Oil of Vitriol*).—A very heavy, colorless, odorless liquid, having a very acid taste and mixing with water with the production of great heat. Used largely in the arts. Turns organic matter black.

**Symptoms.**—Intense burning pain in mouth, stomach, and abdomen; mucous membrane of mouth is swollen, corroded or excoriated, sometimes white; lips swollen and excoriated; vomiting of a blackish fluid, containing shreds of mucous membrane and coagulated mucus; intense thirst with great dysphagia; bowels usually constipated, occasionally diarrhea, the stools containing altered blood and shreds of mucous membrane; urine scanty or suppressed; great feebleness and collapse.

Death may occur in the stage of collapse. It often occurs suddenly either from edema of the glottis, from pulmonary embolism or thrombosis, from perforation of the stomach, or later by the secondary effects resulting from esophageal stricture and destruction of the gastric mucous membrane.

**Treatment.**—Neutralize by giving calcined magnesia, chalk, lime-water, soap and water, and water in large quantity; demulcent drinks; opium or morphin for the pain; external heat; stimulants. The stomach-pump should not be used in sulphuric-acid poisoning.

**MORPHIN POISONING.**—See Opium Poisoning.

**MUSHROOM POISONING.**—Harmless varieties may prove poisonous to some individuals. *Agaricus muscarius* is the most poisonous variety,

containing the active principle muscarin. The fungus is bright red, with yellow spots. As a rule, highly colored fungi, with an astringent, styptic taste and a pungent odor should be avoided; they frequent especially dark and shady places.

**Symptoms.**—These may be divided into gastro-intestinal and nervous.

*Gastro-intestinal symptoms* appear six to ten hours after the fungi have been swallowed. Pain in the stomach and abdomen, nausea, vomiting, and diarrhea. Great thirst; small, weak pulse; skin cold, clammy and livid; great prostration which may result in death.

*Nervous symptoms* consist of muscular twitchings; convulsions; delirium; disorders of special senses, especially of vision; stupor or profound coma.

**Treatment.**—Emetic; castor oil to evacuate the bowels; atropin as the physiological antidote; external heat; stimulants.

**NICOTIN.**—The liquid, volatile alkaloid of tobacco. An acrid, oily liquid of amber color, smelling of tobacco. A very deadly and quickly acting poison.

**Symptoms.**—Burning in throat; dizziness; muscular weakness; nausea; vomiting; skin cold, clammy; pulse rapid and feeble; pupils at first contracted, later dilated; mental confusion, delirium, and convulsions. Death may occur within a short time after the poison has been taken.

**Treatment.**—Emetics or the stomach-tube, followed by tannic acid as an antidote; stimulants; external heat; artificial respiration, if necessary; strychnin.

**NITROBENZOL** (*Nitrobenzene; Oil of Mirbane; Artificial Oil of Bitter Almonds*).—Used in the preparation of anilin dyes and in the arts on account of its flavor (soaps, etc.). Recognized by its highly characteristic odor.

**Symptoms.**—Characteristic intense cyanosis extending over the whole body; headache; dizziness; muscular weakness; breathing irregular and stertorous; vomiting may occur, the vomited matter having the odor of the poison, as does the breath; mental confusion, stupor and coma; pulse weak; temperature lowered; skin relaxed; the pupils may be dilated or contracted, usually dilated.

**Treatment.**—Evacuate and wash out the stomach thoroughly; external heat with friction; artificial respiration and faradism, if necessary; stimulants as required; alcoholic stimulants should not be given until after evacuation of the stomach because alcohol renders the poison more soluble.

**OPIUM POISONING (ACUTE).**—Taken accidentally or with suicidal intent in the shape of morphin or laudanum.

**Symptoms.**—The first stage, which is of short duration, is marked by restlessness; increased mental activity with a feeling of exhilaration; cardiac stimulation and flushed face. This is succeeded by a second stage of stupor, ushered in by drowsiness, followed by deep sleep; slow, full pulse; respirations slow and full; contracted pupils; warm, dry skin. During this

stage, the patient can be aroused, but goes to sleep again when he is not disturbed. The patient passes insensibly into the third stage which is characterized by inability to arouse the patient; cyanosis; respirations very slow and shallow; muscular relaxation; the skin becomes relaxed, cold and clammy; the pupils dilate just before death occurs.

**Treatment.**—Wash out the stomach thoroughly and frequently; solution of potassium permanganate or tannic acid as chemical antidotes; strong, hot coffee by enema; strychnin hypodermically with atropin; keep the patient awake by mild flagellation, shaking, shouting, or by the use of the electric brush swept quickly over his chest, using the faradic current; artificial respiration, external heat and stimulants in the later stage.

**OXALIC ACID.**—Mistaken for Epsom salt; taken with suicidal intent. Occurs in prismatic, colorless, odorless crystals, with a very sour taste. Volatile without charring at a red heat.

**Symptoms.**—After large amounts have been swallowed there is pain in the mouth, stomach, and abdomen; persistent vomiting of altered blood; violent purging of a bloody material; cramps in the legs; the skin is cold, clammy and cyanotic; collapse follows; more rarely convulsions occur.

**Treatment.**—Calcium carbonate in the form of chalk, lime-water, whiting, marble dust, plaster from the walls, or egg-shells powdered and suspended in a little water. Calcined magnesia may be given. Follow these by an enema or castor oil to sweep out the bowel.

**PHENOL (*Carbolic Acid*). AND CREOSOTE.**—Phenol is a white crystalline solid when pure, very deliquescent, and when liquefied is a colorless or reddish colored liquid, having a characteristic odor. Impure phenol is a dark colored liquid.

**Symptoms.**—When pure phenol is swallowed death may follow almost at once from sudden respiratory failure. If the patient does not die at once, he suffers intense burning pain in the mouth, esophagus, and stomach; the mucous membrane is stained and swollen, the eschar being white and surrounded by a zone of inflammation. The face is ghostly; the skin cold and clammy; violent vomiting and purging may be present, although vomiting may be absent. The urine is diminished or suppressed, that which is passed being dark colored; collapse follows with a small, imperceptible pulse, low temperature, and extreme dyspnea. The odor of phenol on the breath and the white eschar on the mouth are characteristic of this poison.

**Treatment.**—Any soluble, non-poisonous sulphate, such as magnesium, or sodium sulphate, as the chemical antidote. Wash out stomach, use emetics or the stomach-pump. Morphin for pain, demulcent drinks, such as albumin, mucilage of acacia, but *no oils*. External heat and stimulants to overcome collapse.

**PHOSPHORUS.**—Employed in the form of a paste as a rat and roach poison; matches are sometimes sucked for suicidal purposes. The paste is recognized by its peculiar garlicky odor, and by the luminous fumes it emits in the dark.

**Symptoms.**—These usually do not appear until eight or ten hours after the poison has been swallowed, and are manifested by a peculiar taste in the mouth; the odor of phosphorus on the breath; burning pain in the alimentary tract; vomiting, the vomit being luminous and consisting of food, mucus, bile, and perhaps blood; purging, the stools being also phosphorescent in the dark; constipation may be present. At the end of 24 or 48 hours a cessation of the primary symptoms occurs which may last two or three days or longer. At the end of this time, jaundice develops and the primary symptoms return with renewed vigor; the vomit is like "coffee-grounds," due to altered blood; obstinate constipation may exist; the fecal masses, if passed, are white and clay colored; the urine is scanty, albuminous and contains casts, sarcolactic acid and bile pigments; the nervous symptoms consist of headache, vertigo, delirium, convulsions, and unconsciousness, followed by death. If the patient survives the acute symptoms, he may die later as the result of fatty degeneration of vital organs.

**Treatment.**—Wash the stomach freely with a 1 per cent. solution of potassium permanganate as a chemical antidote; hydrogen peroxid may also be given; demulcent drinks. *No oils* should be given, as they increase the solubility of the phosphorus. Stimulants. External heat.

#### POTASSIUM NITRATE (*Nitre; Saltpetre*).

**Symptoms.**—After a large dose, the patient experiences violent pain; in the stomach and abdomen; vomiting and purging, the ejected matter sometimes containing blood; occasionally convulsions, labored respiration, cramps in the legs, paresthesia, paralysis of the limbs and aphonia have been observed; collapse occurs, followed by coma and death.

**Treatment.**—Emetics, and wash out the stomach; opium for the pain; demulcent drinks; external heat, with counterirritation over the stomach; stimulants.

**PTOMAIN POISONING.**—Ptomains are alkaloidal bodies, the products of the decay of animal tissues. These are probably the cause of the poisonous action of tainted meat and fish, cream-puffs, ice-cream, *blanc mange*, and cheese.

**Poisonous Fish.**—Vomiting, profuse purging, thirst, great pain in the abdomen, headache, itching of the skin, collapse, and death in some instances.

**Shell Fish, Mussels.**—Erythematous or urticarial eruptions on the skin with itching; abdominal pain, thirst, vomiting, diarrhea; dyspnea; pupils dilated; collapse; paralysis and death.

**Poisonous meat** contains ptomains, those produced when stale meat is just beginning to decay being more virulent than others which replace the first when decomposition is well under way.

**Symptoms.**—Headache, anorexia, rigors, thirst, vomiting, purging, pains in the back or limbs, skin eruptions, delirium, collapse. The temperature is usually subnormal.

**Ices, Ice-cream.**—The cheap varieties are colored with anilin dyes, which may not be free from arsenic. Again, the highly poisonous alkaloid, tyrotoxinon, may have formed in the milk used, and to this principle most cases of poisoning of this kind are traced.

**Symptoms.**—Nausea, vomiting, cramps in the abdomen, collapse; diarrhea may be present.

**Treatment.**—Emetic or stomach-pump if vomiting has not occurred, stimulants, external heat, and artificial respiration if required.

SILVER NITRATE (*Lunar Caustic*).—Used in the form of the fused nitrate as a caustic. Otherwise in colorless, rhombic crystals, freely, soluble, with astringent metallic taste. Yields a white precipitate with chlorids and stains organic matter black.

**Symptoms.**—Violent pain in the stomach and abdomen, soon followed by vomiting and purging; the vomited matter is white at first, turning dark later; the lips are at first white, but soon turn brown, then black; the skin is cold and clammy; cramps in the legs may occur; cardiac depression and collapse. Nervous symptoms, consisting of epileptiform convulsions, and delirium are sometimes severe.

**Treatment.**—Common salt and water, followed by an emetic or stomach-pump; opium for the pain; oils and demulcent drinks; external heat; stimulants.

STRYCHNIN.—An alkaloid occurring in *nux vomica* and *ignatia*. Appears in the form of white, prismatic, odorless crystals which have an intensely bitter taste. Used as a vermin killer.

**Symptoms.**—These may come on suddenly or gradually. If suddenly, the patient may be thrown into tetanic convulsions without warning. If they develop gradually, the patient experiences stiffness at the back of the neck, and muscular twitchings, with a feeling of anxiety and impending suffocation, followed by violent tetanic convulsions in which the body assumes the position of opisthotonos, occasionally emprosthotonos or pleurosthotonos, the eyeballs are prominent, the pupils dilated, and the corners of the mouth drawn into risus sardonicus. Respiration is much impeded or entirely arrested, producing marked cyanosis. The patient is conscious and experiences the most acute physical pain with mental anguish at the prospect of death which he believes to be imminent.

Intervals of relaxation occur in which the patient lies exhausted, the respirations are more rapid and full, and the cyanosis clears up. Any external impulse is sufficient to cause another convulsion, and these may succeed each other so rapidly that the patient dies of cramp asphyxia or from exhaustion.

In tetanus there is usually the history of a wound; symptoms develop much more gradually; the muscles of the jaw are early involved and trismus is much more marked than spasm of the respiratory muscles, and the convulsions are tonic.

**Treatment.**—Emetics or wash out the stomach, if seen early. Amyl nitrite to relax the spasm, followed by chloroform. During anesthesia, the stomach may be washed out and a solution of tannic acid given to act as a chemical antidote, while hydrated chloral with bromids in full doses may be given by enema to act as physiological antagonists. Artificial respiration if necessary.

SULPHURETED HYDROGEN has the characteristic odor of rotten eggs. It forms the bulk of the gas emanating from sewers and cess-pools, some ammonium sulphid and nitrogen occurring with it.

**Symptoms.**—If inhaled in small quantity, irritation of the eyes, nose, and throat occurs, with headache, vertigo, muscular relaxation, nausea, and diarrhea.

If inhaled in large quantities, unconsciousness rapidly follows, with cyanosis, dilated pupils, collapse, and fatal coma, sometimes interrupted by violent convulsions.

In a state approaching purity, sewer gas kills almost instantly; in moderate amount it frequently causes death in 24 hours, all efforts to restore consciousness proving useless.

**Treatment.**—Fresh air; artificial respiration for many hours; ammonia by inhalation; stimulation.

**ZINC.**—The chlorid, in solution, is used as a disinfectant (Burnett's Disinfecting Fluid). A very heavy, corrosive, colorless liquid, of astrigent taste. It partakes of the nature of a corrosive poison.

**Symptoms.**—Burning sensation in throat and stomach, perhaps signs of local corrosion. Nausea, vomiting, purging, dyspnea, collapse, coma, death.

**Treatment.**—Carbonate of potassium or sodium in water; milk; eggs; tannic acid; opium as a sedative; demulcent drinks; external heat, and stimulants.

8	= 123.44
9	= 138.87
10	= 154.3
1 pound avoirdupois	= 453.5925 gm.
1 ounce avoirdupois	= 28.3495 gm.
1 grain avoirdupois	= 0.0648 gm.

### GRAINS TO MILLIGRAMS.

1	= 64.8
2	= 129.6
3	= 194.4
4	= 259.2
5	= 324
6	= 388.8
7	= 453.6
8	= 518.4
9	= 583.2
10	= 648
1 dram or 60	= 3.89 gm.
1 ounce or 480	= 31.1 gm. <sup>1</sup>

## FLUID MEASURES.

1 teaspoonful distilled water	= 1 fluidram	= 3.7 c.c.
1 dessertspoonful distilled water	= 2 fluidrams	= 7.4 c.c.
1 tablespoonful distilled water	= 4 fluidrams	= 14.8 c.c.
1 wineglassful distilled water	= 2 fluidounces	= 59.14 c.c.
1 fluidounce distilled water		= 29.57 c.c. (circa 30 c.c. <sup>1</sup> )
16 fluidounces distilled water	= 1 pint	= 473.11 c.c. (circa 480 c.c.)

<sup>1</sup>A fluidounce of water which measures 30 c.c. does not weigh 31.1 gm., because an ounce of water really weighs but 455.7 grains Troy, and not 480 grains.

## TO CONVERT DEGREES OF FAHRENHEIT'S THERMOMETER TO CENTIGRADE, AND VICE VERSA.

## CENTIGRADE TO FAHRENHEIT.

1	=	1.8
2	=	3.6
3	=	5.4
4	=	7.2
5	=	9
6	=	10.8
7	=	12.6
8	=	14.4
9	=	16.2
10	=	18

To use this table, convert the given number of degrees Centigrade into degrees Fahrenheit, and add  $32^{\circ}$ .

## FAHRENHEIT TO CENTIGRADE.

1	=	0.555
2	=	1.11
3	=	1.665
4	=	2.22
5	=	2.775
6	=	3.33
7	=	3.885
8	=	4.44
9	=	4.95
10	=	5.55

To use this, table subtract  $32^{\circ}$  from the given number of degrees Fahrenheit and convert the remainder into degrees Centigrade.
